PART 1

Fetal and Neonatal Neurology 1

1. Fetal Neurology 5

*Adré J Du Plessis and Michael V Johnston*

**Neuroembryology** 6
Normal Neural Tube Development 6
Disorders of Neural Tube Development 7
Normal Rhombencephalic Development 12
Disorders of Rhombencephalic Development 15
Cerebellar Hemispheric Malformations 20
Normal Prosencephalic Development 22
Disorders of Prosencephalic Development 23
Disorders of Prosencephalic Cleavage 24
Disorders of Midline Prosencephalic Development 27
Disorders of the Fetal Choroid Plexus and Ventricles 30
Disorders of the Choroid Plexus 32

**Normal Cerebral Cortical Development** 33
Disorders of Cerebral Cortical Development 36
Developmental Disorders of Neuronal Proliferation 36
Disorders of Neuronal Migration 38

2. Neurological Diseases in the Perinatal Period 89

*Miriam Martinez-Biarge and Linda S de Vries*

Intracranial Haemorrhage in the Term Infant 89
Germinal Matrix–Intraventricular Haemorrhage in the Preterm Infant 93
White Matter Injury 100
Hypoxic–Ischaemic Encephalopathy 107
Focal Lesions (Neonatal Stroke) 116
PART 2

3. Developmental Brain Malformations

Nadia Bahi-Buisson and Nathalie Boddaert

Disorders of Ventral Induction

Holoprosencephaly

Conditions Related to Holoprosencephaly

Malformations of Cortical Development

Malformations Secondary to Abnormal Neuronal and Glial Proliferation or Apoptosis

Disorders of Migration

Malformations due to Abnormal Cortical Organisation

Abnormalities often Associated with Disorders of Cortical Development

Agenesis and Dysgenesis of the Corpus Callosum

Septo-Optic Dysplasia

Colpocephaly

Midbrain–Hindbrain Malformations

Predominantly Cerebellar Malformations

Cerebellar and Brainstem Malformations

Predominantly Brainstem Malformations

Predominantly Midbrain Malformations

Prenatal Diagnosis, Treatment and Prevention of Brain Malformations

4. Neurocutaneous Diseases and Syndromes

Eleni Panagiotakaki and Alexis Arzimanoglou

Neurofibromatoses

Neurofibromatosis Type 1

Neurofibromatosis Type 2

Other Forms of Neurofibromatosis

Tuberous Sclerosis Complex

Linear Nevus and Related Syndromes

Classic Linear Nevus Syndrome

Related Syndromes with Proliferative Skin and Subcutaneous Tissue Lesions

Neurocutaneous Syndromes with Prominent Vascular Components

Sturge–Weber Syndrome

Syndrome of Haemangiomas and Other Cardiovascular Defects (PHACES Syndrome)

Von Hippel–Lindau Disease

Hereditary Haemorrhagic Telangiectasia (Rendu–Osler–Weber Syndrome)

Rare Neurocutaneous Syndromes with Prominent Vascular Component
Syndromes with Various Cutaneous or Subcutaneous Tissue Anomalies

Ataxia-Telangiectasia and Related Disorders
Disorders Related to Ataxia-Telangiectasia

Neurocutaneous Syndromes with Abnormal Pigmentation
Incontinentia Pigmenti (Bloch–Sulzberger Type)
Incontinentia Pigmenti Achromians (Hypomelanosis of Ito)
Neurocutaneous Melanosis
Other Neurocutaneous Syndromes with Abnormal Pigmentation

Neuroichthyosis Syndromes
Sjögren–Larsson Syndrome
Trichothiodystrophy

Miscellaneous Neurocutaneous Syndromes
Nevoid Basal Cell Carcinoma (Gorlin-Goltz Syndrome)
Progressive Hemifacial Atrophy (Parry–Romberg Disease)
Lipoid Proteinosis (Urbach–Wiethe Disease)

5. Genetic Anomalies and Dysmorphic Syndromes

Karine Pelc and Bernard Dan

Down Syndrome
Fragile X Syndrome
Rett Syndrome
Angelman Syndrome
Prader–Willi Syndrome
The 22q11.2 Deletion Syndrome
Williams Syndrome
Cornelia De Lange Syndrome
Noonan Syndrome
Turner Syndrome
Klinefelter Syndrome
Smith–Magenis Syndrome
Sotos Syndrome
Cri-Du-Chat Syndrome
Kabuki Syndrome

Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

6. Osseous Malformations of the Skull and Craniovertebral Junction

Richard Hayward and Dominic Thompson

Osseous Malformations of the Skull
Craniosynostosis
Craniosynostosis & Craniofacial Syndromes

*Endogenous Toxic Neuropathies* 1232  
*Exogenous Toxic Neuropathies* 1233

**Neuropathies of Systemic and Vascular Diseases** 1234

**Localised Disorders of the Peripheral Nerves (Excluding Cranial Nerves)** 1234

**Traumatic Nerve Injuries** 1235

**Localised Disorders of Cranial Nerves** 1238

### 26. Muscle Disorders 1263

_Monique M Ryan, Francesco Muntoni and Kathryn N North_

**Congenital Myopathies** 1263

**Congenital Muscular Dystrophies** 1267

**Progressive Muscular Dystrophies** 1270  
*Dystrophinopathies (Duchenne and Becker Muscular Dystrophies)* 1270

**Myotonic Diseases and Related Conditions** 1275  
*Myotonic Dystrophy (Dystrophia Myotonica, DM1, Steinert Disease)* 1275  
*Ion Channel Disorders* 1277

**Inflammatory Myopathies** 1281

**Infectious Myositis** 1285

**Metabolic Myopathies** 1286  
*Disorders of Glycogenolysis and Glycolysis – the Glycogen Storage Disorders (GSDs)* 1286  
*Disorders of Lipid Utilisation and Metabolism* 1288  
*Mitochondrial Myopathies* 1289

**Systemic Myopathies of Childhood** 1290

**Other Muscle Abnormalities** 1293

### PART 11 1311

**Neurological Manifestations of Systemic Diseases**

### 27. Electrolyte and Acid-Base Metabolism Disturbances, Nutritional Disorders and Other Systemic Diseases 1317

_Peter Baxter_

**Disorders of Water and Electrolyte Metabolism** 1317

**Nutritional Disorders and the Nervous System** 1321  
*Vitamin Deficiencies* 1323

**Endocrine Diseases** 1327

**Cardiac Disorders** 1331

**Pulmonary Diseases and Other Ventilatory Problems** 1334

**Hepatic Disease** 1335

**Gastrointestinal Disorders** 1337

**Renal Diseases** 1338
PART 12 Developmental and Neuropsychiatric Disorders of Childhood

28. Neurodevelopmental Disabilities and their Management
   Bruce K Shapiro
   1363

29. Autism Spectrum Disorder and Autistic-Like Conditions
   Anne O’Hare and Roberto Tuchman
   1379

30. Attention-Deficit–Hyperactivity Disorder and Co-existing Impairments
   Bruce K Shapiro
   1407

31. Disorders of Speech, Language and Communication
   Anne O’Hare
   Development Disorders
   Verbal Dyspraxia
   Dysarthria in Syndromic Conditions
   Acquired Disorders of Speech and Language
   1421
   1428
   1429
   1430

32. Psychogenic Neurological Disorders
   Paddy Grattan-Smith
   Difficulties Over Words
   Lessons from the Past
   Frequency and Presentation of Psychogenic Neurological Disorders
   The ‘Positive Signs’ of a Psychogenic Neurological Disorder
   Overview of the Signs of a Psychogenic Neurological Disorder
   What Is the Underlying Cause of a Psychogenic Neurological Disorder?
   Psychogenic? Functional? What Is the Correct Name?
   Treatment of Psychogenic Neurological Disorders
   Prognosis

Jean Aicardi (1926–2015)

Jean Aicardi, a clinician, clinical investigator and educator, left us on 3rd August 2015 at the age of 88.

Professor Aicardi had a passionate, life-long commitment to child neurology and clinical epileptology. He obtained his medical degree in 1955 at the Faculté de Médecine de Paris. He worked as a Research Fellow at the Harvard Medical School, headed the Pediatric Neurology Unit at the University Hospital Necker-Enfants Malades in Paris, was Director of Research at the French National Institute of Health and Medical Research INSERM (1986–1991) and was an Honorary Professor of Child Neurology at the Institute of Child Health, London UK (1992–1998).

Jean Aicardi was a pioneer in child neurology who contributed significantly to the description of several neurological entities including Aicardi syndrome in 1969; Aicardi-Goutières syndrome in 1984; Rett syndrome (together with Bengt Hagberg); alternating hemiplegia of childhood and others.

He was awarded several academic honors and distinctions including the Hower Award of the American Epilepsy Society (1986), the Epilepsy Research Award of the American Epilepsy Society (1995), the Ramon y Cajal Award, the International League Against Epilepsy-International Bureau for Epilepsy (ILAE-IBE) Ambassador for Epilepsy Award and the ILAE-IBE Life Achievement Award.

As a teacher Jean Aicardi believed in what he called the ‘members of the young generation’ and in 1999 he easily accepted the invitation to become the Founding Editor of an epilepsy journal devoted to electro-clinical semiology of the epilepsies, Epileptic Disorders, which today is the educational journal of the ILAE. At various times in his career, he was a member of the Editorial Boards of the journals Brain, Brain and Development, Epilepsia, Neuropediatrics, Pediatric Neurology and Journal of Child Neurology.

Jean Aicardi treated everyone with respect. He was always available and willing to provide thoughtful and humble advice to his colleagues and students, to the families that he deeply respected and the sick children he cared about so much. Aicardi had eight brothers and sisters, two of whom died in infancy and another of whom died in a German labour camp in 1945. He loved and respected his family. He was a loving husband and suffered enormously from the loss of his wife, Jeanne Couturier, in 2011.

A tireless clinician and teacher, ‘Monsieur Aicardi’ will be remembered not only as one of the founders of child neurology but also as the mentor of more than 100 child neurologists all
over the world. His clinical ward rounds will remain unfor-
gettable to many of us. He was the one who taught us that ‘a
major part of examination, and one too often neglected, consists
of watching spontaneous activity of the child … the best manner
of assessing CNS function and behaviour’. He strongly believed,
and he was so right, that in this era of ubiquitous technol-
gy, careful observation of clinical signs and symptoms and
their correct interpretation, based upon thorough knowledge,
remain as essential as ever.

On a more personal note, allow me to thank my mentor
and friend. He allowed me to share with him more than 30
years of teaching, discussions on differential diagnosis, on
treatment, in writing papers and books. But above all, he
shared with me important moments of our private lives. He
was always present when I needed him. When the third edi-
tion of this book was published in 2009, I had just moved to
Lyon to work on the development of a clinical epileptology
and neurophysiology department. When he offered me a copy
of his book Diseases of the Nervous System (3rd edn) he wrote
on the cover page “… Our separation was finally not so hard for
me to live with because I am so happy that you finally achieved
what you always desired and merited …”

Some years later, when Jean asked me to take over the editor-
ship of the 4th edition of this book, I was terrified but unable
to say “No”. He helped me in selecting co-editors and authors
(and this is an opportunity for me to thank them again). His
wish was for the book to remain ‘resolutely clinical’.

Merci Monsieur!

ALEXIS ARZIMANOGLOU

Wilkins.
Jean Aicardi: A Brief Curriculum Vitae

- Born November 8th 1926
- Medical degree, Paris Faculty of Medicine (1955)
- Research fellow, Harvard Medical School Boston, USA (1955–1956)
- Assistant Physician Hôpital des Enfants Malades, Paris, France (1957–1964)
- Assistant Physician Hôpital Saint-Vincent de Paul, Paris, France (1964–1979)
- Director of Research INSERM and Head Pediatric Neurology Unit, University Hospital Necker-Enfants Malades, Paris, France (1986–1991)
- Visiting Scientist Miami Children’s Hospital, USA, 1993
- Honoured Guest the XXth Cleveland Clinic Meeting Cleveland USA, 2002
- Honorary Member, European Paediatric Neurology Society, Göteborg, Sweden 2005
- President of the International Child Neurology Association (1990–1994)
- Légion d’Honneur (2009)

ACHIEVEMENTS
- Identified Aicardi’s syndrome in 1969
- Identified Aicardi-Goutières syndrome in 1984

PUBLICATIONS
- *Epilepsy in Children*. Lippincott, Williams and Wilkins, 1993
- *Aicardi’s Epilepsy in Children* (with A Arzimanoglou, R Guerrini) Lippincott, Williams and Wilkins, 2003
- 259 articles in international peer-reviewed journals
- 111 book chapters
Professor Alexis Arzimanoglou is the Director of the Department of Paediatric Clinical Epileptology, Sleep Disorders and Functional Neurology at the University Hospitals of Lyon, France and Visiting Professor at the Universitat de Barcelona, Spain, coordinating the Epilepsy Research Program at the Hospital San Juan de Dèu. He graduated from the Salonia University, Greece, trained in Neurology at Great Ormond Street Hospital, London, UK and at the Hôpital de la Salpetrière and in Child Neurology as a fellow of Jean Aicardi at the Hôpital des Enfants Malades in Paris, France. He then worked with Jean Aicardi for over 25 years. He served as Chair of the Scientific Committee of the European Paediatric Neurology Society; Editor-in-Chief of the International League Against Epilepsy (ILAE) educational journal Epileptic Disorders and Elected member of the European Commission of the ILAE. Together with Jean Aicardi and Renzo Guerrini he authored Aicardi’s Epilepsy in Children. He received the Ambassador for Epilepsy Award from the ILAE and the Aicardi Award for excellence in Paediatric Neurology from the EPNS. He is the editor of seven books and an author or co-author of nearly 150 scientific articles in the fields of cognition and medical and surgical treatment of childhood epilepsies.

Professor Anne O’Hare is Professor of Community Paediatrics and Director of the Salvesen Mindroom Centre for Learning Difficulties, at the University of Edinburgh. She is a developmental paediatrician with extensive clinical experience in neurodisability, neuroscience and child protection. Her research interests include how neurodevelopmental conditions impact on the development of speech, language, communication, motor skills and learning and the development of effective interventions.

Professor Michael V Johnston is a Professor of Neurology, Pediatrics and Physical Medicine and Rehabilitation at the Johns Hopkins University School of Medicine and the Chief Medical Officer and the Blum Moser Endowed Professor of Pediatric Neurology at the Kennedy Krieger Institute in Baltimore, Maryland, USA. He trained in paediatrics, neurology and neuroscience at Johns Hopkins University School of Medicine, and his clinical and research interests include fetal and neonatal neurology, as well as care for older children with cerebral palsy and neurogenetic disorders including Rett syndrome. He has been active in the development of strategies to protect the developing brain from hypoxic-ischaemic injury. He is one of the founding faculty members of the Neurosciences Intensive Care Nursery (NICN) research and clinical care group at Johns Hopkins Hospital, and he has also been a leader of the Phelps Cerebral Palsy Center at the Kennedy Krieger Institute.

Professor Robert Ouvrier is Emeritus Professor of child Neurology at the University of Sydney. After training in general paediatrics in Sydney, Perth and Papua-New Guinea, he undertook specialist training in child neurology at the Royal Children’s Hospital, Melbourne, the University of Kentucky (1969-70) and the Johns Hopkins Hospital, Baltimore USA (1971-72). He was then Head of the Department of Neurology at the Children’s Hospital at Westmead, Sydney for 25 years. In 1999, he became the Foundation Head of the Institute for Neuroscience and Muscle Research at The Children’s Hospital, Westmead. He was President of the International Child Neurology Association from 2006-2010. He is the author of two books, thirty book chapters and an author or co-author of over 150 scientific articles on paediatric neurology.
Authors’ Appointments

Alexis Arzimanoglou  
Director of the Department of Paediatric Clinical Epileptology, Sleep Disorders and Functional Neurology at the University Hospitals of Lyon, France; Visiting Professor at the Universitat de Barcelona, Spain

Nadia Bahi-Buisson  
Professor in Paediatric Neurology, Necker Enfants Malades University Hospital, APHP; Paris Descartes – Sorbonne Paris Cité University, Imagine Institute; INSERM UMR-1163, Paris, France

Alasdair Bamford  
Consultant, Paediatric Infectious Diseases, Great Ormond Street Hospital, London, UK

Karen Barlow  
Paediatric Neurologist, Cumming School of Medicine, University of Calgary, Alberta, Canada

Peter Baxter  
Consultant Paediatric Neurologist, Children’s Hospital Sheffield, UK

Nathalie Boddaert  
Professor and Head of Department, Paediatric Radiology, Hôpital Necker Enfants Malades, Paris, France

Jaume Campistol-Plana  
Professor and Head of the Department of Paediatric Neurology, Hospital San Juan de Déu Barcelona, Spain

Aabir Chakraborty  
Consultant Paediatric Neurosurgeon, University Hospital Southampton NHS Foundation Trust, Southampton, UK

Russell C Dale  
Petre Associate Professor, Paediatric Neurology Research, Paediatrics and Child Health, Children’s Hospital, University of Sydney, Westmead, Australia

Bernard Dan  
Professor of Neuroscience, Université libre de Bruxelles (ULB), Brussels; Director of Rehabilitation, Rehabilitation Hospital Inkendaal, Vlezenbeek, Belgium

Linda De Meirleir  
Head of Paediatric Neurology and Metabolic Diseases and Medical Coordinator for Rare Disorders, Universitair Ziekenhuis (UZ) Brussel, Belgium

Linda S de Vries  
Professor of Neonatal Neurology, Department of Neonatology, University Medical Centre Utrecht, the Netherlands

Gabrielle deVeber  
Director, Children’s Stroke Program; Senior Scientist, Child Health Evaluation Sciences Program; Paediatric Neurologist, Division of Neurology, The Hospital for Sick Children (SickKids); Professor of Paediatrics, The Institute of Medical Science, University of Toronto, Toronto, Canada

Michael S Duchowny  
Director, Neurology Training Programs, Nicklaus Children’s Hospital–Miami Children’s Health System; Professor of Neurology and Pediatrics, University of Miami Miller School of Medicine; Clinical Professor, Department of Neurology, Florida International University College of Medicine, Miami, Florida, USA

Adré J Du Plessis  
Chief, Division of Fetal and Transitional Medicine; Director, Fetal Medicine Institute, Children’s National Medical Center, George Washington University School of Medicine, Washington DC, USA

Michael Eyre  
Specialty Registrar in Paediatric Neurology, Great Ormond Street Hospital, London, UK

Emilio Fernandez-Alvarez  
Professor, Neuropaediatric Department, Hospital Universitario San Juan de Dios, Barcelona, Spain

Robert Forsyth  
Consultant Paediatric Neurologist, Great North Children’s Hospital; Senior Lecturer, Newcastle University, Newcastle, UK

Patricia Franco  
Professor of Physiology, Coordinator of the Paediatric Sleep Unit at the Department of Paediatric Clinical Epileptology, Sleep Disorders and Functional Neurology at the University Hospitals of Lyon & INSERM U1028, Lyon, France

Paddy Grattan-Smith  
Clinical Associate Professor, Paediatrics and Child Health, Children’s Hospital, Westmead, Sydney, Australia

Richard Hayward  
Professor of Paediatric Neurosurgery, Great Ormond Street Hospital, London, UK
Cheryl Hemingway  Consultant Paediatric Neurologist, Great Ormond Street Hospital, London, UK
Michael V Johnston  Chief Medical Officer and Blum Moser Endowed Chair for Pediatric Neurology, Kennedy Krieger Institute; Professor of Neurology, Pediatrics and Physical Medicine and Rehabilitation, Johns Hopkins University School of Medicine, Baltimore, MD, USA
Colin Kennedy  Professor of Neurology and Paediatrics, University of Southampton; Honorary Consultant in Paediatric Neurology, University Hospital Southampton NHS Foundation Trust, Southampton, UK
Adam Kirton  Professor of Paediatrics and Clinical Neuroscience, University of Calgary; Director of Calgary Paediatric Stroke Program, the Alberta Perinatal Stroke Project and the Alberta Children's Hospital Pediatric Non-Invasive Brain Stimulation Laboratory, Alberta, Canada
Ingeborg Krägeloh-Mann  Professor of Paediatrics; Director Paediatric Neurology and Developmental Medicine, University Children's Hospital, Tübingen, Germany
Kenneth J Mack  Professor of Child and Adolescent Neurology, The Mayo Clinic, Rochester, Minnesota, USA
Carey Matsuba  Clinical Assistant Professor, Department of Ophthalmology, University of British Columbia, Vancouver, Canada
Miriam Martinez-Biarge  Neonatologist, Imperial College London, London, UK
Manoj Menezes  Staff Specialist in Neurology, T.Y. Nelson Department of Neurology and Neurosurgery, The Children's Hospital at Westmead; Senior Clinical Lecturer, The University of Sydney, Australia
Robert Minns  Emeritus Professor of Paediatric Neurology and Honorary Professorial Fellow, College of Medicine and Veterinary Medicine, University of Edinburgh, Edinburgh, UK
Francesco Muntoni  Professor, The Dubowitz Neuromuscular Centre, University College London, Institute of Child Health, London, UK
Kathryn N North  Professor and Director of the Murdoch Children's Research Institute and the David Danks Professor of Child Health Research at the University of Melbourne, Australia
Anne O'Hare  Professor of Community Paediatrics and Director of the Salvesen Mindroom Centre, University of Edinburgh, Edinburgh, UK
Robert Ouvrier  Emeritus Professor of Paediatrics and Child Health, The Institute for Neuroscience and Muscle Research, The Children's Hospital at Westmead, Sydney, Australia.
Karine Pelc  Consultant Paediatric Neurologist, Centre Hospitalier Universitaire Saint Pierre, Université Libre de Bruxelles (ULB), Brussels, Belgium
Eleni Panagiotakaki  Senior Consultant, Department of Clinical Epileptology, Sleep Disorders and Functional Neurology in Children, Hôpital Femme Mère Enfant, University Hospitals of Lyon, Bron, France
Monique M Ryan  Director, Department of Neurology, Royal Children's Hospital, Melbourne, Australia
Victoria San Antonio Arce  Head of the Epilepsy, Sleep and Neuropysiology Section, Neurology Service, Sant Joan de Déu Barcelona Children's Hospital, Barcelona, Spain
Mariacristina Scoto  Specialty Doctor in Neuromuscular Diseases; Honorary Senior Clinical Research Associate, The Dubowitz Neuromuscular Unit, University College London; Institute of Child Health and Great Ormond Street Hospital, London, UK
Bruce K Shapiro  Professor of Pediatrics, The Johns Hopkins University School of Medicine, Vice President, Training, Kennedy Krieger Institute, Baltimore, USA
Marc Tardieu  Professor of Pediatrics, Neurology, Université Paris Sud; Head, Immunology of Viral and Autoimmune Diseases, Inserm U1184, Paris, France
Roberto Tuchman  Chief, Department of Neurology, Nicklaus Children's Hospital, Miami Children's Health System, Miami, USA
Dominic NP Thompson  Consultant Paediatric Neurosurgeon, Department of Neurosurgery, Great Ormond Street Hospital, London, UK
David Walker  Professor of Paediatric Oncology, Children's Brain Tumour Research Centre, University of Nottingham, Nottingham, UK
Andrew Whitelaw  Emeritus Professor of Neonatal Medicine, University of Bristol, Bristol, UK
Preface to Third Edition

Diseases of the nervous system in infancy and childhood have a profound impact on the life of patients and their families and are probably the most disruptive of all pediatric ailments. Around 20–30% of hospitalized pediatric patients have a neurological problem, either as a sole or as an associated complaint. However, many well-educated pediatricians not infrequently feel uncomfortable and hesitant about how to treat children and what to tell to parents of patients with neurological disorders.

Diseases of the Nervous System in Childhood is meant for physicians with an interest in pediatric neurological diseases, whether pediatricians, neurologists, child neurologists or physi-cians dedicated to developmental medicine, and deals only with diseases of the nervous system (as indicated by its title). It is res-olutely clinically oriented but, when necessary, some notions concerning pathogenesis and mechanisms are provided.

This third edition has been extensively updated to cover the tremendous volume of new information collected over the past 10 years, while trying to maintain the size of the book within reasonable limits. In spite of considerable efforts the speed of acquisition of new information is such that no textbook can pre-tend to be really up to date with respect to the very latest data. Electronic databases fulfill the need for 'last minute' results, but in a fragmentary and often uncritical manner. Books, on the other hand, aim to give a different, more global and balanced overview of a subject, taking into account the relative importance of the various parts, and assessing and selecting the material in the light of the experience of authors. I believe this synthetic and critical process is more essential than ever in view of the abundance of the material available.

The rapid increase of new data necessitated some rearrangements of this book. Unlike in the earlier editions where I had principally edited all the chapters, I felt this was no longer possible and invited Dr Martin Bax and Professor Christopher Gillberg to be co-editors with me, and they viewed all the ma-terial. In addition, whereas previously I had taken responsibility for the majority of chapters, we decided it was necessary to invite more collaborators to author certain chapters. We are very grateful to those who have given their time and knowledge for the completion of the book.

As before we have not included a chapter on the neurological examination of infants and children. Excellent books and mono-graphs on these topics are available (e.g. Cioni and Mercuri 2008). We have also omitted the chapter on fetal neurology as this highly specialized area of pediatric neurology is also well covered by a number of texts (e.g. Hill and Volpe 1989, Levene et al. 2001).

I wish to introduce this book with a few remarks, based on a 40-year experience, on what could be termed the 'philosophy' of pediatric neurological examination. In this age of ubiquitous technology, I strongly believe that collection of clinical data and their correct interpretation remain as essential as ever.

In the first place, the eminent importance of history taking needs to be re-emphasized, as the history of the disease – as well as that of the child from conception and that of his/her family–forms the initial and most important step of the diagnostic approach. For most conditions, the diagnosis is established by thorough clinical history even before, and much more frequently than by, examination (Dooley et al. 2003). History taking is a dif-ficult art requiring careful listening, patience, clinical acumen and understanding. It also necessitates a thorough knowledge of which information is worth looking for, and constant attention to possibly revealing words that may occasionally emerge out of a casual or even apparently irrelevant conversation.

This emphasis on history taking does not in any way min-imize the essentiality of neurological examination, which should be as thorough as possible and largely guided by histor-ical data. However, in children, and especially in infants or neonates, it cannot be conducted systematically as in adults. Attempts at 'adult-type' examination will lead to crying and fussing. Much of the examination should not require that the child be lying, as the lying position will often frighten the child by reminding him/her of previous unpleasant experiences and prevent the gathering of more important information on cen-tral nervous system functioning. After all, the vertical posture has been a major evolutionary acquisition and, since the emer-gence of Homo erectus, most human activities take place in the standing position.

Indeed, a major part of examination, and one too often ne-lected, consists of watching the spontaneous activity of the child. While an early example of observation is of neonatal and early infantile general movements, which have been shown to have predictive value (Ferrari et al. 1990, Einspieler and Prechtl 2005), later observation should be watching children’s sponta-neous activity with special emphasis on how they relate to their surroundings and to other children or adults, the duration of their capacity of attention, and their
verbal or preverbal communica-tion. Playing or interacting with the child is the best manner of assessing CNS function and provides information not only on purely neurological function but also on behavioural problems, which is clearly essential for the diagnosis of the behavioural syndromes that are currently taking a major place in child pathology. Advan-tage can be taken as often as possible of video-recording for prolonged observation of children’s behaviour and is also par-ticularly useful for the precise study of transient events such as seizures as it allows leisurely and repeated analysis of the ictal phenomena.

It cannot be overemphasized that the basic role of the ner-vous system is to produce not just reflexes but above all com-plex and adaptive behaviours that are much more informative on the status of the central nervous system than elementary responses to imposed stimuli. This is best achieved by pro-longed observa-tion of the qualitative aspects of the sponta-neous activities of the children or infants. All too often, the child is examined but not looked at.

Spectacular advances in medical technologies made over the past decades have revolutionized and enormously increased our diagnostic possibilities, both pre- and postna-tally (and recently even in pre-implantation diagnosis), and also improved follow-up surveillance far beyond what could be imagined 20 years ago. Neuroimaging, especially MRI, has become an almost rou-tine investigation, and with con-tinuing improvements and new developments such as diffusion-weighted MRI, tensor tractog-raphy, functional MRI and MR spectrography can now provide information not only on the anatomy but also on the function of some of the central nervous system structures. Biochemical progress in the molecular structure of proteins and the advent of molecular genetics allow a precise diagnosis of many genetic dis-orders even in the absence of clinical manifestations, represent-ing an entirely new field opening new perspectives in diagnosis and prevention. However, at the same time, the availability of these multiple techniques has made the task of choosing among the possibilities offered much more difficult. Investigations should not be performed indiscriminately or systemati-cally but only after formulation of one (or a limited number) of diagnos-tic hypotheses, arising mainly from history and clinical findings, with a view to validate or reject them on the basis of their con-frontation by clinical and laboratory data. Clinical medicine is and must remain an intellectual process whereby all sources of information, whether clinical stricto sensu or arising from tech-nical aids, are used to formulate a diagnosis that will lead to the best possible care of the patient. One’s last task is to communi-cate and discuss our, some-times complex, findings with the pa-tient and their family. I hope this new edition of Diseases of the Nervous System in Childhood will help the clinician to carry out his/her tasks effectively.

JEAN AICARDI
Paris, September 2008

REFERENCES
Preface to Fourth Edition

Jean Aicardi (1926–2015) authored the first edition of Diseases of the Nervous System in Childhood, which was published in 1992. Professor Aicardi was one of the most insightful clinicians of his time, who had witnessed the birth of child neurology as an entirely new field of medicine. His book rapidly became a premier reference tool for those clinicians around the world who were fascinated by the highly complex field of study – the developing nervous system.

Only six years later in his preface to the second edition (1998), Aicardi wrote “…the pace of progress both in medicine and in communication techniques has been so fast in the past few years that there are those who wonder whether books are still useful. They argue that new data are accumulating so rapidly that only computerized databases and networks can permit users to keep abreast of current developments in basic and clinical sciences, and that books are irredeemably condemned to be outdated even at the time of publication”.

A third edition followed in 2009 because, as Aicardi was already arguing in 1998, “…immediate availability of such an overwhelming volume of information may be a mixed blessing as assessment of the quality and relevance is left to the judgement of each user, whereas books may be of some help in soliciting the most important data and giving an idea of their organization and significance, assuming that the author’s choices are backed by a certain experience and provided they are not excessively biased”.

As Editors of the fourth edition our first challenge was to respect, and as much as possible reproduce, the resolutely clinical orientation of the previous editions. All authors were free either to update the chapters or completely rewrite them, under one condition, that, as Aicardi did, they target the clinical readers. As with the previous editions they were asked to contribute to a reference book for practising child neurologists that would also provide a comprehensive overview for those training in child neurology.

We are happy to acknowledge that, in this era of genomic medicine, all authors respected the fact that understanding the phenotypic spectrum of the huge variety of disorders of the child’s nervous system remains of paramount importance. Family history-taking needs to be taught to all those who wish to practise child neurology. A thorough clinical and physical examination is the second indispensable step towards diagnosis.

The combination of these two steps represents the optimal road to the formulation of a diagnostic hypothesis, then followed by the selection of the most appropriate laboratory and/or imaging investigations and the correct interpretation of the impressive quantity of complex results provided by all types of screening.

The structure of the book was globally respected, but some important changes have been implemented in this fourth edition. The chapter on Fetal Neurology (missing from the third edition) has been reintroduced. Movement disorders, previously discussed in different chapters, are now treated in a dedicated section to better reflect recent advances in the field. Some of the paroxysmal disorders other than epilepsy have also been treated separately and the section on developmental and neuropsychiatric disorders has been modified.

We also respected the wish of Aicardi and deliberately did not include a specific section on the neurological examination of infants and children at various ages or give data on maturation of the nervous system. There are already Excellent books and monographs on these topics.

We are also conscious of the fact that almost unavoidably (considering where nearly all authors and editors were located) the book mainly focuses on child neurology in high-income countries. However, we believe that by respecting the clinical approach, as Aicardi did, a large part of the content will also be useful to those colleagues working in countries where technical facilities are not optimal or may be lacking altogether.

Our aim was not to provide an exhaustive review for each disorder; only some notions on pathogenesis and mechanisms are provided. Nowadays, for each of the disease categories the reader can access other high-quality books and review articles, both in print and/or electronic versions. We, therefore, favoured a comprehensive description of clinical findings to permit diagnostic orientation, prognosis and management.

We also respected the style of the previous editions by providing, per chapter, a rather broad selection of references for further reading. At this point, allow us to thank the publishers for having agreed to respect the space-consuming alphabetical arrangement of the references. Being clinicians ourselves we know, when reading a chapter, how much more convenient it is to immediately identify who wrote a given reference and when. We also believe that having to hand a source of valuable references might prove to be at least as useful as searching in online. In that respect, and although all references were updated, we also asked the authors to include, whenever possible, seminal articles rather than ‘copying and pasting’ references to review publications.
Physicians caring for children with rare or common neurodevelopmental disorders must keep in mind that a 'disease' will always be defined as a disorder of structure or function typically manifested by distinguishing signs and symptoms, with aetiology probably being the most important factor influencing prognosis and outcome. Each diagnostic investigation, taken alone, no matter how sophisticated, provides only a hint towards diagnosis.

Child neurology is reaching a turning point. During its early adolescence the discipline focused on description of numerous disorders. Identifying and homogeneously classifying, as best as possible, these disorders led to a better understanding of underlying mechanisms and to the development of global care practices.

In the 21st century, the development of new technologies needs to be perceived not just as an easy road to diagnosis but as a tool for a better understanding of the causes and as a support for research in discovering novel treatments that will improve the clinical management of affected children.

We remain grateful to Jean Aicardi for his pioneering work. We would like to thank all our co-authors and the publishers for having accepted the challenge to maintain his teaching as reliably as possible, ensuring that it is available for future generations of child neurologists.

Acknowledgements

ALEXIS ARZIMANOGLOU

I am grateful to the families of my patients who during all these years entrusted me with their most precious children and taught me how to listen. Allow me also to acknowledge my own family and personal friends for their constant support. A huge “thank you” to my students who later became my friends and colleagues practicing child neurology in so many different parts of the world. Particularly those with whom I had the pleasure to co-author some of the chapters of this book. Last but not least, I will always be grateful to all those colleagues from whom I learn and keep appreciating their advice: members of the Child Neurology Departments of the San Juan de Déu Hospital in Barcelona, the Robert Debré and Necker-Enfants Malades Hospitals in Paris, the HFME hospital in Lyon; the members of the Société Européenne de Neurologie Pédiatrique, the International League Against Epilepsy, the European Paediatric Neurology Society, the American Epilepsy Society, the U-Task force for paediatric epilepsy surgery, the steering committee of the European Reference Network EpiCARE; all co-authors of this book and my team full of excellence at the University Hospitals of Lyon. I am confident they will recognise themselves. Merci.

ANNE O’HARE

I am grateful to my co-authors Bruce Shapiro, Roberto Tuchman, Carey Matsuba, and colleagues who generously gave of their time to advise: Ailsa McLellan Paul Eunson, Kaseem Ajiloga, Lynne Bremner, Ruth Henderson, Dawn Lamerton and the families who generously granted permission for their imaging to be included.

MICHAEL JOHNSTON

I would like to acknowledge Andrea Poretti, MD a Pediatric neurologist and expert on the cerebellum who very unfortunately passed away before the book was published. Andrea was from Switzerland worked with us at Hopkins and Kennedy Krieger and mentored by Prof Thierry Huisman.

ROBERT OUVRIER

Apart from my co-authors, Manoj Menezes, Paddy Grattan-Smith, Elsdon Story, and Russell Dale, I gratefully acknowledge all those who gave advice, case histories or illustrations: Eugen Bolzshauser, Philip Britton, Chris Burke, Stephane Mathis, Shekeeb Mohammad, Michael Stevens, Chris Troedson, Jean-Michel Vallat, and Eppie Yiu.

Editors

CHAPTER 1
We acknowledge the help of the late Dr Andrea Poretti with this chapter.

CHAPTER 4
All new figures were provided in this chapter by Professor Laurent Guibaud, Department of Foetal and Paediatric Imaging, HFME, University Hospitals of Lyon, France.

CHAPTER 5
The valuable help of Dr Nicolas Deconinck Head of the Neurology Department, Hôpital Universitaire des Enfants

CHAPTER 9
The invaluable assistance of Prof Jaume Campistol Plana, Head of the Child Neurology Department of Hospital San Juan de Déu (Barcelona, Spain) in reviewing this chapter and the foundational work done by Hélène Ogier on this topic in the previous editions of this book are acknowledged.

Authors

Reine Fabiola, Université Libre de Bruxelles (ULB) in Brussels, Belgium and Dr Catheline Vilain the Department of Genetics, Hôpital Erasme, Université libre de Bruxelles in Brussels, Belgium are acknowledged.
CHAPTER 10
We thank Professor Eugen Boltshauser, Professor emeritus Department of Pediatric Neurology, University Children’s Hospital, Zürich, Switzerland; Dr Eppie Yiu Paediatric Neurologist, NHMRC Early Career Fellow at the Department of Neurology, Royal Children’s Hospital Melbourne, Australia; and Professor Elsdon Storey, Professor of Neuroscience, Department of Medicine, Central Clinical School, Monash University Melbourne Vic Australia 3004, for their invaluable contribution to this chapter.

CHAPTER 12
Our late friend and colleague Dr Andrea Poretti, former Director of Pediatric Neuroradiology research at Johns Hopkins, and attending pediatric neurologist at Kennedy Krieger Children’s Hospital prepared several figures for this chapter.

CHAPTER 16
We acknowledge the medical and paramedical team at the Paediatric Clinical Epileptology, Sleep Disorders and Functional Neurology Department and of the Child Neurology Department at the University Hospitals of Lyon, France and the valuable help of our PA Mrs Sophie Naous.

CHAPTER 26
We thank Dr Anna Sarkozy, Dr Adnan Manzur, Dr Pinki Munot and Dr Stephanie Robb for the clinical activities in the Dubowitz Neuromuscular Centre.

CHAPTER 27
I acknowledge the assistance of Dr Dan Connolly, Neuroradiologist, Sheffield Children’s Hospital who helped select and describe the MRs used in the chapter. I am grateful to the following colleagues at Sheffield Children’s Hospital who reviewed the respective sections: Dr Sally Connolly, Paediatric Gastroenterologist/Hepatologist; Professor Paul Dmitri, Paediatric Endocrinologist; Professor Heather Elphick, Respiratory Paediatrician; Dr Jeanette Payne, Paediatric Haematologist; Professor Ajay Vora, Paediatric Haematologist; and Dr Jenny Welch, Paediatric Haematologist.

Non-Invasive Techniques for Monitoring Fetal Hypoxemia and Acidosis
The Fetal Neurological Examination – a Work in Progress
A BRIEF HISTORY OF FETAL NEUROLOGY

The earliest studies of fetal neurological function were focused on fetal motor activity, based on the observation of aborted human fetuses. In 1837, Erbkam published the first descriptions of ‘fetal’ movements from his direct observations of spontaneous miscarriages (Erbkam 1837). In the 1930s a Pittsburgh anatomist Davenport Hooker studied and filmed the activity of human fetuses from clinically indicated surgical abortions (Wilson 2014). The rapid development of fetal neurology in recent years has been driven by three major forces. The first major advance in fetal imaging, starting in the 1970s, provided the original real-time observation of the fetal morphology with 2D-ultrasound. The ability to view the fetus enabled the study of in utero fetal behaviour which in turn generated a school of mainly European investigators, led by the Austrian neuroscientist, Heinz Prechtl and his team (de Vries et al. 1982; Prechtl 1985). These investigators compiled a detailed developmental description of the emergence and evolution of fetal movements and began to apply their observations as a tool to assess the integrity of the developing nervous system. The second major stimulus for the nascent field of fetal neurology has been the advance in our understanding of neurology of the preterm newborn infant (‘ex utero fetus’) over the past 40 years. Finally, there has been a growing recognition that many of the major chronic diseases of childhood and adults have their origins in fetal life (Ravelli et al. 1998; Roseboom et al. 1999; Hales and Barker 2001) including neurological and psychiatric conditions such as attention deficit disorder, autism and schizophrenia (Geddes et al. 1999; Walker et al. 2015). In addition, the role of earlier fetal compromise in predisposing to catastrophic perinatal brain injury is now generally accepted and has focused studies onto the intrauterine support of fetal brain development.

Ongoing advances in the speed and resolution of fetal imaging continue to advance our understanding of the fetus and associated milieu. As the speed and structural resolution of fetal neuroimaging becomes increasingly sophisticated, so does the diagnostic and prognostic expectations of the neurologist grow. Firstly, the increased structural resolution of particularly fetal MRI now detects smaller anatomic changes that require careful distinction from normal variation; this in turn demands an in-depth understanding of normal fetal brain development. Hereafter, an aetiological diagnosis is pursued, often with limited additional fetal neurodiagnostic tools. Particularly pressing issues include the neurodevelopmental prognosis and likelihood of recurrence in future pregnancies. Determining whether the neurological risks are likely to be progressive during and after gestation, as well as how the fetal brain will tolerate the hazards of labour and delivery, need to be considered. Based on the imaged phenotype additional diagnostic testing for genetic or environmental causes may be indicated. Gathering all available diagnostic information in a timely manner is particularly critical in situations where termination of pregnancy is an option. There may considerable pressure on the neurologist in situations where the outcome of the pregnancy may depend on their prognostic opinions. In addition, given the inevitable maternal stress triggered by an unknown fetal diagnosis, as well as the known adverse effects of maternal stress on the fetus, there is frequent pressure on the neurologist to formulate an opinion with limited data and without the benefit of a conventional physical examination of the fetus. If the pregnancy continues the neurologist should provide brain-oriented recommendations for the planning of labour, delivery and the transitional period, with the goal of minimising the risk of secondary brain injury.

The basic expertise needed by a fetal neurologist includes an in-depth understanding of structural and functional neuroembryology, the available neurodiagnostic tools and a first-hand experience of the long-term neurodevelopmental outcomes of the common fetal phenotypes. Although the field is still largely driven by dysmorphology it is inevitable that expertise around the environmental threats to the developing fetal brain will become essential with increasingly sophisticated fetal testing. This will require an understanding of the normal and pathological intrauterine milieu, basic principles of obstetrics, transitional physiology and pathophysiology, as well as the potential brain hazards confronting the fetus and newborn infant with congenital anomalies. In addition, counseling requires an understanding of the legal, cultural, religious and ethical considerations for each individual.

Currently, the practice of fetal neurology remains heavily influenced by standard obstetric protocols for fetal imaging, which vary across different regions. Specifically, most – but not all – fetal neurological concerns arise during the standard
‘anatomy screening’ fetal ultrasound around mid-gestation. As such the majority of consultations are for suspected neurological anomalies on these screening studies and are therefore lesion driven. The future role of the neurologist in fetal care is likely to involve a more active role in the brain-oriented care of high-risk populations, such as the fetus with growth restriction, birth defects and complicated twin pregnancies. The clinical discussions in this section will be confined to those most commonly seen in fetal neurology consultation and the territory covered is by no means exhaustive: many of the diagnoses more commonly made during postnatal period are discussed elsewhere in this book. The focus will be on conditions currently detectable in the fetal period rather than those diagnosed at birth or early infancy and are of presumed fetal origin.

**NEUROEMBRYOLOGY**

**NORMAL NEURAL TUBE DEVELOPMENT**

Development of the human nervous system starts on day 15 post-conception (p/c) when a primitive streak of specialised neuroectoderm forms on the dorsal surface of the embryo. Hensen’s node is a small nodule at the rostral end of the neural plate which directs development of the anterior neural tube. **Dorsal induction** is responsible for the formation and closure of the neural tube as well as the three primary vesicles at the rostral end of the neural tube. **Ventral induction** leads to formation of the cerebral hemispheres, eye vesicles, olfactory bulbs, pituitary glands and part of the face while dorsal induction includes primary and secondary neurulation. **Primary neurulation** begins with formation of the neural plate and tube, ending when the neural tube is separated from the surface ectoderm by the intervening mesenchyme. Formation of the neural plate starts on day 17 p/c and is complete by day 18 p/c when the edges of the neural plate begin to elevate, folding over to form the neural tube (Fig. 1.1). The entire process of primary neurulation is under the inductive influence of the notochord and chordal mesoderm underlying the neural plate/tube. Closure of the neural tube starts on day 20 p/c at the level of the future rhombencephalon. The anterior neuropore at the rostral end of the neural tube closes by day 25 p/c and the posterior neuropore on day 28 p/c at the upper sacral level. In the process of neural tube closure several important events occur: understanding both the normal and disturbed evolution of these developmental events is essential for informed evaluation and counseling of these cases. First, the neural tube becomes separated from the cutaneous ectoderm (disjunction) which then closes over the midline. The neural tube then becomes encircled by the mesenchyme which is interspersed between the neural tube and dermal ectoderm. Exposure to the external surface of the neural tube induces the mesenchyme to develop into the vertebral column, meninges and muscle. When the neural tube fails to close exposure to the internal ependymal surface of the open central canal induces the mesenchyme to differentiate into fatty tissue, a process thought to be responsible for the association between neural tube defects and lipomatous lesions. Finally with closure of the neural tube neural crest cells are formed that come to lie on the dorsolateral aspects of the neural tube, where they develop into the dorsal root ganglia, cranial sensory and autonomic ganglia, as well as other tissues. Disturbances in disjunction, either premature disjunction or failure of disjunction, underline many of the congenital spinal lesions seen in clinical practice.

Closure of the posterior neuropore marks the start of **secondary neurulation** at the caudal eminence. Secondary neurulation occurs in weeks 5 and 6 p/c, forming the sacrococcygeal elements caudal to the closed posterior neuropore and proceeds without direct involvement of the neural plate and tube. As the embryo approaches 30 days p/c this caudal eminence undergoes canalisation with cyst formation and coalescence, ultimately forming the filum terminale and distal conus medullaris. Ventral induction, which extends from 4 to 20 weeks p/c, includes a number of major developmental events. From 4 to 6 weeks p/c, following closure of the anterior neuropore, a series of constrictions form three anterior neural tube vesicles (prosencephalon, mesencephalon and rhombencephalon) (Fig. 1.2). Hereafter, three major flexures, the mesencephalic, pontine and cervical flexures, form in the anterior neural tube.
Patterning of the neural primordium describes the process of regionalisation by which segmented cell differentiation occurs across the developing neuroaxis. Patterning is controlled by a precise spatial and temporal agenda of gene expression along the rostrocaudal, dorsoventral and mediolateral axes of the neural tube. Morphogenetic gradients of inductive signalling and gene expression along each of these axes determine the regional phenotype of neural cells. In this way the developing neuroaxis becomes divided along the rostrocaudal axis into segments or neuromeres, each with a floor, basal, alar and roof plate (Fig. 1.1). Specialised signalling centres called ‘secondary organisers’ develop at genetically determined sites along the neural tube to further refine the local neural identities along the rostrocaudal and dorsoventral axes. Three secondary organisers have been identified at the rostral edge of the neural plate (the anterior neural ridge), in the diencephalon (the zona limitans interthalamica) and at the midbrain-hindbrain junction (the isthmic organiser; IsO) (Vieira et al. 2010) (Fig. 1.3). These secondary organisers are responsible for the graded expression of dorsalising and ventralising factors that generate the ventral motor and dorsal sensory cells of the neural tube. Most important among the dorsalising factors are the bone morphogenic protein (BMP) family produced by the non-neural ectoderm of the roof plate (Fig. 1.1), while proteins expressed in the prechordal and floor plates by the sonic hedgehog (SHH) gene are the major ventralising factors.

DISORDERS OF NEURAL TUBE DEVELOPMENT

DISORDERS OF PRIMARY AND SECONDARY NEURULATION

Dysraphism of the Entire Neural Tube

Craniorachischisis Totalis, the most severe form of neural tube defect, results from complete failure of neurulation and leaves the neural plate entirely uncovered by mesodermal and cutaneous ectodermal structures. These lesions are obviously incompatible with life, the vast majority resulting in spontaneous abortion in early gestation.

Dysraphism of the Anterior Neural Tube

Anencephaly results from failed closure of the neural tube anterior to the point of first neural tube closure at the level of the lower brainstem-cervical junction (i.e. the foramen magnum). In the most severe forms it extends forward to the level of the anterior neuropore at the lamina terminalis, thereby leaving the entire dorsal surface of the cerebrum and brainstem uncovered. Neural structures are not identifiable above the brainstem by fetal imaging (Fig. 1.4) and the few children who survive pregnancy die soon after birth.

An alternative explanation for the pathogenesis of anencephaly is that it is not a disturbance in primary neurulation, but rather due to primary developmental failure of the overlying mesoderm (skull and meninges) and non-neural ectoderm.
Encephaloceles

Encephaloceles are localised defects of neural tube closure anterior to the foramen magnum with extracranial extension of a cystic structure containing meninges, neural tissue and cerebrospinal fluid (CSF) (Fig. 1.5). Venous structures are often included in the cyst or – if intracranial – anomalous venous drainage is common. If parts of the ventricular system are extracranial the term meningoencephalocystocele (Fig. 1.5c) is used: the large majority of encephaloceles are occipital (Fig. 1.5a) while less common sites are frontal (often extending into the nasal cavity; frontoethmoidal) (Fig. 1.5b), temporal and parietal encephaloceles. Anterior encephaloceles tend to have a more favourable prognosis. When the CSF-filled lesions contain no obvious brain parenchyma the term cranial meningocele is used (Fig. 1.5f). Occipital encephaloceles most commonly include occipital lobe tissue, as well as sometimes cerebellar and brainstem tissue. Low occipital encephaloceles (sometimes extending into the cervical spine) may be associated with downward herniation of the cerebellar tissue when it is known as the Chiari III malformation. Encephaloceles may be associated with other intracranial complications, including hydrocephalus (in up to half of patients), microcephaly, subependymal heterotopias and agenesis of the corpus callosum.

Encephaloceles are often skin-covered, in which case maternal and amniotic fluid alpha-fetoprotein (AFP) are normal. The pathogenesis of these lesions is likely to be multifactorial; they have been associated with environmental factors such as early gestational hyperthermia, irradiation, hypervitaminosis A and maternal diabetes. Encephaloceles may be associated with malformations in other systems as well as recognised syndromes such as Meckel-Gruber and Walker-Warburg syndromes.

DYSRAPHISM OF THE POSTERIOR (SPINAL) NEURAL TUBE

These lesions are located posterior to the point of initial neural tube closure, i.e. below the foramen magnum. Terminology describing the various spinal malformations has been used inconsistently, leading to confusion in the field and compromised counselling. Spinal dysraphism is a term used to describe a broad spectrum of anomalies that involve variable degrees non-fusion of the neural, vertebral and mesenchymal tissues of the spine. The term spina bifida refers to interruption of the bony vertebral closure around the spinal cord (Botto et al. 1999). Spinal dysraphic defects may be further categorised as open or closed depending on whether they are skin covered or not. Examples of open spinal dysraphisms include myelo-meningoceles and myeloschisis, while skin-covered, closed...
Chapter 1 Fetal Neurology

Dysraphic lesions include meningoceles and lipomeningoceles. These lesions are illustrated in Figure 1.6.

Open Spinal Dysraphism

Open spinal dysraphism (OSD) occurs from regional failure of neural tube closure in the third week of pregnancy. The fundamental defect in OSD is non-disjunction of the cutaneous and neural ectodermal tissues during closure of the neural tube, leaving the lateral edges of the neural tube in continuity with the skin. By obstructing the normal interposition of mesenchyme between the two ectodermal layers development of the vertebral column is impeded: failure of the cutaneous and neural ectoderm layers to separate prevents skin closure over the defect, leaving the ependymal-lined central canal of the open neural tube (the placode) exposed to the external surface. If the placode is flush with the skin surface the lesion is called a myelocoele (or myeloschisis). Conversely, when there is dorsal displacement of the neural tissue by an expanded anterior subarachnoid space that causes the placode to protrude beyond the skin lesion is called a myelomeningocele (Figs. 1.6a and b). The direct exposure of the spinal neural tissue and meninges to the amniotic fluid is thought to contribute to the neurological dysfunction in affected individuals, which has led to a ‘two-hit hypothesis’ in which the neurological outcome is thought to be determined not only by the underlying neural defect but also injury to the exposed neural tissue through chemical, inflammatory or physical insults (Adzick 2010).

The incidence of OSD lesions is around 0.5–1.0/1000 live births but occurs with considerable regional variability. The precise mechanism(s) for failure of neural tube closure remains unknown and in most cases the aetiology is probably multifactorial, with the majority sporadic in nature (Shaer et al. 2007). Disturbances in folate metabolism have been invoked for several reasons, the first being that antenatal folate administration has decreased the frequency of OSD. Second, mutations of the methylene tetrahydrofolate reductase (MTHFR) gene – which result in disturbed folate metabolism – have been implicated in up to 20% of OSD (Christensen et al. 1999). In a small minority of individuals OSD occurs as part of syndromes such as aneuploides (especially trisomy 18), Meckel–Gruber syndrome (autosomal recessive) and Lehman syndrome (autosomal dominant) (Sepulveda et al. 2004; Hume et al. 1996). A number of teratogenic agents have been implicated including antiepileptic agents (valproic acid, carbamazepine) and vitamin A, as well as maternal factors such as diabetes, obesity and hyperthermia.

About 80% of myelomeningoceles develop between the thoracolumbar and lumbosacral levels (Fig. 1.7). The vast
majority of myelomeningoceles are associated with hindbrain herniation or the Chiari II malformation, a lesion thought to result from leakage of CSF through the open spinal defect. Loss of CSF removes the necessary pressure support required to distend the rhombencephalic ‘ventricle’ (McLone and Knepper 1989) which plays an important role in posterior fossa development. The resulting small posterior fossa results in crowding of the neural structures, obliteration of the cisterna magna, downward displacement of the cerebellar tonsils and vermis and disturbed CSF dynamics. The hindbrain herniation may be progressive through gestation, while myelomeningoceles may be associated with other brain anomalies including callosal agenesis, tectal beaking, periventricular heterotopias, an enlarged thalamic massa intermedia and other migrational anomalies. Split cord malformations (including diastematomyelia), in which a bony or cartilaginous septum divides the spinal canal and any contents, may complicate up to 40% of myelomeningoceles (Schwartz and Barkovich 2012): these malformations may be difficult to identify prenatally.

Diagnosis of OSD can be made in several ways. In many developed countries screening tests of maternal serum AFP levels are available, with diagnostic tests including amniotic fluid levels of AFP and acetylcholinesterase, as well as fetal imaging. Maternal serum and amniotic fluid AFP are normal in closed neural tube defects. In the interpretation of AFP levels it is important to be aware of conditions that may affect the AFP values, including gestational age, fetal demise, twins and abdominal wall defects. Fetal US studies and particularly targeted fetal ultrasound and MRI studies are used to diagnose myelomeningocele, based on the spinal defect and associated signs such as the characteristic shape of the calvarium (the ‘lemon’ sign) and the crowded cerebellum (the ‘banana’ sign) by fetal ultrasound (Fig. 1.8). Microcephaly is common especially between 16–24 weeks but this often resolves spontaneously later in pregnancy, with macrocephaly developing in some individuals who develop hydrocephalus. Other associated features may include talipes equinovarus and hip dislocation. Karyo is indicated if other malformations are detected.

Differential Diagnosis

Differential diagnosis of OSD includes sacrococcygeal teratomas, as well as the skin covered closed neural tube defects, lipomyelomeningoceles, meningoceles and myelocystoceles.

The prognosis of OSD depends on a number of factors that may impact neurological function. Prognostic factors include the segmental level of the spinal lesion, the degree of posterior fossa crowding and hindbrain herniation, the development of hydrocephalus and the presence of associated cerebral malformations. More than 75% of infants with OSD survive into adulthood; however, despite intensive management 14% of infants with myelomeningoceles die before 5 years of age (Oakeshott and Hunt 2003). Neurological deficits may originate from the brainstem level in those with Chiari II malformations: in one large study of myelomeningocele survivors one-third of individuals developed feeding dysfunction, stridor or apnea events (McLone et al. 1985). Brainstem dysfunction in these infants may be delayed until after 3 months of age and increases the mortality rate to 35% (Oakeshott and Hunt 2003). Cognitive outcome in these infants depends on a number of factors including the presence of other cerebral anomalies, such as agenesis of the corpus callosum (ACC), cortical dysgenesis and periventricular heterotopias. These lesions may also underlie the approximately 20% of children with myelomeningoceles who develop seizures. Cognitive outcome in a large but earlier study showed an average IQ of 102 in children where myelomeningocele was not complicated by hydrocephalus, an IQ of 95 where a shunt remained uninfected and an IQ of 73 in children complicated by shunt infection. About 70% of myelomeningocele survivors have an IQ higher than 80 but only half are able to live independently as adults (Hunt 1990). With regard to motor function, movements may be seen by fetal ultrasound or in the early neonatal period at levels below the segmental level of the lesion but are

Figure 1.8 (a) Fetal ultrasound showing the lemon-shaped calvarium and (b arrow) the banana-shaped cerebellum in the crowded posterior fossa.
then lost during subsequent days (Sival et al. 2004; Korenromp et al. 1986). Unaided ambulation can be expected for lesions below S1, while lesions above L2 are entirely or partly wheelchair dependent. Children with lesions at L4/L5 levels will be ambulatory (with or without devices) about 50% of the time; when lesions are above the L2 level scoliosis can be expected to develop at some point. Urinary and fecal incontinence is almost universal in myelomeningocele; hydrocephalus – which develops in about 85% of individuals – (Dias and McLone 1993) may be caused by compression of fourth ventricular egress or from aqueductal stenosis which accompanies myelomeningocele in 40–75% of individuals (Gilbert et al. 1986). The vast majority of children with hydrocephalic OSD will require ventricular shunts, of whom almost half will develop complications in the first year after shunt placement (McLone 1983; Caldarelli et al. 1996).

Management of Open Spinal Dysraphism

Prevention should be the primary goal but is complicated by the multifactorial aetiology of open spinal dysraphism (OSD). Folate supplementation has resulted in a significant decline in the incidence of myelomeningocele; however, compliance with recommendations for folate supplementation remains disappointing. Folate supplementation is optimal and associated with an 83% reduction in OSD rate (Wald 2004) when taken at 4 mg/day for at least 3 months before conception. The optimal delivery mode after fetal diagnosis of an OSD lesion remains controversial: pre-labour Caesarean delivery was associated with improved lower extremity function at two years compared to vaginal delivery and Caesarean after onset of labour (Luthy et al. 1991). Among those with Caesarean after labour onset the outcome was better for those with intact amniotic membranes at delivery (Shurtleff et al. 1994). Other less rigorous studies have shown no difference in outcome between vaginal and abdominal deliveries (Merrill et al. 1998). The postnatal surgical management for myelomeningocele has not changed significantly in years and is essentially focused on providing skin closure, de-tethering the spinal cord and shunt placement where hydrocephalus is significant. Closure of an OSD usually occurs between 24–72 hours after delivery to decrease risks of infection; unless significant hydrocephalus is present at birth shunt placement may be deferred for several days to allow initial healing of the spinal lesion and assess the effects of decreased spinal leakage on CSF dynamics and ventricular size. Significant hydrocephalus may disrupt healing of the spinal repair and necessitate earlier shunt placement.

A three-centre randomised clinical trial (The MOMS Trial Adzick et al. 2011) comparing fetal versus neonatal myelomeningocele repair found that a fetal repair between 19 and 26 weeks’ gestation, for lesions between T1 and S1 spinal levels, was associated with a decreased incidence of shunt-dependent hydrocephalus by 12 months as well as a decrease in hindbrain herniation (Adzick et al. 2011). This procedure has become available at a number of centres in the United States and results from this expanded clinical deployment of the technique are awaited. Since these procedures involve closure of the spinal lesion with skin and dura through a hysteroctomy approach it is unsurprising that significant concerns include scar dehiscence and preterm birth, emphasising the need for careful selection of candidates and adherence to protocol.

Closed Spinal Dysraphism (CSD)

These lesions, which include meningoceles, lipomeningoceles, lipomyelomeningoceles and myelocystoceles, are by definition skin-covered. Although they are often evident as mass lesions elevating the skin surface they are seldom associated with Chiari II malformations. Distinction in the fetal period between open and closed spinal dysraphism may be difficult in some individuals (Husler et al. 2009). Although meningoceles are rarely complicated by Chiari II lesions or hydrocephalus these can occur: conversely, myelomeningoceles and myelocystoceles may not develop Chiari II malformations, or these may occur late in gestation (Husler et al. 2009). The incidence of CSD is not decreased by antenatal folate supplementation. Meningoceles (Fig. 1.9) are CSF-filled meningeal sacs covered by skin usually containing no obvious neural elements. The underlying spinal cord is usually intact but may be malformed into a placode. In addition, other occult spinal lesions may be present and cord tethering may develop. Unlike the lumbar predilection of myelomeningoceles meningoceles are most common in the thoracic levels of the spine. When meningoceles occur in the lumbar region they are thought to arise from abnormal secondary neurulation (Tortori-Donati et al. 2001). The neurological outcome of meningoceles is usually normal.
or near normal, especially in early childhood, but later complications of cord tethering such as disturbances in continence and ambulation may develop. In the minority of meningoceles with placodes and neural elements in the sac, as well as Chiari II malformations, the outcome is significantly worse. A myelocystocele develops from hydromydetic distention of the central canal of the spinal cord that herniates through a defect in the overlying vertebral column but remains skin covered (Midrio et al. 2002). Myelocystoceles may occur in the lower cord (terminal myelocystocele) or in the cervical region. Terminal myelocystoceles (Figs. 1.6 and 1.7) are of caudal mass origin and may be associated with other features of the caudal regression syndrome such as lower abdominal, pelvic, bowel or bladder malformations (Choi and McComb 2000). Severe bladder, bowel and lower extremity motor deficits are frequent complications of terminal myelocystoceles and Chiari II malformations may develop later in gestation. These lesions need to be distinguished from sacrococcygeal teratomas, omphalolexstrophy-imperforate anus-spinal defect (OEIS) complex and myelomeningocele.

**Spinal lipoma.** Spinal dysraphic states are often associated with lipomatous tissue. The underlying basis for this association is likely to be premature disjunction (see above) of the neural and cutaneous ectodermal layers. If neural and cutaneous ectodermal disjunction occurs prior to complete neural tube closure the mesenchyme may become interposed between the leading edges of the closing neural tube, developing into lipomatous tissue thought to underlie the development of lipomyelomeningoceles and spinal lipomas.

**Lipomyelomeningoceles** are CSD lesions in which there is a skin-covered placode associated with a lipoma contiguous with the subcutaneous fat (Fig. 1.6): the lipoma covers the neural elements and prevents them from bulging through the overlying defect, while cord tethering is also common. These lesions are thought to result from premature disjunction of the cutaneous and neural ectoderm, with herniation into the central canal of the mesenchyme where it is induced to become fat, then interfering with primary neurulation: the brain is usually normal with no Chiari II lesion. These lesions have a far better prognosis than myelomeningoceles including continence (Atala et al. 1992), despite sometimes significant malformation of the lower cord (Sutton 1995).

**Caudal regression syndrome** involves a spectrum of malformations in the lower spine resulting from undergrowth or agenesis of the caudal cell mass. Although rare the risk of this condition is increased 200-fold in fetuses of mothers with diabetes: the outcome of this condition depends on the extent of the defect but often includes significant urological and orthopedic complications.

**Sacrococcygeal teratomas** are a rare fetal-onset tumour, more common in females but more malignant in males, that may mimic spina bifida lesions. These teratomas may be cystic, solid or mixed and may protrude in several directions from the sacrum; however, there is no spinal dysraphism or Chiari II defect. These lesions may cause high-output cardiac failure in highly vascular cases which may result in polyhydramnios and fetal hydrops.

### NORMAL RHOMBENCEPHALIC DEVELOPMENT

At around 5 weeks p/c formation of the mesencephalic and pontine flexures begins to define the future rhombencephalic domain (Fig. 1.2). The mesencephalic flexure at the intersection of the mesencephalon and rhombencephalon is the site of the future midbrain-hindbrain (MHB) junction and the pontine flexure causes widening of the neural tube and thinning of the dorsal hindbrain, the site of the future fourth ventricular roof. Subsequent development of the cerebellum and surroundings proceeds through several overlapping stages: (1) patterning events that define the territory of the cerebellar anlagen, (2) development of the fourth ventricular roof and (3) a complex series of proliferative and migratory events that lead to development of the cerebellar hemispheres and vermis. *Patterning of the midbrain-hindbrain junction* (Fig. 1.3) is a pivotal step in the subsequent development of the posterior fossa structures. A critical initial stage is the precise positioning of the isthmic organiser (Iso) at the MHB junction where it develops at the interface between expression domains of two mutually suppressing homeobox transcription factors i.e. Otx2 in the caudal midbrain and Gbx2 in the rostral hindbrain. Suppression by Gbx2 of Otx2 expression permits development of the cerebellum and suppression by Otx2 of Gbx2 expression permits development of the mesencephalic tectum. Disturbances in expression of these gene products result in disorders of rostrocaudal patterning and may cause abnormal gain, loss or transformation of the midbrain and hindbrain structures (see below) (Barkovich et al. 2009). Decreased Otx2 or increased Gbx2 expression will shift the midbrain-hindbrain junction rostrally and vice versa. Once positioned, the Iso becomes defined early by the key molecule it secretes, i.e. fibroblast growth factor (FGF) and FGF8 in particular (Crossley et al. 1996; Basson et al. 2008; Sgier et al. 2007). Development of the mesencephalic tectum is regulated by Fgf8a while cerebellar development is regulated by Fgf8b: these factors ensure regionally specific cell differentiation and migration occur to form the midbrain roof and the cerebellar roof plate. Maintenance of appropriate levels of FGF 8 are essential for medial cerebellar development including the vermis while lesions with marked vermis abnormalities are likely to be due to disruption of early Iso function. Mutations in FGF result in expansion of the roof plate at the expense of vermis progenitor expansion. The rhombencephalon is made up of eight rhombomeres, the first two (R1 and R2) being the origin of the future cerebellum: the vermis arises from the alar plate of R1 and the R1/R2 roof plates while the cerebellar hemispheres originate from the R2 alar plate.

**Development of structures in and around the fourth ventricle roof** is complex (Fig. 1.10) and developmental disturbances in
this region account for many of the posterior fossa lesions seen in clinical practice. Several lines of evidence suggest signalling from the overlying mesenchyme playing a critical role in normal posterior fossa development (Aldinger et al. 2009), while signalling from the overlying leptomeninges is critical for the normal development of the fourth ventricle roof. Although the forkhead box C1 gene is expressed only in the overlying mesenchyme and not in the cerebellar tissue itself Fox C1 mutations are associated with cerebellar hypoplasia, mega cisterna magna and the Dandy-Walker syndrome. There is a well-known association between posterior fossa anomalies and neurocutaneous syndromes such as PHACES syndrome, comprised of posterior fossa anomalies, hemangiomas, arterial anomalies, cardiac/aortic anomalies, eye anomalies and sternal clefts (Mahadi et al. 2012).

Formation of the pontine flexure widens the neural tube, stretching and thinning the dorsal rhombencephalon into a diamond-shaped fourth ventricle roof (Fig. 1.10). At 10 weeks p/c a transverse crease, the plica choroidea, forms across the fourth ventricle roof, dividing it into the anterior (AMA) and posterior membranous (PMA) areas. The plica choroidea forms the future fourth ventricular choroid plexus, while the AMA contains neurons and normally becomes incorporated into the developing vermis, with the PMA containing ependymal tissue but no neurons: these features are important in understanding the prognosis of developmental anomalies in this region. Children with Dandy-Walker malformation (DWM) or vermian hypoplasia – which are of AMA origin – are more prone to neurodevelopmental impairment while those with isolated Blake's pouch cyst or mega cisterna magna – which are of PMA origin – are usually developmentally normal.

A series of perforations develop in the fourth ventricular roof, beginning around the 9th–10th week p/c when the ependymal lining of the fourth ventricular roof herniates through the overlying dura just caudal to the plica chooroidea to form the Blake's pouch (Paladini and Volpe 2006). By the end of the 10th week p/c the Blake's pouch perforates to form the foramen of Magendi. Between 14 and 17 weeks p/c the lateral foramina of Luschka open, an event that may be delayed as late as 26th week and, in up to 20% of humans, may fail altogether.

Development of the Cerebellar Hemispheres and Vermis (Fig. 1.11a–d). Once the fundamental territory of the cerebellar anlagen is established development of the cerebellar hemispheres and vermis proceed through programmed events of neuronal proliferation, migration, differentiation and finally organisation into lobes and lobules. Cerebellar neuronal proliferation occurs in two major regions which arise from different dorsoventral domains of R1. The earliest proliferative activity occurs around 7–8 weeks gestation when the R1 alar plates expand along the rostral edges of the fourth ventricle roof. From this periventricular neuroproliferative zone inhibitory GABA-ergic cells migrate radially into the cerebellar anlage where they form the Purkinje cell layer and the deep cerebellar nuclei; these inhibitory cells, originating in the primary neuroepithelium, express Ptf1a and will become the primary efferent neurons of the cerebellum. At the end of the third month p/c neuronal proliferation accelerates in the secondary neuroproliferative zone along the dorsolateral banks of the fourth ventricle, the rhombic lips. Neurons generated here are excitatory glutamatergic neurons that express Atoh1. These rhombic lip precursor cells migrate tangentially in two major directions. Cells from the more dorsal rhombic lip regions migrate in a caudal direction to form the pre-cerebellar nuclei such as the pontine, inferior olivary and other nuclei. Other Atoh1 neurons migrate in the subpial plane to form the external granular layer, a highly proliferative transient germinal
zone. By 29 weeks p/c the external granular layer covers the entire external surface of the developing cerebellum causing granule cells to undergo a subsequent amplification phase within a transient superficial germinal layer, regulated by the Purkinje cells. Postmitotic neurons from the external granular layer migrate radially into the cerebellar body along Bergman glial fibres across the Purkinje cell layer to form the (internal) granular layer of the mature cerebellum. Through a combination of inward migration and apoptosis the external granule cell layer becomes de-populated in the months after birth.

As discussed below, vermian development is a major prognostic factor in patients with posterior fossa lesions: a detailed assessment is, therefore, important for informed counseling. Understanding of vermis development has changed in recent years. Contrary to earlier understanding it is now known that a single cerebellar anlage is responsible for the formation of both the cerebellar hemispheres and midline vermis, with the latter developing from the proliferation of the mesial primordium and not through fusion of the hemispheres. Vermis development is delayed initially relative to hemispheric development but then begins to accelerate during the third month of gestation. In the sagittal plane growth of the vermis starts at the midbrain-hindbrain junction, proceeds in a craniocaudal direction and is usually complete in this plane by 18 weeks (Bromley et al. 1994), although this may be as late as 24 weeks (Bronshtein et al. 1998) gestation when it completely covers the fourth ventricle, with the caudal edge reaching the level of the obex. At 18 weeks gestation the primary tissue separating the anterior and posterior lobes of the vermis is usually visible (Robinson et al. 2007). Much like the other major midline structure, the corpus callosum, most of the normal vermian growth in the craniocaudal occurs not at the caudal-most (inferior) leading edge but rather in the neovertmian which lies just caudal to the primary fissure. Neovermian growth occurs late, meaning that when the craniocaudal extent of the vermis is less than expected this does not necessarily imply inferior vermian hypoplasia: careful evaluation of the vermis lobulation is required and it is advisable to use the overall term vermian hypoplasia until the precise region of growth failure has been identified. Once fully developed the vermis should have a normal gestational age-appropriate rostro-caudal length, for which there are charts (Imamoglu et al. 2013): the fastigium-declive line should divide the vermis such that there is 1:2 ratio between the anterior and posterior lobes. There is a relatively typical appearance of vermian lobules and fissures, which should all be visible by 27–28 weeks (Robinson et al. 2007).

The role of gene expression in the developing cerebellar primordium is discussed above, from initial patterning to stimulation of the primary neuroepithelial zones. In addition, normal development of the cerebellar hemispheres, vermis and fourth ventricular roof is dependent on signalling molecules

Figure 1.11  (a–d) Primary and secondary neuroproliferative sites in the developing cerebellum.
Developmental anomalies of the cerebellum and brainstem may originate in any of the major stages of development. Disorders of patterning originate very early in development: the rhombencephalic malformations that result from such patterning disorders have been recognised relatively recently and are not as yet well described. The most fundamental hindbrain malformations show features of arrested development around 5 weeks p/c with incomplete flexing of the hindbrain, leaving a residual 'kinked brainstem' with often profound anomalies of cerebellar formation (Fig. 1.12) (Smith et al. 2005).

Disorders of fourth ventricle roof formation are often associated with abnormal posterior fossa fluid collections: disturbances in mesenchymal-neuroepithelial signalling are thought to play a common pathogenetic role in these conditions (Aldinger et al. 2009). These conditions are a common indication for neurology consultation and include the Dandy-Walker spectrum, mega cisterna magna, Blake's pouch cyst and possibly cerebellar hypoplasia and arachnoid cysts (Barkovich et al. 2009).

Developmental disorders of cerebellar hemisphere and vermis include conditions that arise from inadequate proliferation of cells in the posterior fossa neuroepithelial zones and of their subsequent support: as noted above these disorders may result from primary disruption of proliferation in the ventricular zone, the rostral midline (vermis) and more lateral (hemispheric) rhombic lips, as well as migrational and organisational disturbances in the Purkinje cell layer.

There is lack of consensus about the diagnostic criteria and classification of posterior fossa malformations. Some view these malformations as a continuum ranging from severe DWM (with an enlarged posterior fossa) to mild DWM (with a normal posterior fossa), isolated vermian hypoplasia, Blakes pouch cyst (with a normal vermis) and mega cisterna magna (with normal neural structures) (Table 1.1).

Figure 1.13 provides distinguishing structural features of these lesions. The mesenchymal origin of bone and meningeal development is likely to underlie the association between abnormal FOXC1 function and the enlarged posterior fossa seen in both DWM and mega cisterna magna. It has been suggested that the expression of FOXC1 dysfunction may be related to the extent of the gene deletion, which in turn determines the severity of the posterior fossa anomaly (Aldinger et al. 2009).
syndrome (Brossard-Racine et al. 2015) seen in older individuals with cerebellar stroke or tumour (Schmahmann and Sherman 1997). The anatomic substrate for these ‘non-motor’ functions of the cerebellum has been elucidated by recent studies which demonstrate distinct ‘closed’ loop circuitry, not only with the primary motor cortex but with many other higher cortical centres such as the dorsolateral prefrontal cortex. The anatomical basis through which the cerebellum influences cortical activity is the ascending projections from the dentate nucleus (Strick et al. 2009).

### DANDY-WALKER MALFORMATION

The diagnostic criteria for classic DWM are vermian hypoplasia, posterior fossa enlargement with elevation of the tentorium cerebelli and torcular Herophili, as well as cystic dilation of the fourth ventricle (Fig. 1.13). Although about 85% of infants develop hydrocephalus by one year of age (Barkovich et al. 1989) this may be delayed and is a complication rather than an essential diagnostic criterion for the DWM. DWM is a fundamental defect of rhombencephalic roof development, with formation of the large cystic component of this deficiency thought to result from failure of the normal uptake of the AMA into the developing vermis and possibly delay failure of foraminal development in the PMA. The redundant AMA then billows out, possibly driven by cerebrospinal fluid pulsations, leading to cyst formation and expansion of the posterior fossa. Neuropathological studies of the DWM have shown that all vermian lobules are present but hypo/dysplastic, especially inferiorly, and that vermis development appears arrested at about the 12-week p/c level (Kapur et al. 2009; Russo and Fallet-Bianco 2007). It has been speculated that the superior to inferior gradient of increasing hypo/dysplasia of the vermis results from waning isthmic organiser influence with increasing distance (Robinson 2014). The anomalous structures in the DWM are of rhombic lip (rhombomere 1) origin, with largely normal development of the primary ventricular neuroepithelium derivatives, such as the Purkinje cells and deep cerebellar nuclei.

Prognosis of the DWM is highly variable and appears to depend upon the degree of vermian hypo/dysplasia and presence of associated cerebral and extracerebral anomalies. Specifically, if anomalous brain development is confined to the posterior fossa then the primary prognostic factor is lobulation of the vermis, with size of the cystic lesion and posterior fossa being irrelevant. Intellectual impairment, which occurs in about half of patients with DWM, is correlated with

the disturbance in vermis lobulation (Boddaert et al. 2003). Management of the DWM is largely conservative unless significant hydrocephalus or compression effects of the posterior fossa cyst develop. Hydrocephalus is traditionally managed by CSF diversion techniques such as ventriculoperitoneal shunt. Other approaches including endoscopic third ventriculostomy with choroid plexus cauterisation (Warf et al. 2011), as well as cyst-peritoneal shunts and stents between the third ventricle and cyst, have been used (Mohanty 2003).

Dandy-Walker Variant

Elements of the DWM may be seen in other posterior fossa anomalies. This has led to the term Dandy-Walker variant, most often applied to patients experiencing vermian hypoplasia without the other criteria for classic DWM. This term has unfortunately become the default diagnosis for a broad spectrum of posterior fossa lesions with enlarged fluid spaces, leading to inconsistency in classification and prognostication. The existence of this entity is controversial and use of the term has been discouraged. Distinguishing the ‘Dandy-Walker variant’ not only from a DWM but also other conditions such as mega cisterna magna, vermian hypoplasia and Blake’s pouch cyst (see below) may be challenging but is important, since these latter conditions have a significantly better outcome. Typically the term Dandy-Walker variant has been used when there is agenesis/hypoplasia of vermis (distinguishing it from a Blake’s pouch cyst), with cystic enlargement of the fourth ventricle and rotation of vermis (distinguishing it from mega cisterna magna) but with a normally sited torcular and tentorium, i.e. a normal-sized posterior fossa. The Dandy-Walker variant is rarely complicated by hydrocephalus.

VERMIAN HYPOPLASIA

The vermis ‘covers’ the 4th ventricle in a rostro-caudal direction, a process usually complete by 18 weeks but may be as late as 24 weeks gestation. In one study (Patek et al. 2012) vermian hypoplasia diagnosed before 24 weeks gestation were ‘resolved’ by term 50% of individuals, whereas those diagnosed after 24 weeks gestation were all confirmed postnatally. Given the rostrocaudal growth of the vermis it has been assumed that the inferior vermian lobules are the last to form and that a decrease in the rostro-caudal diameter involves at least underdevelopment of the inferior vermis. This has given rise to the term inferior vermian hypoplasia when the longitudinal axis of the vermis is short and the anterior: posterior lobe ratio is less than 1:2 (Fig. 1.14). However, recent reports emphasise that the inferior lobules are actually the first to develop and failure of posterior lobe development and arrested downward growth of the vermis is likely to occur in most individuals as a result of growth failure of the later-forming neovermis, located just caudal to the primary fissure. Since it may be difficult, especially prior to late gestation, to distinguish the different lobules by fetal MRI it is probably wise to reserve diagnosis of inferior vermian hypoplasia to those patients where this can be demonstrated clearly.

Other syndromic forms of vermian hypoplasia include the molar tooth malformations seen in Joubert and related syndromes (Fig. 1.15). To date 27 gene mutations (Table 1.2) mostly autosomal recessive in inheritance, have been associated with Joubert syndrome: these differ in terms of associated systemic findings (including renal, hepatic, ocular, oral-facialdigital and hypothalamic hamartomas). The molar tooth sign consists of elongated thick and horizontally oriented superior cerebellar peduncles, a deep interpeduncular fossa, vermian hypo/dysplasia and variable cerebellar hemispheric findings.
In addition, 30% of patients have additional brainstem and supratentorial anomalies: in these disorders of axonal guidance the midline crossing defect involves the superior cerebellar peduncles and corticospinal tracts, however more than 90% have normal corpus callosum development.

<table>
<thead>
<tr>
<th>Disorder</th>
<th>Description</th>
</tr>
</thead>
</table>
| **Joubert Syndrome**              | A genetic disorder including neonatal respiratory hyperpnea and liver dysfunction associated with later development of eye movement abnormalities, ataxia and intellectual disability. MRI on axial views shows atrophy of the cerebellar vermis associated with the appearance of the roots of a molar tooth formed by the cerebellar peduncles. Children often develop mild retinopathy and nephropathy. Most mutations are in genes that code for endothelial cilia so the disorder is called a ciliopathy. Addition of additional related disorders has led to designation of JSRD [Joubert Syndrome and Related Disorders (Zaki et al. 2008) Neurology 70: 556–65]. In addition to Joubert Syndrome the following disorders with molar tooth sign are also included in JSRD:  
  COACH Syndrome: Cerebellar vermis hypoplasia, Oligophrenia, Ataxia, ocular Coloboma, Hepatic fibrosis  
  CORS (Cerebello-Oculo-Renal Syndrome) with congenital blindness and renal signs including renal failure  
  Oro-facial-digital syndrome type IV with at least one oral facial sign (cleft lip or palate, tongue tumours, notched upper lip) and digital signs including polydactyly or bifid digits. |
| **In addition**                    | 30% of patients have additional brainstem and supratentorial anomalies: in these disorders of axonal guidance the midline crossing defect involves the superior cerebellar peduncles and corticospinal tracts, however more than 90% have normal corpus callosum development. |

**Blake’s Pouch Cyst**

Blake’s pouch (Blake 1900) is a normal dorsal evagination of the fourth ventricle ependymal lining through the midline foramen of Magendie. (Strand et al. 1993). This pouch normally perforates around 9 to 10 weeks p/c to allow communication.
between the fourth ventricle and subarachnoid space. Failure to perforate leads to formation of a cyst that enlarges the fourth ventricle, elevating the otherwise normal vermis and increasing the tegmento-vermian angle (Paladini et al. 2012) (Fig. 1.16). Diagnostic criteria for a Blake's pouch cyst include fourth ventricular enlargement with mild-moderate rotation of a normally formed vermis (with widening of the tegmento-vermian angle) as well as a normally sized posterior fossa and cisterna magna. Although delayed or failed foraminal development may play a mechanistic role in both Blake's pouch cyst and DWM there are a number of fundamental differences between these entities. These lesions originate from different regions of the dorsal hindbrain – the Blake's pouch cyst being a developmental defect of the PMA – while the DWM is a developmental defect of the AMA. Although not easily seen with conventional imaging, identifying the fourth ventricle choroid plexus along the inferior surface of the vermis and roof of the cyst is a useful diagnostic sign of a Blake's pouch cyst. Over half of Blake's pouch cysts spontaneously resolve around 24–26 weeks gestation and almost two-thirds resolve by term, returning the vermis to a normal position, presumably due to delayed fenestration of the fourth ventricular roof (Paladini et al. 2012); such spontaneous resolution does not occur in DWM. Although hydrocephalus develops in a large majority of DWM hydrocephalus, even tetraventricular hydrocephalus, has been described in cases of Blake's pouch cyst but this is an unusual finding. The torcular and tentorium are not elevated in Blake's pouch cysts: although controversial, some authors consider Blake's pouch cyst, Dandy-Walker variant and mega cisterna magna part of the same spectrum, with differences due to the degree and timing of Blake's pouch fenestration (Robinson and Goldstein 2007). Diagnosis of a Blake's pouch cyst is usually incidental, the clinical picture usually benign with a favourable long-term outcome.

MEGA CISTERNA MAGNA

The cisterna magna is the space between the inferior margin of the vermis and the posterior rim of the foramen magnum. The normal cisterna magna is between 3–8 mm and most consider 10mm or more to represent mega cisterna magna. Some authors propose the mega cisterna magna is a Blake's pouch cyst remnant after partial or delayed foraminal opening have allowed the fourth ventricle to return to a normal size (Fig. 1.17) (Robinson and Goldstein 2007). Both mega cisterna magna and Blake's pouch cyst may be associated with other anomalies but when isolated both have an excellent prognosis. In one study 90% of participants affected by isolated mega cisterna magna and Blake's pouch cyst had normal neurological outcomes compared to only 50% of participants experiencing DWM or vermian hypoplasia (Gandolfi Colleoni et al. 2012).

ARACHNOID CYSTS

Posterior fossa arachnoid cysts (Fig 1.18) are enclosed by the pia and arachnoid layers of the meninges and their contents have the same consistency as cerebrospinal fluid. Arachnoid cysts may enlarge to cause compression/distortion of the posterior fossa structures, including elevation of the vermis and/or obstruction of CSF drainage and hydrocephalus, although they do not communicate directly with the ventricular system.
Unless such complications occur posterior arachnoid cysts may remain remarkably asymptomatic.

CEREBELLAR HEMISPHERIC MALFORMATIONS

Anomalies of the cerebellar hemispheres may include hypoplasia, dysplasia or disruptions. Predominant hemispheric underdevelopment is uncommon but may be seen in the pontocerebellar hypoplasias (see below) and in survivors of extreme prematurity. Unilateral cerebellar hypoplasia is usually due to a developmental disruption often following cerebellar haemorrhage rather than primary dysgenesis. The two proliferative regions contribute unequal cell numbers to the future cerebellum, the rhombic lip-derived population far exceeding that from the primary ventricular neuroepithelium; however, the Purkinje cell layer (of ventricular zone origin) provides critical support for the massive proliferation of granule cell precursors (of rhombic lip origin) in the overlying external granular layer: this mitogenic support is mediated by the products of the sonic hedgehog (SHH) gene family (Hatten and Heintz 1995). Impaired neuronal proliferation in either of the two major germinal zones may therefore limit the normal massive expansion of the granule cell precursor pool, resulting in cerebellar hypoplasia. Since this expansion of the granule cell population continues through late gestation and into postnatal life cerebellar hypoplasia may manifest late in development (Malinger et al. 2009). Of note is that cerebellar hypoplasia due to SHH signalling defects affects vermis and hemispheric development equally while earlier isthmic organiser defects (see above) cause disproportionate vermis hypoplasia. Normal migration and organisation of the Purkinje cell layer is essential for normal granule cell proliferation while the Bergman glia (of ventricular zone origin) are responsible for normal

Figure 1.17  (a) Diagram of perforated Blake’s pouch cyst with tegmento-vermian angle returning to normal but leaving large cisterna magna. (b) Enlarged cisterna magna ( ) measured as the distance from the inferior vermis border to the foramen magnum. Adapted from Robinson and Goldstein (2007).

Purkinje cell migration. Mutations in the reelin gene which disrupt cerebellar neuronal migration are a known cause of cerebellar hypoplasia. In summary, Purkinje cell migration defects are likely to underlie many forms of cerebellar hypoplasia.

Rhombencephalosynapsis is a cerebellar malformation with partial (20%) or complete (80%) ‘fusion’ of the cerebellar hemispheres and superior cerebellar peduncles, with midline continuity of the deep cerebellar nuclei (Fig. 1.19). The superior vermis is consistently absent although a wide range of associated brain anomalies may be present, including fused thalami and fornices, absence of the septi pellucidi, callosal agenesis and hydrocephalus, with features of aqueductal stenosis. On axial MRI views the fourth ventricle has a ‘diamond’ shape while the co-occurrence with holoprosencephaly suggests a disturbance in dorsal-ventral patterning; typically the transversely oriented cerebellar folia extend across the midline without interruption by the vermis. Most individuals have some degree of neurodevelopmental impairment but the range is very broad.

**PONTOCEREBELLAR HYPOPLASIAS**

Given the common origins of the cerebellum and certain brainstem regions it is unsurprising that developmental anomalies may co-occur in these structures. Cerebellar anomalies on fetal imaging warrant careful evaluation of the brainstem structures by fetal MRI: in general the presence of an associated brainstem anomaly implies a significantly worse prognosis for cerebellar lesions (Patek et al. 2012). One such group of conditions is the pontocerebellar hypoplasias (PCH) (Table 1.3), characterised by a small pons and varying degrees of cerebellar defect, even near-total absence (Barth 1993; Parisi and Dobyns 2003; Maricich et al. 2011). The neurodevelopmental prognosis is bleak, with global delay which is usually severe and progressive: unlike most other fetal rhombencephalic anomalies these autosomal recessive conditions have a primary developmental origin and subsequent progressive atrophy. Currently six forms have been described based on their clinical, imaging and pathology findings with some of these forms such as types 5 and 6 extremely rare. Type 1 PCH also has prominent anterior horn cell degeneration, resulting in bulbar dysfunction which manifests in the fetal period as polyhydramnios and later contributes to the respiratory and feeding complications that lead to early death, usually before the age of one. Type 2 PCH is associated with prominent microcephaly, dyskinesias and seizures; most affected children die in late infancy-early childhood.

**Pontine tegmental cap dysplasia** (Rauscher et al. 2009) (Fig. 1.20), another posterior fossa anomaly in which disturbed
Axonal guidance has been implicated, consists of a flat ventral pons, a 'cap' or beak protruding from the dorsal pons into the fourth ventricle and severe hypoplasia of the middle and inferior cerebellar peduncles. It is associated with cranial neuropathies, most commonly of the eighth nerve. This condition is associated with hearing loss, facial anesthesia and paralysis as well as abnormal swallowing, while gross motor and cognitive deficits may also be present.

**NORMAL PROSENCEPHALIC DEVELOPMENT**

Between 3 and 5 weeks p/c three major vesicles form at the rostral end of the neural tube: the prosencephalon (the future telencephalon and diencephalon), the mesencephalon (midbrain) and rhombencephalon (metencephalon and myelencephalon) (Fig. 1.2). At this time the anterior neural tube develops three major flexures, the mesencephalic, pontine and cervical flexures. Ventral induction proceeds through a series of connected steps that include (1) formation, (2) cleavage and (3) midline development of the prosencephalon (Volpe et al. 2009).

**PROSENCEPHALIC FORMATION**

The prosencephalon divides into two secondary vesicles, the telencephalon and diencephalon, at around 5 weeks gestation. The telencephalon gives rise to the cerebral hemispheres, putamen and caudate nucleus while the diencephalon develops into the thalamus, hypothalamus, globus pallidus and optic vesicles.

**PROSENCEPHALIC CLEAVAGE**

During the early fetal period the forebrain is completely embedded in a solid meninx primitiva, which plays an important role in prosencephalic development. Around 35 days p/c the human telencephalon is cleaved into left and right vesicles, through a combination of increased apoptosis and decreased proliferation: these events are under the control of complex signalling pathways in the midline prosencephalon. Responsible signalling molecules include bone morphogenetic protein (BMP) and WNT (Fernandes and Hebert 2008; Hebert et al. 2002; Fernandes et al. 2007), expressed in the dorsal midline, fibroblast growth factor (FGF) in the rostral midline and SHH signalling in the ventral midline. During neural embryogenesis BMP and SHH have opposite, even antagonistic, patterning effects in the dorsoventral plane: disturbances in these relationships may result in the holoprosencephaly spectrum of anomalies (see below).

**MIDLINE PROSENCEPHALIC DEVELOPMENT**

The lamina terminalis forms the anterior tip of the neural tube. In the dorsal aspects of the lamina terminalis lies the commissural plate, which gives rise to three major commissures that link the two sides of the telencephalon. These commissures
develop under the attracting or repelling influence of molecules secreted by glial cells and, to a lesser extent, neurons in the prosencephalic midline (Fame et al. 2011; Nishikimi et al. 2013). The anterior commissure crosses in week 10, followed by the hippocampal commissure in week 11; a midline glial ‘sling’ develops at the future junction of the genu and body of the corpus callosum, with the first callosal fibres crossing in weeks 12 and 13, after which the callosum expands in both directions (Barkovich and Kjos 1988; Rakic and Yakovlev 1968; Achiron and Achiron 2001), while pioneer neurons originating from the cingulate cortex later cross the midline and enter the contralateral cortex (Koester and O’Leary 1994). Under the influence of specific guiding and growth substances present in the interhemispheric space, callosal fibres develop rapidly such that by weeks 14–15 all five parts of the mature corpus callosum (rostrum, genu, body, isthmus and splenium) are present, although short in rostral-caudal extent. The hippocampal commissure, which eventually lies below the isthmus-splenium junction, guides the crossing fibres of the future splenium, eventually the most prominent part of the callosum. Subsequent caudal-ward growth of the callosum is largely due to accelerated growth the anterior and central parts of the callosum, itself due to rapid expansion of the frontal cortices: consequently, the splenium is displaced backwards. The callosum reaches full longitudinal extent between by 19–20 weeks, after which it grows in thickness. Failure of the callosum to reach full longitudinal extent may be due to failure of any or all of these callosal elements to form. The fornix and adjacent septum extend between the anterior and hippocampal commissures: as the callosum expands and pushes the anterior and hippocampal commissures further apart the fornix and septum pellucidum are stretched out into their final position.

**Cavum Septi Pellucidi:** The commissural plate also gives rise to the septal leaflets. The space between the septal leaflets forms one common cavity which is then divided into the cavum septi pellucidi anterior to the level of the foramen of Monro and the cavum vergae behind this plane (Raybaud 2010). The walls of the cavum septi pellucidi become apposed from back to front, starting at about 6 months gestation, closing completely in 85% of normal infants by 3 to 6 months postnatal. The cavum septi pellucidi is an important imaging landmark since its presence indicates that the corpus callosum must be present, at least partially, however, the converse does not apply and the cavum septi pellucidi may be absent even with an intact corpus callosum. The cavum velum interpositum (Fig. 1.21) may become enlarged and create diagnostic difficulties: it is bordered above by the columns of the fornices and hippocampal commissure and below by the tela choroidea of the third ventricle. The anterior extension of the cavum velum interpositum is at the foramen of Monro, while the internal cerebral veins course along the floor of the cistern and under the splenium of the corpus callosum to join the vein of Galen. The cavum velum interpositum extends posteriorly into the pineal region beneath the splenium of the corpus callosum, with the course of the internal cerebral veins displaced away from the splenium of the corpus callosum. The fornices are anatomic boundaries between the cavum vergae and the cavum velum interpositum, while the columns of the fornices are downwardly displaced with enlargement of both, resulting in a concave upper border of the cavum velum interpositum.

**DISORDERS OF PROSENCEPHALIC DEVELOPMENT**

The most fundamental disturbances of prosencephalic development include aprosencephaly (absence of telencephalic and diencephalic structures) and accompanying subset, atelencephaly (Fig. 1.22), in which the telecephalon is absent but diencephalon (including the thalami) persists (Marcourelles and Laquerriere 2010; Volpe et al. 2009; Li et al. 2011b): these lesions are rare and lethal.

---

**Figure 1.21** (a,b) Postnatal axial and (c) midline sagittal MRI scans with the cavum velum interpositum indicated (*). In (c) the white arrow-head indicates the cavum seti pellucidi and the white arrow indicates the fornix. Modified from Radiology MRI (http://radiologymri.blogspot.com/2011/07/cavum-velum-interpositum.html).
DISORDERS OF PROSEQUENCEPHALIC CLEAVAGE

**Holoprosencephaly** (HPE) is the next level of disordered ventral induction and patterning. The resulting spectrum of anomalies results from complete or partial failure of prosencephalic cleavage. The fundamental mechanism is disturbed dorsoventral patterning, either under-ventralisation or over-dorsalisation. The SHH pathway is the major ventralising factor: disruption and resulting disturbed ventral induction is thought to be the common mechanism underlying development of the classic holoprosencephaly phenotypes. Since the dorsalising effects of BMP signalling have opposite, even antagonistic, effects on the ventralising actions of SHH, increased BMP signalling may also cause impaired ventral induction due to disrupted SHH signalling, leading to the holoprosencephaly spectrum of lesions (Fernandes and Hebert 2008). Some authors consider septo-optic dysplasia to be part of the holoprosencephaly spectrum (Simon and Barkovich 2001; Li et al. 2011b), but here we consider it an anomaly of midline prosencephalic development (see below). The incidence of holoprosencephaly varies geographically and is significantly more common in spontaneous aborted fetuses. About 80% of infants with HPE have midface malformations but these have a very broad phenotypic spectrum, ranging from a single central upper incisor and mild hypotelorism to cyclopia with a proboscis. The incidence of HPE is around 1:10000 live-born infants but is much higher in aborted fetuses, affecting an estimated 1:250 gestations. These conditions have been classified previously into three grades of decreasing severity (alobar, semi-lobar, lobar) although this spectrum has recently been expanded to include syntelencephaly as well as ‘minimal’ (non-cleavage of the subcallosal/septal forebrain) and ‘microform’ HPE (not detectable by MRI) forms which have been proposed: recently a forme fruste of holoprosencephaly (‘interhypothalamic adhesion’) has also been proposed (Whitehead and Vezina 2014). Some authors consider septo-optic dysplasia to be part of the holoprosencephaly spectrum (Simon and Barkovich 2001; Li et al. 2011b), but here we consider it an anomaly of midline prosencephalic development (see below). The incidence of holoprosencephaly varies geographically and is significantly more common in spontaneous aborted fetuses.

**Alobar holoprosencephaly** (Fig. 1.23) is the most severe form in which prosencephalon is undivided with no midline cleavage. The forebrain is lined by predominantly entorhinal cortex with very little neocortex while typically there is fusion of the thalamic, hypothalamic and basal ganglia nuclei.
resulting in absence of the third ventricle. There is a large horse shoe-shaped monoventricle and a dorsal cyst while hydrocephalus is common, presumably due to the absent third ventricle. The olfactory bulbs, corpus callosum and cavum septi pellucidi, as well as interhemispheric fissure are absent, while optic nerves may be fused, absent or normal. Major facial and ocular defects are present more often than other forms, ranging from cyclopia to cebocephaly and ethmocephaly to the more common but less severe features of hypotelorism, cleft lip and absent premaxillary bony anlage. All forms of HPE may have a single or azygos anterior cerebral artery (ACA) but the alobar form may also have absence of the middle and anterior cerebral arteries. The presence of a single ACA may be useful in the fetal period for distinguishing mild forms of holoprosencephaly from septo-optic dysplasia (Bernard et al. 2002). The dorsal cyst is present in virtually all alobar forms and progressively less so in the semilobar and lobar forms, relating to the degree of thalamic fusion which causes the CSF to balloon out posteriorly. In **semilobar holoprosencephaly** (Fig. 1.24) the anterior aspects of the prosencephalon fail to separate as do the thalami, leaving transverse convolutions that cross the anterior midline and absence of the anterior corpus callosum, and a small or absent third ventricle. A monoventricle is present but with posterior aspects of the cerebral hemispheres appropriately cleaved within an interhemispheric fissure (IHF), usually an intact splenium, a posterior falk and no dorsal cyst. There is a spectrum of severity for semi-lobar holoprosencephaly and in the mildest form there may be cleavage of all but the most anterior aspects of the hemispheres: in fact, the precise distinction of the semilobar and lobar forms may be difficult. Both forms may be difficult to identify on the 18–20 ultrasound scan, and an absence of the cavum septum pellucidum may be the only clue (Winter et al. 2010): facial malformations may also be mild or absent.

**Lobar holoprosencephaly** (Fig. 1.25) has complete separation of the hemispheres except for the most ventral anterior regions, with a hypoplastic genu and absence of the cavum septum pellucidum (Winter et al. 2010). As such the interhemispheric fissure is present along the entire dorsal midline and the thalami are completely or mostly separated, with the third ventricle present and some frontal horn formation. The fused fornices appear as a linear structure running within the third ventricle from the anterior to hippocampal commissures: such intraventricular fused fornices may be a specific sign of lobar HPE (Pilu et al. 1994). The frontal horns of the lateral ventricles may be rudimentary but the third ventricle is usually fully formed, albeit often dysmorphic. The olfactory bulbs may be absent or hypoplastic, while facial anomalies may be minimal to absent.

Holoprosencephaly is most commonly associated with microcephaly although hydrocephalic macrocephaly may develop as a result of hydrocephalus due to aqueductal stenosis, which occurs in about 40% of individuals. Deep grey nuclear involvement is common in all forms of holoprosencephaly with some level of noncleavage essentially universal in the hypothalamus and very common in the caudate nuclei (96%), lentiform nuclei (85%) and thalami (67%) (Simon et al. 2000): in addition to these classic forms other variants of holoprosencephaly are now recognised. **Syntelencephaly** (Fig. 1.26) or the midline interhemispheric fusion variant, involves failed cleavage of the central frontoparietal regions of the cerebral hemispheres, with separation of the basal forebrain, anterior frontal and occipital lobes (Lewis et al. 2002). The genu and splenium of the corpus callosum are normally formed but the body is absent and there may be incomplete separation of the thalami and caudate nuclei. While the basal/ventral forebrain is most involved in the classic phenotypes the dorsal parts of the hemispheres are involved in syntelencephaly variant while the basal forebrain may be normal. Thus syntelencephaly is likely to represent not failure of ventralisation like other forms of HPE but rather disrupted dorsalisation due to either primary impairment of BMP expression or excessive SHH signalling with secondarily decreased BMP expression and disturbed dorsal induction (Fernandes and Hebert 2008). In syntelencephaly the sylvian fissures are often vertically oriented and continuous across the midline at the vertex (Simon and Barkovich 2001). Cortical dysplasias and subcortical heterotopias are present in over half of individuals.
experiencing syntelencephaly (Simon and Barkovich 2001) and within the same family a wide spectrum of holoprosencephalic phenotypic severity may be seen from most severe to essentially normal; endocrine anomalies may be associated with holoprosencephaly.

Aetiology: HPE appears to have a multifactorial aetiology with a complex inheritance pattern that includes both genetic and environmental factors. Holoprosencephaly is commonly associated with other extracerebral anomalies, including congenital heart disease (especially transposition of the great arteries), scalp defects, limb reduction defects and postaxial polydactyly. Abnormalities in chromosome number may occur in up to 45% of individuals including trisomies 13 (most common), triploidy (less common) and 18 (uncommon) (Olsen et al. 1997; Bellone et al. 2010). In addition, for up to 25% of individuals affected by holoprosencephaly this occurs in recognisable genetic syndromes such as Meckel-Gruber, Aicardi, Pallister-Hall, pseudo-trisomy 13, Smith-Lemli-Opitz and velocardiofacial syndromes. Genetic causes for HPE are found in about 20% of live-born cases (Bellone et al. 2010).

Some have proposed a multifactorial origin for HPE with interaction required between a genetic predisposition and environmental factors (Rosenfeld et al. 2010). Non-syndromic isolated HPE is usually inherited as an autosomal dominant condition associated with deletions or mutations in at least 12 specific gene loci including SHH, ZIC2, SIX3 and TGIF. The ZIC2 mutation has distinct facial features with upslanting palpebral fissures, bitemporal narrowing, large ears, short nose with antverted nares and a broad philtrum (Itoh et al. 2011), with clinical testing for these now available. Maternal diabetes increases the risk of HPE by up to 200-fold.

Prognosis: Although outcome is significantly worse among those with severe brain and facial dysmorphism even the more severe forms of holoprosencephaly are not uniformly lethal. About half of children with alobar HPE die by 5 months but up to one-third of infants survive beyond

---

**Figure 1.25** Lobar holoprosencephaly in a 25-week gestation fetus. Fetal T2-weighted image showing fusion of the ventral forebrain, hypothalamus, and thalamus. (a) absence of the frontal horns of the lateral ventricles (top arrow) and small third ventricle (bottom arrow); (b) diencephalic fusion (solid arrow); (c) basal forebrain fusion (solid arrow).

**Figure 1.26** Postnatal MRI in an infant with syntelencephaly, the midline interhemispheric fusion variant of holoprosencephaly, with failed cleavage of (a) the central frontoparietal region and (b) thalami. The genu and splenium of the corpus callosum are normally formed (a, arrows), but the body is absent.
their first birthday (Barr and Cohen 1999). About half of children with lobar HPE will learn to walk, use their hands meaningfully and speak in single words or phrases. Survivors of HPE may develop a number of complications including neurodevelopmental and endocrine disorders such as diabetes insipidus, thyroid hypoplasia, adrenal hypoplasia, hypogonadism and growth hormone deficiency (Fernandes and Hebert 2008). Hydrocephalus is most common when a dorsal cyst is present.

**DISORDERS OF MIDLINE PROSENCEPHALIC DEVELOPMENT**

**AGENESIS/DYSGENESIS OF THE CORPUS CALLOSUM**

Current fetal ultrasound screening and MRI confirmation has changed our understanding of the incidence, associated findings and prognosis of ACC. ACC, partial or complete, is one of the most common referral diagnoses for fetal neurological consultation (Fig. 1.27). As discussed above, the corpus callosum forms from several different midline elements, with previous understanding of partial ACC being that the splenium was always deficient. Although partial ACC often appears fore-shortened in the anterior-posterior plane this is not necessarily due to failure of the posterior body, isthmus or splenium, to develop but may result from failure of any of the components of the corpus callosum to form or expand appropriately; consequently there are multiple variants of callosal hypo/agenesis.

**Diagnosis:** Fetal movements make fetal imaging of the corpus callosum challenging: reliable diagnosis of absence by fetal ultrasound may require considerable expertise. Fetal ultrasound has a false positive rate for ACC as high as 20% (Fratelli et al. 2007; Pilu et al. 1993; Vergani et al. 1994) and lacks sensitivity for detecting associated anomalies. Fetal MRI detects additional intracranial anomalies in more than 20% of patients (Sotiriadis and Makrydimas 2012) while postnatal MRI identifies further anomalies in another 15% of patients thought to be isolated ACC by fetal MRI (Santo et al. 2012). Neuroimaging findings supportive of the diagnosis of ACC include absence of the cavum septi pellucidi, a ‘high-riding’ third ventricle, colpocephaly, widening of the interhemispheric fissure and parallel orientation of the lateral ventricles. The frontal horns of the lateral ventricles may have a crescentic or ‘steer-horn’ configuration in the coronal plane, due to the bundles of Probst displacing the lateral ventricles (Fig. 1.27f) (Raybaud 2010).

Figure 1.27 **Agenesis of the corpus callosum.** (a–c) MRI at 25 weeks gestation (a–c) and in (d–f) the newborn period (d–f). Note parallel and colpocephalic configuration of lateral ventricles on axial views (a and d), radial gyral configuration of medial cortex (e), and Probst bundles (f, arrow). Note also the ‘steer-horn’ configuration of the frontal horns of the lateral ventricle (f).
Sulci on the medial cerebral surface of the hemispheres have a radial ('sunburst') orientation and Doppler ultrasound may show an abnormal vertical trajectory of the pericallosal arteries. Several types of midline cyst and lipoma may be present in the expected location of the corpus callosum (see below): these cysts are dorsal to the third ventricle with which they may or may not communicate.

ACC may be isolated or complex, i.e. associated with other malformations; distinguishing between these forms has important prognostic implications (Goodyear et al. 2001; Jeret et al. 1987). ACC has been associated with a large number of chromosomal disorders and more than 200 genetic syndromes (Huang et al. 2012). Most cases of ACC are complex but the reported incidence varies across studies, depending in part on the imaging modality and study design. Complex forms of ACC comprise between 50% to 90% of all cases (Santo et al. 2012; Tang et al. 2009; Hetts et al. 2006). Cerebral sulcal anomalies have been reported in half of all patients suffering from ACC cases and these include polymicrogyria, lissencephaly, pachygyria and schizencephaly (Hetts et al. 2006). Posterior fossa anomalies are also common, with DWM reported in up to one-third of individuals (Barkovich and Raybaud 2012). Other neurological syndromes that may include ACC are Aicardi (see below) and Walker-Warburg syndromes; myelomeningocele is also a common association.

Most individuals experiencing ACC display no syndromes. However, ACC has been described as part of at least 80 chromosomal, genetic and sporadic syndromes. Chromosomal anomalies, most commonly trisomies, are present in close to 20% of ACC overall (Santo et al. 2012; Li et al. 2012), although rarely in isolated ACC (Santo et al. 2012). Finally, certain inherited metabolic diseases may be associated with ACC including non-ketotic hyperglycinemia, as well as pyruvate dehydrogenase deficiency among others (Prasad et al. 2009).

**Prognosis:** With the advent of routine fetal ultrasound the detection of isolated ACC has increased. The reported prognosis of truly isolated ACC is highly variable (Goodyear et al. 2001; Moutard et al. 2003): in a recent report 75% of isolated ACC had favourable neurodevelopmental outcomes (Sotiriadis and Makrydimas 2012). To date no specific gene loci have been identified for isolated ACC: the presence of additional anomalies, such as sulcal anomalies and migration defects, are major determinants of outcome, a significant issue in countries where the threshold for legal termination is around 24 weeks gestation, since many of the critical processes in cortical development have not normally occurred by then. The rate of normal outcome in truly isolated ACC is variable but ranges from 40% to 75% in different studies (Li et al. 2012), severe abnormality in 10%, (Sotiriadis and Makrydimas 2012) with the mild-moderate neurodevelopmental abnormality in the remainder. Conversely, when ACC is associated with other cerebral or chromosomal anomalies virtually all children have major neurodevelopmental abnormalities (Noguchi et al. 2014).

**Aicardi Syndrome** (Fig. 1.28) is an X-linked dominant condition lethal in males which should be considered in the female fetus with ACC. The diagnosis can only be confirmed postnatally since other criteria must be met, including ocular anomalies (retinal lacunae or colobomata) which may not be detectable in the fetus and infantile spasms. In the female fetus Aicardi syndrome is more likely to occur when agenesis of the corpus callosum is associated with cortical dysplasia (especially polymicrogyria or heterotopias), posterior fossa lesions (cysts or cerebellar hypoplasia), subependymal cysts around the third ventricle or choroid plexus lesions (cysts or papillomas). Ventriculomegaly is usually present and often markedly asymmetrical, while vertebrocostal anomalies may be seen in half of patients displaying Aicardi syndromes. The neurodevelopmental prognosis is universally dismal.

**ACC with midline meningeal dysplasia.** In agenesis of the corpus callosum both midline cysts and/or lipomas may occur as manifestations of disordered mesenchymal development. The interhemispheric cysts can be broadly classified as communicating or non-communicating (Barkovich and Raybaud 2012): communicating or Type 1 midline cysts...
are unilocular and usually not associated with other major cerebral or cortical dysgenesis. Although the falx cerebri is often hypoplastic or absent the primary mechanism of Type 1 cysts is upward expansion of the tela choroidea and third ventricle (‘high-riding’ third ventricle) rather than mesenchymal dysplasia. Type 1 single cysts can be further subclassified as Type 1A when macrocephaly and hydrocephalus are present: type 1B when 1A features are accompanied by developmental ventricular obstruction (thalamic adhesion, hamartoma); and Type 1C when microcephaly is present. Non-communicating or Type 2 midline cysts are multiloculated lesions, separate from the ventricles and resulting from cystic meningeal dysplasia. The cysts usually increase in size during gestation and children are usually born with hydrocephalus: these can be subclassified as Type 2A when accompanied by hydrocephalus alone, Type 2B (Aicardi syndrome; see above) and Type 2C when heterotopias and other anomalies of the head and brain are present. Interhemispheric lipomas associated with agenesis of the corpus callosum probably arise from abnormal differentiation of the meninx primitiva, which forms the leptomeninges.

Partial ACC (Fig. 1.29). The corpus callosum is not fully formed in anterior-posterior extent until 20 weeks gestation and the diagnosis of partial ACC prior to that time may be difficult. Although this lesion often appears to result from stunted growth of the posterior corpus callosum partial ACC may result from failed development of any one or more callosal elements. As discussed above the corpus callosum is formed from a number of separate elements which all arise rapidly between 13 and 14 weeks p/c: thereafter, growth in the anterior-posterior axis is the result of progressive addition of fibres to each of these elements and longitudinal growth.

Neocortical crossing fibres, especially from the frontal association cortex, are late additions to the callosum and their failure to grow will lead to a foreshortened corpus callosum: therefore partial ACC are not different degrees along a continuum but rather different malformations, each with a different developmental disorder, often with different genetic defects. In this condition the pericallosal arteries take an upward turn, at the posterior limit of the residual corpus callosum. Partial ACC is often associated with other genetic or chromosomal syndromes: reports of long-term outcome in these fetuses are highly variable.

**DEVELOPMENTAL ANOMALIES OF THE CAVUM SEPTI PELLUCIDI**

The cavum septi pel lucidi is an important landmark in fetal neuroimaging. A well-visualised normal cavum septi pellucidi is reassuring for normal development of the central-midline forebrain and excludes many complex malformations. Conversely, absence of the cavum septi pellucidi is a potential marker for a range of other cerebral anomalies and failure to establish presence may be an indication for fetal MRI. Fetal ultrasound is usually capable of alerting to the absence of the cavum septi pellucidi; however, the paired columns of the fornix may mimic the cavum septi pellucidi on fetal ultrasound and be falsely reassuring (Pilu et al. 2005). Cerebral anomalies commonly associated with absence of the cavum septi pellucidi include the holoprosencephaly spectrum, septo-optic dysplasia, callosal dysgenesis/hypogenesis, severe hydrocephalus (especially in aqueductal stenosis) and schizencephaly (Fig. 1.30), usually in the frontoparietal regions. The septum pellucidum develops in conjunction with the anterior callosum, so when absence of the cavum septi pellucidi is associated with partial ACC incomplete posterior extension of the callosum results from failure of anterior callosal development. In such cases the hippocampal commissure may mimic the genu. Septo-optic dysplasia (De Morsier Syndrome) includes absence of the cavum septi pellucidi, hypo/dysplasia of the optic nerves/chiasm and hypothalamic-pituitary dysfunction. Prenatal diagnosis and counseling for septo-optic dysplasia is difficult because of the broad spectrum of associated presentations and it may be impossible to determine the severity of disease prenatally. For these reasons absence of the cavum septi pellucidi warrants careful early postnatal evaluation for the manifestations of hypothalamic-pituitary dysfunction such as hypoglycemia and electrolyte disturbances, as well as ophthalmological and endocrine evaluation. Septo-optic dysplasia is distinguished from milder forms of holoprosencephaly by a lack of fused thalami: it has been suggested this may be diagnosed by low levels of maternal estriol during pregnancy (Lepinard et al. 2005). Truly isolated absence of the cavum septi pellucidi, which occurs in a minority of individuals, is difficult to establish with certainty in the fetal period with current conventional MRI and postnatal imaging is warranted. The neurodevelopmental outcome of this
disorder is controversial and although some reports indicate good outcome (Damaj et al. 2010) others suggest severe psychomotor impairment may occur (Belhocine et al. 2005).

**DISORDERS OF THE FETAL CHOROID PLEXUS AND VENTRICLES**

**VENTRICULOMEGALY**

Cerebral ventriculomegaly is diagnosed in up to 1% of fetuses, making it a leading referral diagnosis for fetal neurological consultation (Melchiorre et al. 2009a; Gaglioti et al. 2009). Routine fetal anatomic ultrasound reliably identifies fetal ventriculomegaly and is an important tool for following ventricular size, configuration and evolution over gestation. However, it is an imaging sign that may require fetal MRI to establish the etiological diagnosis and provide reliable prognostication. The most reliable prognostic fetal neuroimaging features include the severity, progression, aetiology and presence of associated findings.

*Diagnosis and classification:* By convention fetal ventricular size is measured as the diameter of the lateral ventricular atrium on an axial view and is relatively stable at around 6–7mm during normal development between 14 weeks and term (Almog et al. 2003). A widely used criterion for diagnosing ventriculomegaly has been ventricular diameter ≥10mm (>4 standard deviations above the mean). A number of classification criteria have been used, albeit inconsistently (Melchiorre et al. 2009a; Sotiriadis and Makrydimas 2012; Guibaud 2009; Parilla et al. 2006; Glenn and Barkovich 2006; Gaglioti et al. 2009), to categorise ventriculomegaly including mild, moderate, or severe, unilateral or bilateral, symmetrical or asymmetrical and transient, stable or progressive. Severe ventriculomegaly – which is uncommon – is applied when the maximal atrial width exceeds 15mm (Glenn and Barkovich 2006; Guibaud 2009; Gaglioti et al. 2009). Milder forms are far more common, which have been further categorised by some authors into mild (10–12mm) and moderate (12–15mm) forms. If the maximum ventricular diameter is <15mm then other anatomic anomalies are unlikely to occur. The most common scenario is milder degrees of ventriculomegaly, often unilateral or asymmetrical, which remain unchanged or normalise on follow-up studies. Conversely, when ventricular size is >15mm, the likelihood of spontaneous reversal is low; a small number of cases evolve to a severe form of progressive ventriculomegaly. Severe unilateral ventriculomegaly is rare and suggests either occlusion of the foramen of Monro or hemispheric tissue loss.

*Pathogenesis:* Several broad pathogenetic mechanisms may underlie ventriculomegaly. These include obstructed CSF drainage, underdevelopment of the cerebral parenchyma or injury and tissue loss around the ventricles. In this chapter the term hydrocephalus is used when obstructed CSF drainage is thought to be the underlying pathogenetic mechanism. The generic term ventriculomegaly will be used for ex vacuo forms of ventricular enlargement due to parenchymal hypoplasia or atrophy. Fetal imaging has advanced our understanding of ventricular development however commonly applied criteria for distinguishing between normal and abnormal ventricular size remain population-based statistical norms while outcome-based criteria remain lacking. Fetal head measurements may help distinguish between hydrocephalic and non-hydrocephalic ventriculomegaly, with large ventricles and large head circumference suggesting hydrocephalus; conversely, an accompanying small head is suggestive of an ex vacuo ventriculomegaly. Fetal hydrocephalus is present in the minority of fetal ventriculomegaly cases. Certain sites are more common for impeded CSF flow, including the aqueduct of Sylvius and the fourth ventricular foramina. Aqueductal stenosis is inferred when the lateral and third ventricles are enlarged and the fourth ventricle is normal in

![Figure 1.30](a) Fetal and (b) neonatal MRI scan showing absent cavum septi pellucidi with severe bilateral open-lip schizencephaly.
Aqueductal stenosis (Fig. 1.31) may result from brainstem dysgenesis, aqueductal forking, webs, membranes and nodules (e.g. hamartomas) (Fig. 1.31b, c) as well as from occlusion by hemorrhagic products and intrauterine infections including toxoplasmosis (Gay-Andrieu et al. 2003) and parvovirus B19 infection (Katz et al. 1996). Conversely, obstruction of fourth ventricular CSF egress through the foramina of Magendi and/or Luschka results in tetraventricular hydrocephalus. Such fourth ventricular obstruction may occur in several ways including posterior fossa crowding (in neural tube deficits and Chiari II malformations), posterior fossa cysts, masses, hemorrhage or DWM. Persistent Blake’s pouch with delayed opening of the foramina may sometimes underlie transient, self-resolving fetal hydrocephalus (Robinson and Goldstein 2007).

Aetiology: Congenital CNS infections are an etiological consideration in fetal ventriculomegaly but the positive detection rate based on maternal serology testing is highly variable. Postnatal studies in symptomatic children with known congenital cytomegalovirus (CMV) show a high incidence of mild-moderate ventriculomegaly (de Vries et al. 2004). However, ventriculomegaly is rarely the only feature and is usually associated with other features such as a periventricular ‘halo’, calcifications, pseudocysts, intraventricular synechiae as well as cortical and cerebellar malformations. In a review of previous studies (Devaeean et al. 2010) evidence of congenital infections was present in 0.4% of mild ventriculomegaly (10–12mm) and 1.5% moderate ventriculomegaly (12–15mm) (Devaeean et al. 2010). Conversely, others (Malinger et al. 2011) have reported a much higher incidence of positive maternal CMV serology in ventriculomegaly patients. Vauloup-Fellous et al. (2014) reported that an IgG avidity assay can distinguish between a recent primary infection and past infection, which may be useful for tailoring antibiotic treatment to prevent deafness in actively infected individuals. Toxoplasmosis is a rare case of ventriculomegaly and usually results from aqueductal stenosis. The usual complication of fetal parvovirus B19 infection is fetal anemia, but mild ventriculomegaly may also be seen (Weiland et al. 1987; Hartwig et al. 1989). Dysmorphic ventriculomegaly is most commonly seen in individuals affected by callosal dysgenesis when the ventricles retain a fetal configuration called colpocephaly in which the frontal horns are relatively normal while the posterior aspects are significantly enlarged with a tear-drop shape (Pilu 1993); in one large study of 430 individuals affected by ventriculomegaly 13% had ACC (Li et al. 2012). Chromosomal disorders, especially aneuploidy, may be associated with fetal ventriculomegaly however when ventricles are ≤15mm the detection rate for chromosomal anomalies is low, around 5% or less (Li et al. 2012; Gaglioti et al. 2009). Conversely, ventriculomegaly of any size associated with other fetal anomalies has an aneuploidy rate >15% (Bromley et al. 1991; Pilu et al. 1999; Mercier et al. 2001; Gaglioti et al. 2005). Differential diagnosis: Ventriculomegaly is usually readily recognised by experienced ultrasonographers but may on occasion be mistaken for other fluid-filled supratentorial lesions such as hydranencephaly (Fig. 1.32), holoprosencephaly (Figs. 1.23–1.25) or enlarged cavum septi pellucidi or cavum velum interpositum (Fig. 1.21).

Prognosis: Factors known to have prognostic importance in fetal ventriculomegaly are the underlying mechanism (hydrocephalic, dysgenetic, hypoplastic/atrophic), rate of...
progression, the aetiology, associated parenchymal brain anomalies, associated syndromic-dysmorphic features or chromosomal anomalies and the ventricular configuration. An important reason for fetal MRI brain studies in fetal ventriculomegaly is to identify associated brain anomalies: with such methods the additional diagnostic yield for associated brain anomalies ranges from 5% to 60% (Salomon et al. 2006; Morris et al. 2007; Hannon et al. 2012) and these significantly increase the risk of adverse neonatal and long-term outcome (Nicolaides et al. 1990; Gaglioti et al. 2005). The likelihood of finding associated brain malformations increases with increasing ventricular size, reaching as high as 60% when ventricles >15mm (den Hollander et al. 1998; Gaglioti et al. 2005; Breeze et al. 2005; Hannon et al. 2012; Falip et al. 2007; Weichert et al. 2010). Most but not all studies (Gaglioti et al. 2005, Pilu et al. 1999, Goldstein et al. 1990) report a low rate of associated anomalies when ventricles are <15mm. Serial ultrasound is usually adequate to monitor the course of ventricular enlargement. Mild isolated unilateral, non-progressive ventriculomegaly usually remains stable or spontaneously resolves itself, has no significant associated findings and has a favourable neurodevelopmental outcome (Pagani et al. 2014; Pasquini et al. 2014; Melchiorre et al. 2009b; Melchiorre et al. 2009a). Spontaneous resolution occurs in almost half of patients ≤12mmHg and in 25% of those between 13 and 15mm (Melchiorre et al. 2009b, Melchiorre et al. 2009a; Parilla et al. 2006) while 16% show significant progression of ventriculomegaly (Parilla et al. 2006). In isolated and mild ventriculomegaly (<15mm) the actual ventricular size has no prognostic significance (Melchiorre et al. 2009b) while ventriculomegaly of >15mm rarely resolves spontaneously. In one study children with fetal diagnosis of mild isolated ventriculomegaly who had persistent ventricular enlargement at 2 years of age were at risk for mild fine motor and expressive language delay (Lyall et al. 2012). In patients experiencing isolated ventriculomegaly on fetal MRI the additional yield for associated anomalies detected by postnatal MRI ranges from 10 to 28% (Goldstein et al. 1990; Patel et al. 1994; Pilu et al. 1999; Mercier et al. 2001; Breeze et al. 2005; Hannon et al. 2012).

**DISORDERS OF THE CHOROID PLEXUS**

The choroid plexuses develop between 6–7 weeks p/c, starting in the fourth ventricle, but becoming most voluminous in the lateral ventricle and by 20 weeks having an adult configuration. The choroid plexus starts as neuroepithelial projections that go on to form the choroidal villi: within the matrix small tubules or cysts form from pinched off sections of neuroepithelium.

Choroid plexus cysts (Fig. 1.33) can grow but usually stay <10mm in size and are most commonly seen in the 2nd trimester when they are detected in up to 1% of fetuses. These cysts are rarely diagnosed before 16 weeks p/c and most resolve by 24 weeks p/c. Choroid plexus cysts have been associated with chromosomal disorders, and are seen in up to 50% of trisomy 18 patients but are rare in trisomy 21 (Bromley et al. 1996). Bilateral choroid plexus cysts and subependymal germinolysis have been associated with congenital viral infections including CMV (Herini et al. 2003); however, isolated choroid plexus cysts diagnosed prenataally are not associated with developmental disorders (DiPietro et al. 2011) Choroid plexus papillomas are rare tumours in the fetus, usually presenting with hydrocephalus due to excessive CSF production and potentially from foraminal obstruction (Verma et al. 2014).
NEURONAL PROLIFERATION

The central 'ventricle' of the neural tube is preserved in some configuration along the entire developing nervous system. The lining of this ventricular system contains the primary neuroproliferative regions responsible for cellular population of the brain and spinal cord, as well as distinct regions responsible for specific neuronal populations of the future cerebrum. In addition it is now known that cells migrating away from these primary neuroproliferative zones are capable of setting up important secondary germinal zones where cellular proliferation continues or resumes: examples of such secondary sites include the subventricular zone and external granular layer of the cerebellum (discussed below). The future forebrain or prosencephalon is divided on each side into a basal and alar plate (Fig. 1.1), each of which contains neuroepithelial sites for cellular proliferation that produce neurons with distinctly different destinations, migratory pathways and functions. The alar plate (or pallium) of the dorsal telencephalon is lined by a smooth sheet of neuroepithelium, the ventricular zone, which generates the excitatory glutamatergic pyramidal neurons of the cortex. The neuroepithelium of the ventral telencephalon (the subpallium) expands into two major proliferating cell masses, the lateral and medial ganglionic eminences (LGE and MGE), structures that form the diencephalon and basal ganglia and generate the inhibitory GABA-ergic interneuronal population of the future cerebral structures. The lateral ganglionic eminence is of diencephalic origin and will form the caudate and putamen, while the medial ganglionic eminence as well as the ventricular/SVZ (Letinic et al. 2001). The SVZ is a secondary neuroproliferative region that comes to lie between the ventricular zone and the intermediate zone. It is formed by cells generated in the underlying ventricular zone and in turn generates later migrating cells, mainly neurons but also glial cells. Whereas the ventricular zone generates the projection neurons of the deeper neocortex later neurons of SVZ origin populate the more superficial layers. In late gestation and the early postnatal period the SVZ expands greatly while the ventricular zone shrinks to an ependymal layer of one cell in thickness lining the ventricle. After their neuronal guiding function is complete the glia produce neurons, astrocytes and oligodendrocytes: the cellular progeny of radial glial cells in the subventricular zone remain an ongoing source of stem cells in the mature brain capable of generating neurons.

NEURONAL MIGRATION

Neuronal migration is a complex series of events under the guidance of numerous substances (mainly glycoproteins) in the extracellular space interacting with surface and other markers on the migrating cell (Fig. 1.34). Together these interactions generate distinct molecular signals that trigger the onset, continuation and cessation of migration: disturbances in this highly coordinated process result in the neuronal migration defects discussed below. The migrating cells move along the surfaces of other structures such as glial cells (gliophilic migration), the principal guides for radial migration and neuronal axons (neurophilic migration) primarily involved in interneuronal tangential migration. More recently a vasophilic form of migration has been described, in which blood vessels are used as guides. Broadly speaking there are two forms of migration: radial and tangential.

There are two forms of radial migration. In the very earliest stages, when the cerebral wall is very thin and the cell is able to connect with both the ventricular and pial surfaces, the nucleus migrates out to the surface (somal translocation), followed by retraction of the ventricular edge of the cell. These earliest migrating cells will form the pre-plate which is eventually split into the marginal zone (which includes Cajal–Retzius cells) and the deeper subplate zone. Radial glial cells become the primary mode of radial migration as the cerebral mantle thickens. Clonally related neurons migrate out toward the periphery along these radial glial fibres. Radial glial cells leave the VZ clustered in fascicles, but upon reaching the subplate they defasciculate and enter the cortex as individual fibres. Of note is that this interface between the intermediate and subplate zones is an important site for the development of heterotopias (see below).
which includes axonal development and connectivity, neurite outgrowth, synaptogenesis, programmed cell death (apoptosis), glial proliferation and differentiation. These processes are responsible for the major third trimester increase in brain growth with 50% of cortical volumetric growth occurring in the final 6 weeks of gestation.

The subplate zone is a transient layer of neurons that plays a critical role in cortical organisation, synaptic development

Tangential migration is the principal mode of migration for inhibitory interneurons generated in the ventral neuroepithelium of the ganglionic eminences. In the ventral telencephalon proliferation of GABA-ergic interneurons becomes evident as early as 6–7 weeks p/c, resulting in two thickened regions of the periventricular zone, the medial and lateral ganglionic eminences. After leaving the neuroepithelium these interneurons initially migrate along a circuituous tangential path parallel to the cortex, doing so in three streams, moving through the subventricular, intermediate and marginal zones: once in the dorsal telencephalon these neurons switch their migration radially to their destination in the cortical plate. The ganglionic eminences generate the vast majority of cortical interneurons however an additional subpopulation of interneurons is generated in the SVZ of the dorsal telencephalon. More recent studies have shown that many GABA-interneurons arise from the ventricular/SVZ and migrate radially into the cortex (Leticic et al. 2002).

CORTICAL ORGANISATION

An important characteristic of the developing nervous system is the critical role played during specific periods by transient structures, such as the ganglionic eminences and periventricular germinal matrices, the subventricular zone, and the external granular layer of the cerebellum (see below).

By 20–24 weeks gestation migration is largely complete, leaving a cerebral mantle with a characteristic lamination pattern (Fig. 1.35) consisting of the ventricular zone, subventricular zone, intermediate zone, subplate zone, cortical plate and marginal layer. Hereafter, the major events in brain development are focused on cortical organisation (or re-organisation)
and connectivity. Subplate neurons are among the earliest to migrate out from the ventricular zone to form the original preplate. Subsequently, cortical plate neurons are generated and these migrate out to split the preplate into two layers, the outer molecular layer and inner subplate. Next, the subplate undergoes rapid differentiation and transiently expresses a variety of receptors for neurotransmitters and growth factors, making it the site of the earliest synaptic activity, functional activity and connectivity. This rapid growth of the subplate zone peaks between 22 and 34 weeks gestational age. The subplate is the critical functional link between waiting afferents and their cortical targets. Specifically, this is the site of initial synaptic activity, functional activity of receptors for neurotransmitters and growth factors, making it the site of the earliest synaptic activity, functional activity and connectivity. This rapid growth of the subplate zone peaks between 22 and 34 weeks gestational age. The subplate is the critical functional link between waiting afferents and their cortical targets. Specifically, this is the site of initial synaptic contact and ‘pioneering’ guidance between ‘waiting’ thalamocortical afferent axonal projections and cortico-subcortical efferents. Thalamocortical and trans-callosal axons, two major afferent systems forming the core of the gyral white matter, share waiting periods in the subplate prior to their growth into the cortical plate. The subplate has an abundant hydrophilic extracellular matrix rich in signalling molecules critical for axonal guidance, normal cortical connectivity and structural plasticity. The subplate neurons elaborate a dendritic tree to receive synaptic input and send axonal projections to the cortex and to the subcortical nuclei: at this stage the subplate is the most active layer of the developing cortex in generating action potentials and has the synaptic apparatus for most cortical neurotransmitter systems including monoaminergic and cholinergic arousal and activating systems.

Around 24–25 weeks gestation the majority of thalamocortical axons are residing transiently in the superficial subplate while some have begun to enter the cortical plate to take up their permanent positions, establishing the necessary anatomic substrate for extrinsic cortical input from both the sensory and associative nuclei of the thalamus. The developing cortex is now poised to transition from spontaneous endogenous activity to a sensory-expectant form of functioning. Between 26–28 weeks gestation thalamocortical afferents continue to arrive in layers III and IV of the cortical plate, establishing the first synapses in a deep to superficial pattern. By 31–33 weeks gestational age connectivity between the thalamocortical axons and cortical layer IV becomes established setting the stage for functional sensory-driven development. Functional thalamocortical synapses are necessary but not sufficient for conscious cortical processing. Between 31–34 weeks gestational age primary gyri and sulci begin to appear and the cortex develops a six-layered pattern: hereafter the subplate plays a critical role in the accelerated development of cortico-subcortical and transcallosal cortico-cortical development. Neuronal network connectivity follows a broadly consistent pattern during development, with long-range connections developing well in advance of shorter cortico-cortical connec-

tions. Early synaptic activity in the developing cortex regulates axonal and dendritic growth and branching leading to thalamo-cortical, cortico-cortical and cortico-thalamic connectivity (Mire et al. 2012). Between 35 and 37 weeks gestational age interhemispheric synchronisation becomes established and by 38 weeks gestational age there is maturation of long intra-hemispheric (associative) and interhemispheric (callosal) cortico-cortical connectivity. Between 35 and 37 weeks gestational age there is intense development of inter- and intra-hemispheric connections, accompanied by major changes in the electrocortical activity.

Regression of the transient subplate layer begins around 27 weeks gestation with developmental apoptosis of subplate neurons and continues into postnatal life until about 90% of subplate neurons have been pruned. During this subplate regression the abundant hydrophilic extracellular matrix shrinks, making it less distinct on fetal MRI. Residual subplate persists longest in the gyral crests than in the depths of sulci, particularly in the associative cortical regions, presumably because of the ongoing role of the subplate in the prolonged development of long cortico-cortical associative circuitry and postnatal shaping of tertiary gyri. In the prefrontal associative cortex the remnants of subplate persist over the first 6 postnatal months.

**Synapse formation.** The normal processes of synapse formation and pruning have major temporal differences across the different regions of the brain. In each region there is an initial accumulation of synaptic density to a peak, followed by active apoptotic pruning. The earliest regions to embark on this course are the brainstem and cerebellum, followed by the hippocampus and posterior neocortex (Sarnat et al. 2010; Huttenlocher and de Courten 1987) and lastly in the frontal cortex, with many of these later phases peaking after birth. In the neocortex the earliest synapses develop between 12 and 14 weeks p/c in the earliest migrating neurons (Tiu et al. 2003; Sarnat et al. 2010), i.e. those that form the preplate, which later splits into the molecular and subplate layers. Abnormalities in both development and pruning of synapses are associated with a variety of neurodevelopmental conditions but these are rarely diagnosed in the fetal period.

Apoptosis is a critical part of brain development and is related to morphogenesis, proliferation and the regulation of progenitor pool size. Apoptosis is an active energy consuming process and in conditions of cerebral energy failure may become inhibited. It is particularly active in areas where rapid structural changes are occurring, where it helps regulate the appropriate size and shape of the structures. Apoptosis plays a particularly important role in the timeline of transient structures and has a different time-course across the regions of the brain. For example, by weeks 6–7 p/c apoptosis is already markedly active in the ventricular zone and preplate (Zecevic and Rakic 2001) and by week 11 p/c has commenced in all cortical layers, although it remains most active in the proliferative zones. Between 12–22 weeks apoptosis has increased significantly throughout the telencephalon; failure of normal apoptosis may lead to lesions with excessive neural parenchyma.
Although developmental brain anomalies are often classified into the putative developmental process disturbed (e.g. proliferation or migration) there are often multiple stages involved in a single patient; for example, disturbances in neuronal proliferation may be followed by disturbed neuronal migration and organisation.

Acquired lesions originating early in development may be difficult to distinguish from primary dysgenesis since a cicatrical response might be lacking. Disorders of brain size may be due to disturbances in cellular proliferation or in apoptosis.

**MICROCEPHALY**

Fetal microcephaly is variably defined as a head circumference >2SD below the mean or below the 3rd centile for gestational age (Table 1.3). There is ongoing controversy about the best standard for diagnosing microcephaly and whether this should be adapted for ethnicity. In addition, fetal centiles may differ from gestational-age adjusted postnatal centiles and fetal head circumference charts are not sex specific. A significant correlation has been described between maternal microcephaly and infant head size at birth (Stoler-Poria et al. 2010). Dominantly inherited microcephaly has a better outcome in some (Dorman 1991) but not all studies (Stoler-Poria et al. 2010) with most based on a postnatal diagnosis. In a substantial proportion of individuals head circumference will improve postnatally (Stoler-Poria et al. 2010).

Infants with a birth head circumference between 2 and 3SD below the mean often have a favourable outcome, especially in the absence of other factors such as brain anomalies (Kurtz et al. 1980) or syndromic conditions. Some studies show that fetal head circumference 2–3SD below the mean for gestational age is not associated with significant differences in intellectual outcome from controls, although behavioural, emotional and executive function impairments are more common (Pilu et al. 1998; Huizink et al. 2003). The latter finding has been ascribed to the higher rate of frontal lobe underdevelopment in these infants (Pilu et al. 1998) or greater maternal psychoaffective stress (Huizink et al. 2003). When birth head circumference falls between 3 and 4SD below the mean the risk of intellectual disability increases to 50% (Dolk 1991) although many still have relatively normal intellectual ability. Once head circumference is more than 4SD below the mean the intellectual outcome is universally poor (Dolk 1991).

The role of overall fetal growth in the outcome of microcephaly is unclear. Fetal growth restriction and a fetal head circumference 2–3SD below the mean increases the risk of learning disabilities. Some studies describe a better outcome for microcephalic newborn infants with normal birthweight (Dolk 1991) while others found no difference between symmetrical or asymmetrical microcephaly (Stoler-Poria et al. 2010).

While microcephaly describes a small head, micrencephaly refers to a small brain. Although head circumference and biparietal diameter are still the primary measures of head size and surrogate for brain size the advent of quantitative fetal MRI (Limperopoulos et al. 2010; Clouchoux et al. 2012b) has better enabled the direct volumetric measurement of the fetal brain parenchyma and is likely to improve prognostication based on brain size in future.

A valuable step in formulating a prognosis for microcephaly is to distinguish primary genetic causes from acquired-destructive forms. Acquired forms often have relatively moderate microcephaly but severe intellectual disability, major neurological abnormalities and often a history of a sentinel event/mechanism. Microcephaly may be accompanied by prominent cerebellar hypoplasia and can be divided into primary microcephaly when there is a known or suspected genetic cause or secondary microcephaly when an insult to the fetal brain results in impaired growth. Attempts at categorising microcephalies based on MRI features have considered the presence of associated cortical thickness, simplified gyral patterns, callosal anomalies, heterotopias and forebrain development (Barkovich and Raybaud 2012). Decreased cortical thickness in microcephaly is suggestive of decreased cellular proliferation and can be seen in in utero infections.

Primary microcephaly (microcephaly vera) is associated with an overall normal brain configuration but neurons in cortical layers II and III are severely depleted. Microcephaly vera is genetically heterogeneous with a recessive inheritance (Suri 2003) and MCPH 1–5 gene loci which encode for microcephalin. Markedly hyperkinetic behaviour is common but the neurological examination usually shows very few gross abnormalities and seizures are rare. Intellectual disability is usually mild and most children acquire at least some functional language. Microlissencephaly is an extreme form of microcephaly with a thick cortex and markedly decreased cortical sulci (agyria-pachygyria). Cerebral underdevelopment is especially prominent in the frontal lobes, with cerebellar and brainstem hypoplasia, while enlarged ventricles may be associated. Unlike microcephaly vera microlissencephaly is associated with gross neurological abnormalities, profound intellectual disability and epilepsy.

Radial microbrain is an extreme form of microcephaly where the brain may weigh less than 50 g where radial columns are fairly normal but severely deficient in neurons. Radial microbrain differs from atelencephaly in which there is no cortical structure.
Chapter 1 Fetal Neurology

MACROCEPHALY

In the evaluation of fetal macrocephaly the first step is to distinguish between hydrocephalus, space-occupying lesions and megalencephaly, which can usually be achieved fairly reliably by fetal ultrasound, while a family history of macrocephaly with normal outcome is suggestive of dominant familial macrocephaly. Primary megalencephaly may result from abnormalities in neuronal proliferation, migration and organisation and may be syndromic (Sotos syndrome, neurofibromatosis): these conditions are discussed elsewhere in this text.

Hemimegalencephaly (Fig. 1.36) results from unilateral hamartomatous overgrowth of a cerebral hemisphere with associated disturbances of proliferation, migration and differentiation, and an abnormal gyral pattern with pachygyria or polymicrogyria. Ventriclemegaly or ventricular asymmetry is a common referral diagnosis in the fetal period for lesions ultimately diagnosed as hemimegalencephaly. The cerebral cortex in the affected hemisphere is thickened and un laminated with loss of cellular alignment, heterotopias and giant balloon cells. Both the cerebrum and cerebellum may be involved in some individuals: the prognosis is poor and
affected children usually develop severe intellectual disability, hemiparesis and early-onset intractable epilepsy.

DISORDERS OF NEURONAL MIGRATION

The successful migration of neurons from distant neuroproliferative zones to their final cortical destination involves the precise orchestration over time and space of signalling guides expressed as gradients of extracellular signals and transcription factors. Neuronal migration disturbances may result from a host of genetic or acquired (disruptive) events across this landscape: the phenotypic expression of disturbances in these complex processes depends on the underlying mechanism, the timing of such and its severity (see also Chapter 3).

Neuronal migration defects have been categorised into a number of different classification schemes that change as new genetic and mechanistic insights emerge. In this chapter on fetal neurology we focus on those lesions that can be diagnosed in utero by current fetal imaging techniques into the following categories (Guerrini and Parrini 2010).

1. **Focal/multifocal neuronal migration defects** which include schizencephaly, mild subcortical band heterotopia and nodular heterotopia.

2. **Diffuse neuronal migration defects** which include lesions in the agyria-pachygyria spectrum such as lissencephaly type 1, severe subcortical band heterotopia and the cobblestone lissencephaly complex (lissencephaly type 2).

Another schema for categorising neuronal migration defects is based on the stage of migration affected and includes four groups. These are lesions originating (1) before (schizencephaly) or at the onset (periventricular nodular heterotopia) of neuronal migration; (2) during the ongoing process of migration (agyria-pachygyria spectrum); (3) from failed penetration of the subplate (lissencephaly with cerebellar hypoplasia) and (4) at the end of migration leading to overmigration (Type 2, cobblestone complex).

Disrupted signalling in neuronal migration leads to a broad spectrum of neuronal migration defects which can result from failure of neurons to leave the proliferative zone (defective ‘go’ signal), abnormal early detachment from radial glial cells or over-migration (defective ‘stop’ signal) when neurons migrate through gaps in the pial limiting membrane into the subarachnoid space. Each neuronal migration defect reflects specific signalling disturbances. For example, *filamin 1 (FLN1)* is important for cellular locomotion and FLN1 mutations disrupt those signals necessary for postmitotic neurons to leave the ventricular zone, resulting in bilateral periventricular nodular heterotopia (Fox et al. 1998). *Doublecortin (DCX)* is expressed in the leading edges of migrating neurons where it interacts with guidance signals in the extracellular environment. Mutations in DCX, an X-chromosome product, cause band heterotopias in females and lissencephaly in males (X-linked lissencephaly) while mutations of the *LIS1* gene cause heterotopias and/or lissencephaly. Mutations in *LIS1* and *DCX* genes are responsible for 40–75% of type 1 lissencephalies (Dobyns 1989) as well as a milder defect, subcortical laminar heterotopias (Froimcourt et al. 2003). Brain lesions associated with the *LIS1* and *DCX* mutations have a fairly typical microscopic picture with a thin outer layer of cells made up of cortical layer 1 and the layers destined to make up cortical layers 5 and 6. This outer band is separated by a cell-sparse layer from a broad underlying layer of cells that became arrested in their migration toward cortical layers 2 and 3 (Forman et al. 2005), while milder forms of *DCX* and *LIS1* mutations may cause band heterotopias. *Reelin (RELN)* is a large glycoprotein molecule secreted by the Cajal-Retzius cells in the outermost cortical (molecular) layer (cortical layer 1) and plays a fundamental role in the columnar and laminar organisation of the cortical cells (Ogawa et al. cortical layer 1). For the migrating waves of neurons destined to populate cortical layers 2–6 in an inside-out sequence reelin plays an essential stopping role once these neurons reach their appropriate cortical location. It also serves an important role in neuronal migration, cortical lamination and positioning.
as well as the polarity of the apical cells. Reelin usually signals the normal detachment of migrating neurons from the radial glial cells; with reelin mutations there is abnormal lamination of a thickened cortex, while marked cerebellar and brainstem hypoplasia are also common. It also appears to have an ongoing stabilising role in maintaining cortical layering (Forster 2014; Frotscher et al. 2009). Certain gene products such as tubulin (TUB) play multiple roles in brain development: TUB genes encode for alpha and beta tubulins important for neuronal proliferation, migration, neuronal guidance of radial glia, neuronal differentiation and cortical organisation (Ayala et al. 2007). TUB gene mutations are usually sporadic or de novo and associated with a spectrum of dysgenetic brain lesions including neuronal migration disorders, such as lissencephaly and polymicrogyria (Breuss et al. 2012) and posterior fossa anomalies such as cerebellar and pontine hypoplasia, tectal dysplasia and asymmetries of the midbrain and pons (Cushion et al. 2013).

**FOCAL OR MULTIFOCAL NEURONAL MIGRATION DEFECTS**

The principal gene mutations responsible for this class of NMD are DCX, FLN1 and ARFGEF2 (Guerrieri and Parrini 2010).

**Lissencephaly (Smooth Brain):** Disruption of neuronal migration outward from the germinal zones into the cerebral cortex resulting in a loss of the normal gyral pattern including lissencephaly, agyria or subcortical band heterotopia. Pachygyria, or localised areas of thickened cortex, is considered a form of lissencephaly.

**Genetic causes of lissencephaly (Classic, Type 1; Miller-Dieker Syndrome):** Mutations in the LIS1 gene (PAFAH1B1) due to 17p13.3 microdeletion or mutations in the X-linked gene doublecortin (DCX).

Doublecortin mutations cause double cortex in females (also known as subcortical band heterotopia or laminar heterotopia) and affected males show X-linked lissencephaly.

Other mutations associated with lissencephaly:

- **TUBA1A gene:** alpha-tubulin
- **DYNC1H1 gene:** dynein heavy chain isoform
- **KIF2A:** kinesin heavy chain
- **TUBG1:** gamma-tubulin
- **NDE1:** can cause microlissencephaly.

RELN gene mutations can cause lissencephaly with cerebellar hypoplasia (Norman-Roberts syndrome).

**Genetic causes of cobblestone lissencephaly (Type 2)**

Defects in O-mannosylation of alpha-dystroglycan and related genes most common causes:

- **POMT 1 and 2 genes:** involved in mannosyl-transferase reactions
- **FKRP gene:** fukutin-related protein
- **SRD5A3 gene:** endoplasmic reticulum
- **ATP6V0A2 gene:** Golgi apparatus
- **GPR56 gene:** G-protein-coupled receptor

Mutations in these genes cause brain disorders associated with congenital muscular dystrophy presenting as: Walker–Warburg Syndrome, Muscle-eye-brain disease, Fukuyama congenital muscular dystrophy or Congenital muscular dystrophy types 1C and 1D.

**Genetic causes of polymicrogyria**

Mutations in the phosphoinositide-3-kinase regulatory subunit PIK3R2B can cause bilateral perisylvian polymicrogyria (BPP) or polymicrogyria-polydactyly-hydrocephalus (MPPH)

PIK3R2 regulates PIK3-AKT-mTOR which is involved in tuberous sclerosis

Polymicrogyria can be observed in Joubert syndrome, Aicardi Syndrome, Goldberg-Sprintzen syndrome, and Zellweger syndrome

Mutations in TUBA8, beta-tubulins and related genes are also associated with polymicrogyria.

**Schizencephaly: Unilateral or bilateral clefts in cerebral cortex**

Non-genetic in most cases, caused by CMV infection or vascular events can be caused by Col4A1 mutations.
that segment of the cerebral mantle, presumably because of agenesis or destruction of progenitor cells. This results in a cleft extending through the entire cerebral mantle ending in a pial-ependymal seam by the apposition of the outermost pial layer and the ventricular ependyma. Grey matter lines the entire cleft although it is abnormal, usually polymicrogyric. These clefts most commonly occur superior to the Sylvian fissure and may be unilateral or bilateral. Schizencephaly is classified into open- and closed-lip types (Figs. 1.30 and 1.37): in open-lip schizencephaly ample CSF is visible along the extent of the cleft while in the closed-lip form CSF is minimal to absent. Up to half of open-lip schizencephaly may later become closed-lipped over time (Nabavizadeh et al. 2014) while in up to 75% of schizencephaly patients the septum pellucidum is absent (Granata et al. 2005) especially when clefts are in the central perisylvian region. Schizencephaly may also be associated with other malformations such as septo-optic dysplasia, ACC and heterotopias.

Open-lipped schizencephaly is complicated by hydrocephalus in up to 50% of patients (Packard et al. 1997). Schizencephaly may be due to genetic mutations such as the homeobox EMX2 gene or acquired lesions early in fetal life (Curry et al. 2005) which are usually vascular or infectious, specifically fetal CMV encephalitis (Iannetti et al. 1998). As schizencephaly originates at the onset of neuronal migration in the third month of gestation it is usually detectable by fetal ultrasound and MRI: the neurodevelopmental outcome for the defect includes mild-moderate intellectual impairment, congenital hemiparesis, macrocephaly and focal seizures.

**Heterotopias** may take several different forms including periventricular nodular heterotopia, subcortical nodular heterotopia and transmantle heterotopia. Band heterotopia, especially more severe forms, are currently considered a forme fruste of the agryia-pachygyria spectrum although the overlying cortex may be relatively preserved. About 50% of **periventricular nodular heterotopia** (Fig. 1.38) patients were also affected...
by mutations in the FLNA (filamin-A) gene. Mutations in the ARFGEF2 gene have also been associated with heterotopia: their location may result from failure to migrate from primary proliferative zone or due to excessive proliferation resulting from failure of the stop-signal for proliferation. Heterotopias are often part of more complex malformations: by MRI these lesions appear as nodules of grey matter along the ventricular wall commonly associated with ventriculomegaly. In fact, ventriculomegaly is often the initial referral indication for fetal MRI, rather than heterotopia which are not well seen by fetal ultrasound. If isolated and unilateral heterotopia may be MRI, rather than heterotopia which are not well seen by fetal ultrasound. If isolated and unilateral heterotopia may be MRI, rather than heterotopia which are not well seen by fetal ultrasound.

**DIFFUSE NEURONAL MIGRATION DISORDERS**

The lissencephalies: The human fetal brain starts off with a smooth agyric surface which then begins to develop sulci and gyri at specific time-points during gestation. Failure to develop such gyral patterns may be an early sign of a spectrum of neuronal migration disorders called the lissencephaly continuum. There are two major forms of lissencephaly, types 1 and 2 and four less common forms sometimes called variant lissencephaly: these are lissencephaly with cerebellar hypoplasia (LCH), X-linked lissencephaly (XLIS), X-linked lissencephaly with ambiguous genitalia (XLAG) and micro-lissencephaly (Forman et al. 2005). Although both major forms have failure of normal gyral formation they differ fundamentally in the mode of disrupted neuronal migration, with under-migration in type 1 and over-migration in type 2. Specifically, type 1 lissencephaly results when neurons are arrested in their migration prior to their arrival in the appropriate cortical laminae: overall the cerebral wall in type 1 lissencephaly has the appearance of a 12–13 week gestation brain. In Type 2 there is an over-migration of neurons beyond their designated laminae and into the subarachnoid space. As a result the histological features of the cortex are completely different, although both forms have failure of normal gyral development and thickened cerebral cortex. In type 1 a more superficial cellular layer has poorly aligned/oriented cells and the deeper cell layer has arrested ectopic neurons while in type 2 lissencephaly the cortex has no recognisable organisation, with large clusters of heterotopic neurons and no lamination. Protruding out onto the surface of the brain are nodules of neural tissue made up of neurons that have migrated through the pial lining, giving a cobblestone appearance.

**Lissencephaly Type 1**

Figure 1.40 is part of an agyria-pachygyria spectrum with varying degrees of absent sulcal-gyral formation. The gene mutations associated with this spectrum are LIS1 (AR) and DCX (X-linked), although ARX, TUBA1A and RELN mutations are also known to be associated, with dysregulation of microtubular function the common underlying mechanism for disturbed neuronal migration in these conditions (Francis et al. 2006). Any lesion along this spectrum may be associated with mutation of either LIS1 or DCX, however type 1 lissencephalies are most commonly associated with LIS1 mutations while DCX mutations are more common in subcortical band heterotopia. More than half of classic lissencephaly patients have mutations of the LIS1 gene on chromosome 17 and about 25% have mutations in DCX or XLIS (on the X chromosome). All known genetic causes of type 1 lissencephaly have a thickened cortex but important differences exist in the topography and histopathology (Forman et al. 2005). Mutations in LIS1 and DCX have a different topography of lissencephalic cortex, being more severe posteriorly with LIS1 mutations and more severe anteriorly with DCX mutations. Classic type 1 lissencephaly due to LIS1 mutation results in a small brain with tortuous surface vessels, the cortical lesion having a broad swath of neurons prematurely arrested in their migration causing a thickened, usually 4-layered ‘cortex’ overlying a thin ribbon of white...
matter, with olivary nuclei ectopic and dentate nuclei abnormally convoluted. On fetal MRI classic lissencephaly shows a very thick smooth cortex with shallow sylvian fissures and an axial figure-of-eight shape to the cerebrum. 

\textit{LIS1} mutations are associated with two clinical syndromes, classic type 1 lissencephaly (isolated lissencephaly sequence; ILS) and the Miller-Dieker syndrome. Isolated lissencephaly sequence is not associated with other major brain or extracerebral anomalies, with callosal agenesis uncommon. In Miller-Dieker syndrome – which forms a minority of type I lissencephaly – additional dysmorphic facial features are present, including a narrow forehead, upturned nostrils, long upper lip, digital abnormalities and retinal hypervascularisation. Miller-Dieker syndrome is associated with codeletion of \textit{LIS1} and \textit{YHAWAE}, a contiguous gene (Cardoso et al. 2003), possibly explaining the broader dysmorphic phenotype: most \textit{LIS1} mutations are de novo. The prognosis of both forms of type 1 lissencephaly is bleak with severe intellectual disability diffuse atonic weakness and microcephaly, which is usually mild, while life expectancy is reduced.

In addition to type 1 lissencephaly \textit{TUBA1A} mutations result in microcephaly, spastic cerebral palsy (CP) and intellectual disability (Bahi-Buisson et al. 2008).

The \textit{pachygyria} phenotype (Fig. 1.41) is milder than lissencephaly and the thickened cortex having abnormally broad gyri. Pachygyria occurs in several different syndromes, with most individuals affected as a result of sporadic mutations of the \textit{LIS1} gene: congenital CMV encephalopathy may resemble this phenotype.

The majority of individuals affected by \textit{subcortical band heterotopia} (Fig. 1.42) are girls, as a result of mutation of the sex-linked \textit{DCX} gene that codes for doublecortin. Expression is highly variable as the superficial cortex in subcortical band heterotopia may appear normal or mildly abnormal with shallow sulci. The cortex is separated by a narrow strip of white matter from a thick band of grey matter whose border with the overlying white matter is smooth: in girls the band may range from thick and diffuse to thin and localised. Compared to \textit{LIS1} lissencephaly the band of arrested neurons is thinner and the cortex thicker with a more advanced gyral pattern. Seizures and cognitive impairment are frequent complications although occasional patients appear to develop normally: some have found an inverse relationship between the thickness of the subcortical band and cognitive level (Barkovich et al. 1994).

\textit{X-linked lissencephaly} (XLIS) results from a \textit{DCX} mutation. In males with XLIS the lissencephaly resembles that in \textit{LIS1} but has a frontal predominance (Dobyns et al. 1999) while

\textbf{Figure 1.40} Postnatal MRI in (a) coronal and (b) sagittal planes showing smooth cortex (arrows). Inferior vermian hypoplasia is evident in case of \textit{lissencephaly with cerebellar hypoplasia} (LCH) in b*.

\textbf{Figure 1.41} \textit{Pachygyria} on axial MRI showing broad gyri and thickened cortex (arrows).
LCH may also occur with protein (reelin) essential for normal neuronal migration. The reelin gene encodes an extracellular matrix-associated proteins to the basement membranes, while similar binding defects may occur in the retina. A number of gene mutations have been associated with these conditions: merosin deficiency is one cause of abnormal basement membrane attachment and results in the merosin-deficient congenital muscular dystrophy group of disorders which is in turn associated with a spectrum of brain anomalies including microcephaly, leukoencephalopathy, neuronal migration defects and cerebellar lesions including hypoplasia and cyst formation (van der Knaap et al. 1997; Triki et al. 2003). Although infants with type 2 lissencephaly occasionally have normal eyes, muscle involvement is usually inevitable and has the appearance of severe muscular dystrophy.

### Lissencephaly Type 2

In type 2 lissencephaly the cortex is moderately thickened with irregular surfaces at both the pial aspect and interface with the subcortical white matter, which leaves the cortical surface with a cobblestone appearance and little to no overlying subarachnoid space (Fig. 1.43). The white matter is decreased in volume and dysmyelinated while severe cerebellar dysplasia (PMG) with cysts and brainstem hypoplasia may be present. Unlike type 1 lissencephaly in which neuronal migration is prematurely arrested type 2 lissencephaly results when deficient ‘stop signals’ cause over-migration beyond the pial-glial limiting membrane forming neural ectopia into the subarachnoid space. In type 2 lissencephaly disturbances in tangential migration may also play a role (Kato and Dobyns 2005; Marcorelles et al. 2010). About two-thirds of type 2 lissencephaly patients have evidence of an α-dystroglycanopathy related to a defect of O-glycosylation of the extracellular matrix proteins. Mesenchymal signalling is important for normal development of the underlying fetal brain, evident in cerebral malformations that result from developmental defects in the overlying pial basement membrane. The outer surface of the brain is normally covered by a glia limitans which is in turn covered by the pial basement membrane. In the cerebellum the astrocytic end-feet are those of the Bergman glia and in the cerebrum, the radial glial cells. Leptominges around the cerebellum are critical for the proliferation and migration of granule cells in the external granular layer and for normal CBM lamination (Wang and Zoghbi 2001). Inadequate fusion between the pial basement membrane and footplates of the radial glial cells results in disorders of neuronal migration and premature radial glial apoptosis. In the remaining 30% of patients no genetic cause is currently known.

Three subtypes of alpha-dystroglycanopathy have been described (Devisme et al. 2012), namely the Walker–Warburg syndrome, Fukuyama disease and muscle-eye-brain disease.

The association between muscle, eye and brain lesions results from common abnormalities in the basement membranes of the pia limitans and muscle fibres, resulting in defective attachment of radial glial cells and contractile muscle proteins to the basement membranes, while similar binding defects may occur in the retina. A number of gene mutations have been associated with the following conditions: merosin deficiency is one cause of abnormal basement membrane attachment and results in the merosin-deficient congenital muscular dystrophy group of disorders which is in turn associated with a spectrum of brain anomalies including microcephaly, leukoencephalopathy, neuronal migration defects and cerebellar lesions including hypoplasia and cyst formation (van der Knaap et al. 1997; Triki et al. 2003). Although infants with type 2 lissencephaly occasionally have normal eyes, muscle involvement is usually inevitable and has the appearance of severe muscular dystrophy.
Part I  Fetal and Neonatal Neurology

Walker–Warburg Syndrome

Walker-Warburg syndrome (Fig. 1.43) has a striking phenotype with profound anomalies of the brain and eyes, enabling diagnosis in the fetal period. Inheritance is usually autosomal recessive due to a mutation of the POMT1 gene. It is the most severe of the muscle-eye-brain syndromes, with most patients showing no developmental progress before they die, usually in the first year of life. The cortex is thick and often double-layered with complete disorganisation due to subcortical heterotopic islands, with the overlying meninges often thick and opaque, with few sulci detectable. Hydrocephalus is common usually due to the thickened meninges, decreased extra-axial CSF spaces or aqueductal stenosis. Hydrocephalus further obliterates the extra-axial fluid, while the pyramidal tracts and corpus callosum may be absent with an encephalocele present. The cerebellum is small with an absent vermis; as with other conditions in this spectrum the white matter is severely under-myelinated. Striking posterior fossa anomalies may be present including pontine hypoplasia, thickened midbrain tectum with fused colliculi and abnormal Z-shaped kinking of the thin brainstem with marked cerebellar hypo/dysplasia. Ocular anomalies include microphthalmia, glaucoma with intra-ocular haemorrhages and colobomas.

Fukuyama Disease

Fukuyama congenital muscular dystrophy is an autosomal recessive disorder due to a mutation in the fukutin (FTCD) gene. The resulting fukutin deficiency may result in disruption of the pial-glial limitans and muscle disease dominates the postnatal clinical picture: in Japan this is the most common form of congenital muscular dystrophy. There is a broad range in severity of brain findings in Fukuyama’s congenital muscular dystrophy but in general the phenotype is milder than that of Walker-Warburg syndrome. The cobblestone lissencephaly is less severe with hydrocephalus, callosal dysgenesis and encephaloceles uncommon: consequently, the diagnosis is less easily made by fetal imaging. Delayed sulcation and subcortical cerebellar cysts may be the only clues on fetal imaging.

Muscle-Eye-Brain Disease

Muscle-Eye-Brain disease is associated with a number of gene mutations. Early in infancy severe hypotonia is present but by late childhood marked spasticity has developed as well as severe cognitive impairment and epilepsy.The cortex is markedly abnormal resembling polymicrogyria with delayed myelination and widely dilated ventricles which may be hydrocephalic in origin. Fetal imaging may show a small ventral pons with a cleft and a large often rounded tectum as well as cerebellar cysts.

Disorders of Cortical Organisation

Polymicrogyria (Fig. 1.44) is a cortical malformation that has origin during the period from late neuronal migration into...
the phase of cortical organisation. The gross appearance of the cortex is one of many excessively small and shallow folds giving a ‘pebbled’ appearance. Macroscopically the cortex may appear to be thickened but this appearance is due to overfolding, evident on microscopy in which the cortex typically shows loss of neurons with greater or lesser loss of lamination and the appearance of fused molecular layers in the folds. Polymicrogyria has been categorised by some as layered or unlayered: layered (classic) polymicrogyria, has four distinct cortical layers and is thought to be postmigrational in origin. Patients often have gliotic changes and laminar neuronal necrosis suggesting an insult occurring after completion of migration (Toti et al. 1998). Unlayered polymicrogyria is thought to originate from disturbances in the terminal phases of migration, resulting in a poorly laminated cortex with disorganised heterotopic neurons, often arranged in columns descending into the subcortical white matter. Several different forms are described but central to all is disorganisation of the normal six-layered cortex and abnormal sulcation. The regional distribution of polymicrogyria is varied but the sylvian fissure is involved in the majority of patients. The syndrome of bilateral perisylvian polymicrogyria (developmental Foix-Chavany-Marie syndrome) (Graff-Radford et al. 1986) is associated with dysphagia and dysarthria (a pseudobulbar palsy), seizures and cognitive impairment, as well as motor deficits including arthrogryposis (Gropman et al. 1997). Polymicrogyria often occurs in association with other dysegnetic lesions including schizencephaly, callosal agenesis and cerebellar hypoplasia: this form of brain anomaly may be seen after acquired lesions such as congenital CMV infection and ischaemic lesions (Barkovich et al. 1995). The features of polymicrogyria on fetal MRI may be relatively subtle: the cortical irregularity may be best seen on the inner surface of the cortex at the underlying white matter interface rather than on the outer surface. The extent of neurodevelopmental impairment in these infants is related to the extent and topography of the polymicrogyria, aetiology and presence of associated cerebral anomalies or syndromic features.

**Other disorders of cortical organisation:** A number of more localised or focal cortical anomalies are known but these are seldom detected by fetal imaging and therefore not discussed here.

**FUNCTIONAL DEVELOPMENT OF THE FETAL BRAIN**

Functional and structural development of the fetal brain are intimately connected. Three aspects of functional development of the fetal brain are discussed here, namely (1) electrochemical development; (2) development of cerebral energy metabolism and vasoregulation; and (3) the behavioural expression of fetal brain development.

**Electrochemical Development**

Two central processes are essential for electrochemical development of the fetal brain. These are (1) development of efficient, stable synapses under both excitatory and inhibitory control and (2) development of behaviourally relevant and sensory driven electrical activity from an earlier system of primitive endogenous discharges. Early neurotransmitter systems differ significantly from those in the mature brain, with neurons able to communicate through activation of membrane receptors early in development before these receptors are organised into synapses. Gamma amino-butyric acid (GABA)-ergic synapses and networks develop before glutamatergic synapses and in contrast to a later role, GABA is initially excitatory and responsible for all cerebral excitatory activity. This early excitatory action of GABA results because the early resting chloride gradients across the neuronal membranes are reversed. Therefore, opening of chloride channels by GABA during early development is depolarising (excitatory) as opposed to the later hyperpolarising inhibitory action. Early GABA release is tonic and non-vesicular, diffusing to distant neurons and acting in a paracrine manner. Neurotransmitter clearance from the synaptic cleft is slow in the immature brain because re-uptake channels are lacking. Together these features result in a primitive pattern of gross, non-discrete neural activity, generating very large spontaneous currents that manifest as major discharges called giant depolarising potentials (GDP) or spontaneous activity transients (SAT). Spontaneous bursts of discontinuous activity are a fundamental feature of the developing nervous system and are active before sensory systems become functional (Pallas 2001; et al. 2006). Although these massive electrical discharges convey little if any information they are a key stimulus for early neuronal development (Vanhatalo and Kaila 2006), providing critical trophic support for neuronal survival: deprivation of such activity leads to apoptotic cell death (Blankenship and Feller 2010; Colonnese and Khazipov 2012). These endogenous discharges are also important for early synapse development and the fundamental construction of activity-dependent wiring and functional neural networks (Khazipov and Luhmann 2006; Tolner et al. 2012): this early endogenously driven brain activity is independent of external sensory input (Bourgeois et al. 1989; Colonnese and Khazipov 2012). Later, with the transition of GABA to an inhibitory role and the development of the interneuronal inhibitory system, spontaneous discharges decrease and disappear.
Development of connections between the sensory experience of the environment and developing cortex is the pivotal step in subsequent development of the nervous system. The epigenetic experiential sculpting of discrete, sensory-driven and behaviourally relevant neural activity is dependent on a number of systems becoming aligned. Linkage between the environment and cortex constitutes the pivotal developmental switch required for epigenetic influences on brain development. First, neural connectivity must be established between sensory receptors and the developing cortex. Efficient synaptic systems must develop that are under both excitatory and inhibitory control, with functional neurotransmitter re-uptake channels at the synaptic cleft. Only under these conditions can organised and topical communication between neurons occur and lead to the development of neuronal circuitry.

Electrical discharges are increasingly triggered by glutamatergic pyramidal neurons with development of the glutamate neurotransmitter system. During the early phases of glutamatergic system development GABA-ergic neurons play a permissive or facilitatory role in the activation of glutamatergic discharges. Central to the development of a behaviourally relevant nervous system is the switch in GABA activity from excitatory to inhibitory, with this switch occurring when chloride pumps become more efficient and mediate a fall in intracellular chloride. Hereafter, inhibitory GABA acts in concert with excitatory glutamate at discrete synapses to enrich the efficacy of synaptic function.

The first synaptic activity develops among the neurons that were first to migrate, namely the preplate neurons which become split into the molecular and subplate layers. The precise onset of spontaneous electrocortical activity in the human fetal brain is unclear but in preterm infants scalp EEG recordings show alternating bursts of activity and quiescence from around 24 weeks of gestation (Hellsström-Westas et al. 1991; Klebermass et al. 2006). Whether the time course and development of these EEG patterns in the preterm infant are similar to those in the gestational age-equivalent fetus remains unclear. Modulation of these SAT by peripheral sensory stimulation acting through thalamocortical connections plays a putative role in the linking of the subplate to the cortex at around 28 weeks gestation (Price et al. 2006). Hereafter, the SAT evolve through several stages, increasing initially over the sensory cortices after which they generalise. At ~30 weeks gestational age interhemispheric synchrony of the SAT is inconsistent and might be mediated by brainstem centres. After 34 weeks gestational age increasing SAT synchrony develops as callosal connectivity advances, while in animals there is also intermittent activity at the brainstem level which may contribute to the synchrony, as evidenced by the coherence developing between heart rate variability and SATs in humans (Vanhatalo and Kaila 2006; Pfurtscheller et al. 2005): these discontinuous patterns become increasingly more continuous with maturation (Dreyfus-Brisac 1962; Lombroso 1985). Continuous activity becomes more established around term gestation as the thalamocortical fibres make their final cortical connections.

With development of inhibitory interneuronal circuits within the cortex higher frequency continuous multifrequency electrocortical activity develops. Such higher frequency activity in the beta and theta range is now known to be essential for ongoing development of cortical function (Buzsaki and Draguhn 2004; Steriade, 2006; Palva et al. 2005). SATs persist until term after which they may be pathological: the coupling of SAT bursts to changes in cerebral oxygenation suggest they are energy-dependent (Roche-Labarbe et al. 2007).

Cerebral Energetic and Vasoregulatory Development

Normal development of the fetal brain is critically dependent on an oxygen substrate supply capable of supporting the energy demands of the complex structural and functional maturational processes. Consequently, oxygen substrate deprivation is an important cause of fetal brain lesions, ranging from destructive injury to developmental disruption or substructural disturbances in programming.

Development of the fetal brain circulation: At 4 weeks p/c, after the neural tube closes, a primordial system of endothelium-lined vascular channels is in place and by the end of the first trimester the cerebral hemispheres are covered by an extensive mesh of leptomeningeal arteries. Subsequent cerebral vascular development is tightly coupled to regional parenchymal maturation. Arterial development is largely complete in the brainstem and cerebellum by 24 weeks gestation and in the basal ganglia and diencephalon by 28 weeks. During the third trimester rapid development of the cerebral hemispheres, in particular the cortex, is associated with major changes in the hemispheric vasculature. From the original simple vascular plexus extensive anastomoses develop covering the cerebral surface. Large penetrator arteries develop at the base of the brain to supply the basal ganglia, diencephalon and periventricular germinal matrix. From the cerebral convexity thinner penetrating vessels descend into the hemispheres: by 24 weeks of gestation, when the major phase of cerebral neuronal migration has been completed, these thin penetrators extend from the pial surface into the periventricular regions. Between 24 and 28 weeks shorter penetrators rapidly develop to support the period of intense cortical organisation, axonal outgrowth and synapse formation. Cerebral vascular density increases during gestation (Ballabh et al. 2004): angiogenesis increases rapidly in the cerebral cortex after 26 weeks and by 35 weeks has reached adult levels of vessel density and diameter (Mito et al. 1991).

Energy metabolism in the immature brain: Cerebral energy metabolism in the human fetus remains poorly understood largely because of inaccessibility to available measurement techniques. Current knowledge is limited to inferences from animal studies and studies of the preterm born human (Kinnala et al. 1996; Powers et al. 1998; Altman et al. 1993; Altman et al. 1988) both sources with questionable applicability to the human fetus. A number of factors have perpetuated the misperception that anaerobic glycolysis is the major
energy source for fetal cerebral metabolism. First, the fetus is hypoxemic in terms of both circulating free and bound oxygen with the partial pressure of oxygen in the umbilical vein (28–35mmHg) and artery (16–28mmHg) being significantly lower than in the postnatal circulation. At the same time the fetus has an oxygen demand two-fold that of an adult. Second, earlier studies suggested that energy synthesis through mitochondrial oxidative phosphorylation was less efficient in the immature brain (Murthy and Rappoport 1963). Third, the immature fetal brain is uniquely capable of using alternative energy substrates such as lactate and ketones during periods of glucose limitation (Stanley et al. 1979). However access to these alternative energy sources is but one part of a system of compensatory mechanisms (see below) to protect the immature brain during energy deprivation: although the immature brain is capable of using these alternative energy substrates (Hellman et al. 1982) aerobic glucose metabolism (with little or no lactate production) provides the principal energy support for the developing fetal brain. In fact, at no stage of fetal brain development is anaerobic glycolysis alone capable of meeting all energy requirements: although cerebral energy demand starts off low in early fetal life it escalates rapidly during the third trimester to support the function of enzymes such as Na/K-ATPase which are critical for maintaining electrocortical activity and the propagation of action potentials. With these escalating cerebral energy demands there is a concurrent increase in the number and functional capacity of cerebral mitochondria with increasingly efficient energy production (Murthy and Rappoport 1963).

A system of compensatory mechanisms maintains cerebral oxygen metabolism in the fetus. The fetus has an intrinsic system of compensatory mechanisms that enables it to tolerate moderate oxygen deprivation. This system coordinates responses mediated by a series of rapid neurally mediated cardiovascular reflexes and slower endocrine and behavioural responses aimed at both increasing oxygen/substrate supply to critical organs and decreasing oxygen metabolism. In fact, these fetal compensatory mechanisms normally maintain the fetus in a state of oxygen surplus (Martin, 2008; Bennet et al. 2003): understanding of these fetal responses to hypoxia is based largely on animal models, primarily fetal sheep and to a lesser extent from the preterm infant (or ex utero fetus). Fetal cardiovascular and metabolic autoregulatory systems are sufficiently developed even early in development to buffer against hypoxia for surprisingly long durations with little or no injury (Gunn et al. 2001; Gunn and Bennet 2008; Bennet et al. 2003). In fetal sheep adaptive circulatory responses to moderate hypoxemia can be maintained for prolonged periods as long as metabolic acidosis does not develop (Bocking et al. 1992; Richardson et al. 1989; Rurak et al. 1990a; Rurak et al. 1990b). In fact, in these animals global and cerebral oxygen metabolism fails only when the circulating pH falls below 7.0. In this manner intrapartum uterine contractions, which result in sharp decreases in maternal arterial supply of the placenta (Janbu and Nesheim, 1987) and therefore in repeated mild hypoxemia, are normally well tolerated (Modanlou et al. 1974; Huch et al. 1977; Wiberg et al. 2006).

During hypoxemia the fetus activates several endogenous compensatory responses to preserve fetal oxygen metabolism in critical tissues (including the heart and brain) by decreasing energy utilisation and increasing substrate supply (Boddy et al. 1974; Natale et al. 1981; Bocking and Harding 1986; Richardson, 1992; Richardson et al. 1992; Giussani et al. 1993). Initially, tissue oxygen delivery can be maintained by increasing oxygen extraction but when umbilical venous oxygen content falls below 50% of normal a series of hemodynamic responses is activated, known as circulatory centralisation (Wladimiroff et al. 1986) or brain sparing. These responses are mediated by neural (mainly adrenergic), circulating (catecholamines, serotonin, and angiotensin-II) and local mechanisms (e.g. nitric oxide, prostaglandins). Changes include increased shunting of oxygenated umbilical venous return

across the ductus venosus (Jensen et al. 1991; Bristow et al. 1983) and foramen ovale, as well as into the cerebral and coronary circulations (Peeters et al. 1979). In the systemic circulation hypoxemia triggers chemoreceptors which then activate a series of autonomic responses: these include a vagally mediated bradycardia (to decrease myocardial energy demand) and peripheral vasoconstriction to increase blood pressure mediated by neural and circulatory adrenergic stimulation (Peeters et al. 1979; Richardson et al. 1996). Maturation of fetal responses to hypoxemia has been best studied in ovine models, in which a moderate hypoxic insult elicits little or no fetal heart rate changes before 0.7 of gestation. Hereafter, hypoxemia triggers an initial bradycardia followed by mild tachycardia, a response that becomes increasingly robust over the remainder of pregnancy (Iwamoto et al. 1989; Matsuda et al. 1992; Fletcher et al. 2006). Although this sequential response to hypoxemia is interpreted as the emergence of autonmotically mediated responses to hypoxia at 0.7 of gestation, coincident with maturation of neurohormonal regulators and chemoreceptor function (Hanson 1997; Jensen 1996), it might also reflect the increasing oxygen demand toward the end of gestation (Shelley 1961; Szymanowicz et al. 1988; Wassink et al. 2007). Hypoxia-activated chemoreceptors are known to be functional in the normal fetus (Bennet et al. 2003) (Bartelds et al. 1993; Jensen and Hanson 1995) however, fetal reflex responses to hypoxia differ in several ways from the adult. For example, in the hypoxic fetus, rapidly acting, neurally mediated chemoreflexes suppress fetal breathing movements (Moore et al. 1989) and fetal heart rate: these cardiac decelerations are vagally mediated and presumably serve to decrease cardiac energy metabolism (Fletcher et al. 2006). The decrease in fetal heart rate reduces the cardiac output and blood pressure triggering sympathetically mediated vasoconstriction. This in turn restores blood pressure and diverts more oxygenated blood flow to the heart, adrenals and brain. If hypoxemia persists the slower activation of endocrine and paracrine endothelial responses follows (Martin 2008; Bennet et al. 2003): if hypoxemia remains moderate an accumulation of circulating catecholamines causes a gradual tachycardia, presumably to improve cardiac output. In this manner the moderately hypoxemic fetus is able to maintain normal oxygen delivery to vital organs for long periods of time (Bennet et al. 1998; Richardson et al. 1993).

Although most, if not all, intrinsic cerebral vasoregulatory (or autoregulatory) systems begin to develop during the fetal period, their efficiency is related to the maturational level of the fetus (Bilger and Nehlig 1993). During fetal hypoxemia there is not only a global increase in cerebral blood flow but also a redistribution of cerebral perfusion preferentially to those brain regions developing most actively at that particular gestational age (Cavazzuti and Duffy 1982). Initially the fetal brainstem has a particularly robust vasodilatory response; toward term this capacity develops in the thalamus and basal ganglia as well as regions of the cortex (Tolcos et al. 2003). If hypoxemia is sustained oxygen utilisation in the fetal brain is actively suppressed, ‘powering down’ neuronal activity, slowing the EEG and decreasing fetal movements. The adenosine triphosphate (ATP) breakdown product, adenosine, accumulates during hypoxia and plays a prominent role in the cerebral cellular and vascular responses to sustained hypoxia. Specifically, adenosine activates vascular A2 receptors causing regional cerebral vasodilation, increasing perfusion and oxygen delivery (Blood et al. 2002). Adenosine also stimulates presynaptic A1 receptors inhibiting synaptic transmission and decreasing cerebral metabolism and oxygen demand (Blood et al. 2003).

In chronic hypoxic conditions cerebral cellular metabolism is downregulated and there is an increased production and secretion of vascular growth factors, including vascular endothelial growth factor (VEGF) (Martin et al. 1998) and hypoxia-inducible factors (HIF) (LaManna et al. 1992) leading to increased capillary density.

**DEVELOPMENT OF FETAL MOVEMENTS AND BEHAVIOUR**

The study of fetal movements goes back to observations made almost two centuries ago on aborted fetuses. In 1837 Erbikam described his observations of fetal movements after spontaneous miscarriages (Erbikam 1837). In the 1930s the Pittsburgh anatomist Davenport Hooker studied and filmed the activity of human fetuses from clinically indicated surgical abortions (Wilson 2014). For many years there was debate about whether these fetal movements were spontaneous or evoked, such as in 1952 when Hooker proposed that fetal movement was ‘a spontaneous reflex for which the stimulus is not yet known’ (Wilson 2014). More recently our understanding of the maturational trajectory of fetal activity and behaviour has accelerated for several reasons. First, the advances in survival of increasingly preterm infants has provided a window on these evolving patterns. Second, advances in fetal imaging, both ultrasound and more recently MRI, have allowed the characterisation of spontaneous and reflex fetal movements, behavioural patterns and state changes (de Vries and Fong 2006). Fetal motor activity starts early and develops into a complex repertoire of movements and behavioural states. Fetal movements depend on the gestational age and amount of intrauterine space available: these are therefore more pronounced in younger fetuses and polyhydramnios.

Fetal movements start at 7 weeks p/c as slow sideways bending of the fetal axis, coincident with the rapid development of synapses in the cervical cord. Breathing movements, initially irregular, are seen with movement of the diaphragm from around 8 to 12 weeks p/c and reflect cervical origin of the phrenic nerve. By 8–10 p/c weeks whole body movements, including the trunk and extremities, develop and may be either fast, explosive startles or slower, more complex movements (‘general movements’) (Prechtl et al. 1979) that include rotation. General movements are fluent, becoming increasingly complex and variable in speed and range until the late second–early third trimester, after which they decrease as term...
approaches: general movements persist until around 20 weeks postnatal when they are gradually replaced by purposeful movements. Manual exploration of the face with occasional thumb sucking is common between 14 and 20 weeks, decreasing thereafter. In the neurologically abnormal fetus these general movements become abrupt, fragmented, monotonous and repetitive, often more forceful and of greater amplitude. The initial simple movement patterns originate from spontaneous discharges in the spinal and brainstem circuitries. With development of descending, especially inhibitory, pathways from higher brain centres these spinal–brainstem activities become modulated into more complex and variable movements. Progressive organisation into complex and distinct behavioural patterns, reactivity and habituation to stimuli denotes supraspinal modulation of endogenous spinal–brainstem activity.

Around 20 weeks gestational age fetal activity becomes diurnal with peak movements in the evening accompanied by a diurnal variation in fetal heart rate. Fetal behaviours develop a periodic nature after midgestation in which periods of activity and quiescence alternate (Nijhuis et al. 1982; de Vries et al. 1985). Early diaphragmatic activity begins with frequent fetal hiccups that subsequently evolve to more rhythmic respiratory movements (Pillai and James 1990.) Over time the breathing movements become increasingly influenced by emerging behavioural states, diurnal variation, maternal glucose, hyperoxia and carbon dioxide levels (Baier et al. 1990). Breathing movements tend to be decreased in abnormal conditions like maternal substance abuse, smoking, oligohydramnios and fetal hypoxia. As term approaches fetal breathing movements normally decrease markedly.

By 28 weeks of gestation the topographic organisation of neural connections, particularly at the thalamocortical level, begins to allow the emergence of goal-directed behaviours. Such cerebral modulation of fetal behaviour can be demonstrated by the development of habituation to repeated stimuli. From around 36 weeks of gestation fetal behavioural states emerge, characterised by combinations of behavioural conditions that remain stable for periods of time. In addition, between 34–38 weeks of gestation major kicking movements decrease and are replaced by lower amplitude coordinated movements.

Fetal behavioural states begin to emerge toward the end of the second trimester, initially consisting of quiet sleep (rapid eye movements and mouthing) and active sleep (clusters of movements). The active awake state has a high level of kicking and a high heart rate.

**Placental Function**

**Placental Development and Support of the Fetal Brain**

An understanding of normal placental development and function is important for the understanding fetal brain development. Likewise, many of the acquired brain lesions in the fetus directly or indirectly involve the placenta. The placenta contains tissue of both fetal and maternal origin and is perfused by two circulations, the maternal uteroplacental circulation and the fetoplacental circulation. The main functional units of the placenta where most of the fetal-maternal exchange occurs are the terminal branches of the chorionic villi (Fig. 1.46), comprised of an outer syncytiotrophoblast layer (in direct contact with the maternal blood), an inner cytotrophoblast layer, a basement membrane and the endothelial cells of the fetal vessels. Nutrients, therefore, must cross from the syncytiotrophoblast through the fetal capillary endothelium to reach the fetal circulation. In these terminal villi the fetal and maternal (in the intervillous space) circulations are separated by a single tissue layer several cells thick, making them in essence functionally distinct (Wilkening et al. 1982). Although the primary determinant of fetal growth is placental nutrient transport the placenta has numerous other functions: these include anchoring the conceptus and integrating the embryo/fetus with the maternal circulation, suppressing immune rejection by the maternal system, synthesis of endocrine/growth factors, excreting waste products and epigenetic programming.

After implantation at 1 week post-conception the trophoblast develops into a multinucleated syncytiotrophoblast and mononucleated trophoblast. The trophoblast in turn develops down two pathways, the villous and extravillous trophoblast, both essential for successful implantation and placentation. The villous trophoblast is responsible for oxygen-nutrient transport and endocrine function while the extravillous trophoblast establishes the placental circulation by invading the endometrium and inner third of the myometrium, also transforming the maternal spiral arteries by breaking down the muscularis and remodelling the endothelium. In so doing the autonomic and local vasomotor responsiveness is lost, transforming the uteroplacental circulation into a dilated low resistance and poorly contractile system that is essentially pressure passive to the maternal systemic circulation. The lacunae between the syncytiotrophoblast and the decidua form the intervillous spaces will be perfused by maternal blood.

The relationship between oxygen and normal fetal/placental development remains complex, in part due to the maturational changes in fetal antioxidant systems. During placental development there is a delicate balance between pro- and antioxidant forces, when both low and high oxygen levels may impair placental development. At the same time reactive oxygen species also play an important role as second messenger systems in many normal signalling pathways and serve as critical intermediates of multiple homeostatic systems. During the first trimester a low oxygen environment is essential for normal placental implantation and development as well as for normal fetal organogenesis, angiogenesis and cell proliferation (Ottoesen et al. 2006): higher placental oxygen levels during the first trimester result in miscarriage and teratogenicity. Secretions of the endometrial glands provide early support of the fetoplacental unit and maternal circulatory support is not established until the end of the first trimester. At the start of the second trimester fetal growth accelerates with greater
demand for placental transport and protein synthesis. This is particularly true of the brain with rapid increase in mass, resulting from development of synaptic, dendritic and axonal elements in the cortical and subcortical grey matter. Concurrently there is an abrupt ‘oxygen transition’ with a three-fold increase in the fetoplacental oxygen content, together with a surge in antioxidant enzyme synthesis (Schneider 2011). After midgestation both placental circulations show an exponential increase in perfusion which occurs by different mechanisms. The uteroplacental blood flow increases up to five-fold as remodeling of uterine resistance vessels converts it into a high capacitance circulation while fetoplacental blood flow increases primarily through proliferation of arterioles in the terminal villi resulting in a low resistance system with a large surface area (Stuart et al. 1980; Trudinger et al. 1985). Fetoplacental vessels lack autonomic innervation with vasoregulation depending on local or circulating vasoactive substances (46–50) (Kiserud and Acharya 2004), such as the vasoconstrictors angiotensin-II, endothelin and prostanoids (54) and the vasodilator, nitric oxide. Catecholamines have minimal effect on the fetoplacental circulation: consequently the surge in catecholamines during fetal hypoxemia causes significant vasoconstriction in the fetal peripheral circulation but not in the fetoplacental, myocardial or cerebral circulations.

Transporter function, both nutritional and excretory, develops in the placenta utilising both active and passive transport systems. Nutrient transfer occurs by simple (e.g. glucose) or facilitated diffusion (e.g. amino acids) with placental functions regulated by an array of signals and channels. Insulin growth factors (especially IGF-1) are important regulators of placental nutrient transport. Glucose transport is strongly influenced by maternal glucose levels, the process being facilitated by at least six glucose transporters. Amino acid transport occurs through as many as 20 different transporters and results in fetal amino acid levels higher than maternal. Maternal lipoproteins are taken up by placental lipoprotein receptors.

In addition to transferring maternal molecules to the fetus the placenta is also able to synthesise critical substrates for brain development. The endocrine and metabolic roles of the placenta are complex. Hormones (hCG, hPL, oestrogen and progesterone) and growth factors are secreted by the syncytiotrophoblast layer of the chorionic villi and released into both the maternal and fetal circulations. Fetal brain synthesis of neurosteroids, potent agonists of GABA-A receptors, is particularly important for brain development and dependent on precursors produced by the placenta. One such neurosteroid is allopregnanolone, the levels of which are markedly elevated in the fetal brain particularly during the third trimester when it is thought to increase sleep in the normal fetus through a tonic suppression of fetal behavioural state. In animal models allopregnanolone increases sharply with acute hypoxic stress and acts as a neuroprotectant reducing apoptotic cell death especially in the hippocampus.
Around midgestation the placenta can synthesise serotonin (5-HT) from maternal substrates (Bonnin et al. 2011); 5-HT plays an important role in neuronal proliferation and axonal outgrowth at this time. The placental source of 5-HT is provided primarily to the forebrain in animal models. Deprivation of this source of 5-HT might underlie some of the emotional and psychiatric outcomes in patients affected by placental failure.

The normal placenta provides important barrier functions to a host of hazardous influences. Maternal stress has an increasingly apparent adverse impact on the developing fetus and especially the fetal brain (Bale et al. 2010) while excess exposure to catecholamines and glucocorticoids is harmful to the developing fetus (Meyer 1985). Two placental systems normally act as a functional placental barrier against maternal and fetal stress, namely the enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD-2) and norepinephrine transporter (NET). Glucocorticoids, which are normally important for fetal growth and development, have adverse fetal consequences when produced in excess (Hahn et al. 1999). The normal placenta regulates fetal glucocorticoid exposure through the enzyme 11β-HSD-2 (Krozowski et al. 1995) which inactivates cortisol to inert cortisone. Placental 11β-HSD-2 production increases with fetal maturation (Murphy and Clifton 2003) but both expression and activity are decreased by factors such as hypoxia, nutritional deprivation and sustained maternal stress. In placental failure attenuation of 11β-HSD-2 activity exposes the fetus to elevated levels of corticosteroids and leads to fetal growth restriction and programming for later disease.

The human placenta expresses norepinephrine transporters (NET) (Ramamoorthy et al. 1993) and other neurotransmitter transporters (Hayer-Zillgen et al. 2002). The fetus has a high production rate of catecholamines and placental catecholamine clearance is an important homeostatic function of the placenta (Bzoskie et al. 1995). Norepinephrine is a major catecholamine released during pregnancy, with the placental NET responsible for specific reuptake and fast termination of norepinephrine’s action after neuronal release: elevated norepinephrine levels may downregulate the placental expression of 11β-HSD-2 (Sarkar et al. 2001). Sustained high levels of norepinephrine may override the NET system, resulting in downregulation of placental 11β-HSD-2 and increased fetal exposure to cortisol. Blood levels of norepinephrine are particularly high in conditions such as pre-eclampsia (Manyonda et al. 1998) possibly because of a decrease in NET (Bottalico et al. 2004). In conditions of placental dysfunction decreases in NET may result in high norepinephrine levels and be associated with vasoconstriction (Bottalico et al. 2004) including in the umbilical vein.

The placenta serves other critical barrier functions including suppression of immune rejection of fetal tissue as well as a barrier against viruses, inflammation and autoimmune processes. The immune functions of the placenta are complicated but include immunological suppression of rejection as well as selective transfer of immune function to the fetus. For example, immunoglobulin G (IgG) is transferred from the maternal circulation to the fetus by 20–24 weeks while IgM transfer is blocked.

**ACQUIRED ENVIRONMENTAL INFLUENCES ON THE FETAL BRAIN**

The structural consequences of an insult to the developing brain are dependent not only on the nature and dose of the insult but also maturational timing. Maturational timing matters because the developing brain has specific periods of critical development and vulnerability, when an insult might have enhanced effects. A critical period is a unique and limited time window during which a specific developmental event must occur, with failure to do so having significant and permanent repercussions. A vulnerable period during normal development occurs when the fetal brain is particularly exposed to specific insults or when fetal defenses are lacking. Since critical periods often have increased cerebral energy demands they become vulnerable periods for insults involving cerebral energy deprivation. Intrauterine insults may elicit a broad range of responses in the fetal brain, with a corresponding wide range in the nature and emergence of clinical manifestations. The latency to onset of clinical manifestations following a fetal brain insult may extend across the lifespan and depends largely on the severity, developmental timing and chronicity of the fetal insult.

After mid-gestation, when cerebral energy substrate demands escalate, a system of compensatory mechanisms (discussed above) develops in the cerebral circulation that buffers the developing brain against transient perturbations in energy supply. Consequently, the fetal brain develops the capacity to respond to insult with a graded response. Low-intensity insults that are brief may trigger effective compensatory (homeostatic) responses that dampen or nullify the insult: these have brief adaptive value but no enduring effect on brain development or function. With more sustained chronic or repetitive low-level insults the fetus may successfully maintain trajectory of brain development through compensatory mechanisms (homeorhesis) that come at a cost, such as activation of epigenetic programming that results in later-emerging consequences such as autism and schizophrenia. More severe but non-destructive insults may cause obvious structural disruptions in brain development, sometimes grossly indistinguishable from primary dysgenetic lesions. Finally, severe insults, especially during critical/vulnerable periods, may be destructive with fetal demise or an obvious fetal/neonatal encephalopathy and features of injury on brain imaging. In summary, the response of the fetal brain to insult depends on the pathway through which the immature brain channels the insult, i.e. adaptive, disruptive or destructive. There are currently no techniques for distinguishing the insult thresholds responsible for activation of adaptive, homeorhetic, disruptive or destructive processes (Gluckman et al. 2005).

In the next section we consider important examples of insults to the fetal brain in the context of their maternal, placental or fetal origin.
Fetal Brain Insults of Maternal Origin

Changes in the maternal environment may result in changes in placental function with effects on the fetus (Bale et al. 2010). The primary mechanism is through changes in the expression of placental transporters that regulate the transfer of glucose, amino acids and vitamins. Maternal endocrine substances including glucocorticoids, insulin growth factors, insulin and leptin serve as intermediaries to effecting these changes.

Maternal diabetes mellitus: It has been known for some time that exposure to maternal hyperglycemia may have adverse effects on fetal organ development and function (Freinkel 1980). Gestational and pregestational diabetes mellitus complicate between 5–15% of all pregnancies, with the former usually developing during the third trimester after major organogenesis is complete. Conversely, pregestational diabetes mellitus, types 1 or 2, may result in periconceptional hyperglycemia if poorly controlled, with adverse consequences (Balsells et al. 2009). In fact, about 10% of infants born to pregestational diabetic mothers of either type have evidence of birth defects involving blastogenesis in the first 4 weeks post-conception. Higher levels of maternal haemoglobin A1c, a marker for poor glycemic control, have been positively associated with increasing rates of birth defects. The developing human nervous system is especially vulnerable to hyperglycemia, resulting in 15-fold increase in neurological malformations including anencephaly, holoprosencephaly and syntelecephaly as well as neural tube defects and the caudal regression syndrome (Farrell et al. 2002; Salbaum and Kappen 2011). Gestational diabetes on the other hand only slightly increases the rate of major malformations but significantly increases the risk of perinatal neurological complications resulting from macrosomia (obstructed labour, perinatal asphyxia and brachial plexus palsy) and glucose metabolic derangement (Castori 2013). In addition to these major disruptive and destructive lesions children born to diabetic mothers are at increased risk for neurological anomalies including impaired motor function, attentional issues, intellectual impairment and learning disabilities, as well as later schizophrenia (Van Lieshout and Voruganti 2008; Isohanni et al. 2001; Cannon et al. 2002; Kim-Cohen et al. 2003). A recent large retrospective study found that gestational diabetes mellitus diagnosed before 26 weeks gestation (but not pre-existing type 2 diabetes) was a significant independent predictor of subsequent autism in the offspring (Xiang et al. 2015).

There are likely to be several mechanisms underlying these neurological consequences of diabetes in the fetus. Hyperglycemia may activate a cascade of events that include chronic tissue hypoxia, oxidative stress and inflammation (Philips et al. 1984; Georgieff 2006). Poorly controlled maternal hyperglycemia may activate a cascade of events that include chronic tissue hypoxia, oxidative stress and inflammation (Philips et al. 1984; Georgieff 2006). Poorly controlled maternal diabetes mellitus increases oxidative stress because hyperglycemia depletes antioxidants and increases the generation of reactive oxygen species (Li et al. 2013). Oxidative stress alters placental endothelial function including nitric oxide and adenosine pathways which are critical to vasoregulation in the non-innervated placental circulation (Guzman-Gutierrez et al. 2014). Hyperglycemia also reduces fetal iron levels which may in turn disturb cortical development especially in hippocampal structure and function (Deregnier et al. 2000; Siddappa et al. 2004) as well as development of monoaminergic neurotransmitter systems (Beard et al. 2006; Lozoff and Georgieff 2006). Chronic tissue hypoxia is likely to be triggered by chronic elevated insulin levels which increases fetal oxygen metabolism beyond that which the placenta is able to sustain: in addition, maternal diabetes may be associated with vasculopathy resulting in fetal growth restriction (Moore 1997).

MATERNAL MALNUTRITION

For many years the primary focus of nutritional management of pregnancy was on the prevention of maternal nutritional deprivation. Classic studies (Barker and Clark 1997) of maternal starvation during the Dutch famine of 1944–45 and other disasters has formed the basis for understanding the role of epigenetic disorders in developmental programming that lead to chronic disorders such as later obesity, the metabolic

Fetal and Neonatal Neurology

Table 1.6  Prenatally-acquired destructive disorders of the fetus

| Localised or bilateral encephalomalacia due to congenital infections: toxoplasmosis, cytomegalovirus Herpes simplex or zoster |
| Trauma causing subdural or epidural haematoma in the fetus |
| Porencephalic cysts or other localised ischaemic lesions due to hypoxia-ischaemia, infection, strokes due to thrombophilic disorders, collagen vascular diseases in mother |
| Intracranial/intraventricular haemorrhage due to germinal matrix or choroid plexus haemorrhages |
| Periventricular leukomalacia due to infections or hypoxia-ischaemia |
| Periventricular haemorrhagic infarction due to localised venous thrombosis |
| Venous sinus thrombosis due to infections or dehydration |
| Allergic thrombocytopenia due to maternal anti-platelet antibodies |
| Haemorrhage due to clotting disorder such as haemophilia |
| Intracranial haemorrhage due to arteriovenous malformation, vein of Galen malformation, arterial aneurysms |
| Lesions in the subcortical white matter from metabolic disorders such as hypoglycemia, mitochondrial disorders |

---

Part I Fetal and Neonatal Neurology
syndrome and diabetes as well as neurological sequelae such as schizophrenia (Geddes et al. 1999; Eide et al. 2013), attention deficit disorder, and autism (Fattal-Valevski et al. 1999). The effects of maternal malnutrition on fetal brain development are mediated in part by decreased levels of 11β-HSD-2 and elevated fetal cortisol exposure. Animal studies suggest that during acute maternal nutritional deprivation a catabolic gene expression programme is activated in the placenta and under such conditions the placenta itself may be catabolised to provide critical energy and accretion substrate to the developing fetus (Broad and Keverne 2011) including critical structural substrates for development of the hypothalamus. In contrast to nutritional deprivation obesity has become the major nutritional problem in pregnancy in the United States and other developed countries. In fact, it is estimated that in the United States almost one-third of women in the reproductive age group are now obese (Hedley et al. 2004), meaning that the adverse fetal effects of maternal obesity are increasingly recognised.

Specific nutritional deficiencies such as folic acid and iron deficiency (Georgieff 2008) have been associated with specific neurological conditions and are discussed in greater detail elsewhere. Maternal folate deficiency is associated with neural tube defects, with folic acid a form of vitamin B9 and essential for multiple functions including fetal and placental growth. This has led to recommendations from the Food and Drug Association and the Centres for Disease Control in the United States for folic acid fortification of flour and folate supplementation for all women capable of pregnancy. Estimates of a reduction in neural tube defects since these recommendations have ranged from 26–50% although this number remains controversial: the picture may be clouded by a concomitant increase in obesity in recent years and the known association with neural tube defects (Ray et al. 2005).

**Exogenous Maternal Insults**

Several commonly prescribed medications may be associated with structural anomalies in fetal nervous system development. Alcohol intake during pregnancy may cause a complete or partial form of fetal alcohol syndrome which includes fetal growth restriction, microcephaly, specific facial anomalies as well as long-term neurodevelopmental impairments: there also appears to be a dose–effect relationship with no clear safe threshold. Since many of these children have few if any structural anomalies but clear alcohol-related neurobehavioural disorders (ARND; ‘behavioural teratogenesis’) the diagnosis has now been expanded to fetal alcohol spectrum disorders (FASD). Cocaine, a presynaptic blocker of monoaminergic neurotransmitter (dopamine, norepinephrine and serotonin) reuptake, causes elevated circulating catecholamine levels with elevated sympathetic tone which may particularly marked in the fetus (Padbury et al. 1986). Cocaine may interfere with multiple steps in normal brain development from neuronal proliferation to migration and cortical connectivity (Gressens et al. 1992). In addition, the destructive ischaemic and haemorrhagic brain lesions seen in some cocaine-exposed fetuses may result from the vasoconstrictive effects of cocaine. Through catecholaminergic effects cocaine may have the same generic effect as other forms of fetal stress (such as fetal growth restriction) which alters fetal developmental programming through epigenetic mechanisms. Cocaine down-regulates norepinephrine transporter (NET) in the placenta (Bzoskie et al. 1997) increasing circulating norepinephrine in the fetus, thereby downregulating 11β-HSD-2 (see above) and causing a chronic state of fetal hyper-cortisolism. Long-term follow-up of children exposed to cocaine in utero have shown a significantly lower burden of major neurodevelopmental disability than once feared (Frank et al. 2001); however follow-up studies have shown less striking but more prevalent disturbances in arousal, behavioural regulation and attention. These disturbances in behavioural regulation and executive function appear to be the major long-term consequences of prenatal cocaine exposure (Lester and Lagasse 2010). Methamphetamine has become the premier drug of abuse in many parts of the world. Like cocaine effects are largely mediated by increased catecholamine activity through excessive release of dopamine and serotonin and inhibition of monoamine re-uptake. The consequences of prenatal methamphetamine exposure are less well known but their effect on catecholamine metabolism would predict adverse effects on the development of neural connectivity. Methamphetamine is also known to have vasoconstrictive effects and in animal models causes a decrease in uteroplacental perfusion and fetal hypoxia (Stek et al. 1995). As with other drugs of abuse, polypharmacy and associated socioeconomic factors complicate the clear delineation of long-term methamphetamine effects on the fetal nervous system. Selective serotonin reuptake inhibitors (SSRIs) are the most commonly prescribed medications for the more than half million pregnant women with major depressive symptoms in the United States each year. SSRIs block the re-uptake of serotonin (5HT) by binding to the serotonin transporter, increasing circulating 5HT. With the growing understanding of the role played by serotonin in normal brain development there has been widespread concern for the long-term neurodevelopmental effects of these agents. Recent reports have not shown an increased risk of malformations after fetal SSRI exposure (Rahimi et al. 2006) although earlier studies did suggest an increase in cardiac malformations and pulmonary hypertension (Chambers et al. 1996): the vasoconstrictor effects of 5HT might underlie the transient decrease in uterine artery blood flow in animal models (Morrison et al. 2002). During the early postnatal period these infants may present with excessive irritability, tremors, insomnia, poor feeding and abnormal posturing (Kallen 2004): this behavioural phenotype is transient but the long-term outcome of these infants is unclear.

**Fetal Infections**

The impact of intrauterine infections and more specifically fetal encephalitis on long-term neurological outcome, including deafness and visual impairment, has been recognised for
some time. Some agents such as congenital rubella have been reduced to largely historical interest in countries with effective immunisation programmes but remain a problem in the developing world. With the advent of effective antiretroviral agents the maternal-fetal transmission of HIV has been significantly reduced (Read 2010). The rate of varicella developing in pregnant women ranges from <1 to 3 per 1000 and very few (<2%) deliver infants with congenital infections. Conversely, other agents such as lymphocytic choriomeningitis virus (LCMV) have been recognised only recently as hazards for the fetal brain. Although neonatal herpes simplex encephalitis is a devastating and potentially treatable disease with an incidence ranging from 0.025 to 0.3 per 1000 live births the vast majority of these are acquired during the birth process, with only 5–10% representing congenital infections (Kimberlin 2004).

The vast majority of congenital infections are acquired through the maternal circulation and placenta where infection may lead to placental inflammation, vasculitis and placental insufficiency, with risks of fetal demise, miscarriage and intrauterine growth restriction. Despite improved fetal imaging the majority of congenital CNS infections are detected in the neonatal period when the infant displays non-specific features such as jaundice, hepatosplenomegaly, rash, intrauterine growth retardation, microcephaly, hydrocephalus or chorioretinitis, some of which are not accessible during the fetal period. The neurologist may become involved when fetal imaging studies detect cerebral anomalies or more general fetal growth restriction. Features common to congenital encephalitis infections include periventricular hyperechogenicities, intracranial calcifications, cystic encephalomalacia, hydrocephalus or ex vacuo ventriculomegaly and periventricular leukomalacia. The structural effects and neurodevelopmental consequences of congenital encephalitis are determined by multiple factors including the infectious agent and the associated specific cellular tropism, maternal immunity and the timing of maternal infection. Less well understood are the genetically regulated factors that determine the maternal or fetal response to the infectious agent.

Broadly speaking, the imaging features of fetal encephalitis can be categorised as destructive or disruptive, often occurring in combination. Features of a destructive process include tissue loss, parenchymal calcifications and haemorrhage. Calcifications may occur in regions of cellular necrosis as a result of direct viral cytopotoxicity or vasculitis and are especially common in areas of rapid neuronal proliferation such as the periventricular regions. Disruptive lesions may closely resemble primary dysgenetic lesions and unless there are associated destructive lesions the distinction may be difficult. Although disruptive lesions such as cortical dysplasia, schizencephaly or polymicrogyria are likely to result from an interaction between the infection-inflammation and the underlying genetic programme the precise pathogenesis remains unclear. Intriguing similarities between the imaging and neuropathological features of congenital viral infections (especially CMV and LCMV) and rare familial disorders such as pseudoTORCH syndromes (Briggs et al. 2008; Abdel-Salam et al. 2008) suggest that much remains to be learned about the interplay of virus infections and the genes that determine the complex patterns of neural development.

**Cytomegalovirus** (Fig. 1.47) has become the most commonly recognised cause of fetal viral infection in most developed countries. During primary maternal infection the fetal transmission rate is around 50%. The rate of congenital infection by CMV in the United States and Europe is around 0.6% of all newborn infants, and of these about 20% will manifest symptoms either at birth (10%) or develop long-term sequelae such as hearing loss, cognitive deficits or motor impairment (Istas et al. 1995). Humans are the natural host and only reservoir for CMV affecting humans and transmission
is the result of direct contact through infected saliva, urine, semen or cervical secretions. Most maternal primary CMV infections are asymptomatic and if symptoms develop they may range from mild flu-like illness to a mononucleosis syndrome. Vertical transmission can occur at any time during gestation but the risk is highest during the first half of this period. Women who are seropositive for CMV pre-conceptually are less likely than seronegative women to give birth to infants with congenital CMV disease (Fowler et al. 2003). Specifically, pre-existing maternal immunity confers significant but not full protection against fetal transmission. Fetal transmission may still occur in about 1% of patients affected by fetal transmission through reactivation of the maternal infection (Stagno et al. 1982) or infection with a different strain of CMV (Boppana et al. 2001).

The diagnosis of fetal CMV encephalitis should be considered in patients affected by fetal microcephaly with specific fetal neuroimaging signs. Intracranial calcifications on antenatal US are a common presentation and present in about 50% of congenital CMV patients. Other imaging abnormalities associated with congenital CMV encephalitis include hydranencephaly and cerebral cortical malformations such as polymicrogyria, schizencephaly, pachygyria/lissencephaly and cortical dysplasia (Bale et al. 1985; Hayward et al. 1991) findings that suggest infection prior to the 20th week of gestation. Congenital CMV infection is commonly associated with cerebellar hypoplasia.

**Differential Diagnosis:** A number of fetal infections are associated with intracranial calcifications; however, the calcifications in congenital CMV are usually in a periventricular distribution. Although brain parenchymal calcifications in congenital toxoplasmosis (see below) tend to be more diffusely scattered this pattern can also be seen in CMV or LCM virus infections (Bonthius et al. 2007; Bale et al. 1985); the cerebral and cerebellar lesions in congenital CMV and LCMV may also be indistinguishable (Wright et al. 1997; Bonthius et al. 2007; Bale et al. 1985; Hayward et al. 1991). Congenital HSV infections may be associated with calcifications that typically involve the thalamus and basal ganglia (Hutto et al. 1987).

**Diagnosis:** If the pregnant mother is seropositive for CMV-specific IgM it is important to perform a CMV IgG avidity test. If the CMV IgG avidity is low it suggests an acute or recent infection. Avidity remains low for about 18–20 weeks after infection and if low before 18 weeks gestation the sensitivity for predicting a pregnancy at risk is very high (Lazzarotto et al. 2000). Conversely, if maternal CMV-specific IgG avidity is high during the first 12–16 weeks of pregnancy then there is low risk of fetal transmission. Amniotic fluid CMV polymerase chain reaction (PCR) testing has high sensitivity and specificity; however, the threshold viral load predictive of symptomatic fetal infection is not known. If the amniotic fluid CMV PCR is negative fetal infection is unlikely. While culture of CMV from the saliva or urine of an infant during the first three weeks of life remains the criterion standard for the diagnosis of congenital CMV disease congenital infection is established by detection of CMV-specific IgM in the serum of the infant or CMV nucleic acids in urine or saliva using PCR. Where fetal infection is suspected postnatal confirmation must be made within three weeks of birth.

**Prognosis:** Survivors of congenital CMV are at high risk of a broad spectrum of long-term, often debilitating neurodevelopmental sequelae including CP deafness, visual dysfunction, epilepsy and developmental delay/intellectual disability. Unsurprisingly, CMV encephalitis with earlier onset, which tends to be associated with neuronal migration defects, and those with intracranial calcifications are more likely to have severe adverse neurodevelopmental sequelae (Noyola et al. 2001). The acute neonatal presentation of this condition, including systemic abnormalities such as hepatosplenomegaly, thrombocytopenia and anemia, is discussed further in the section on neonatal neurology. Prior to the availability of ganciclovir about 80% of infants with symptomatic congenital CMV infections had permanent disability attributable to CMV infection (Pass et al. 1980) with at least 50% developing sensorineural hearing loss (unilateral or bilateral, mild to profound) and 10–20% developing chorioretinitis. In fact, CMV is currently the most common non-genetic cause of permanent hearing loss among children living in the United States and is responsible for 20–25% of all children suffering from hearing loss (Grosse et al. 2008; Fowler et al. 1997). A late onset form of progressive or fluctuating sensorineural hearing loss may develop in children with congenital CMV disease, even among infants without symptomatic CMV infection in the neonatal period (Fowler et al. 1997; Grosse et al. 2008). Epilepsy, often presenting as infantile spasms in the first year, may develop, especially with disruptions in brain development.

**Treatment:** Postnatal ganciclovir is likely to reduce the risk of permanent deafness but its effect on other neurodevelopmental outcomes remains uncertain. The development of an effective vaccine for eliminating congenital CMV disease has been remarkably slow. Furthermore, recent data suggesting the larger role for non-primary maternal infection makes the efficacy of vaccination questionable. At present neither the ACOG nor CDC recommend universal maternal screening for seropositivity for several reasons. First, maternal seropositivity does not rule out fetal infection: in the United States about two-thirds of patients with congenital CMV and the vast majority in resource-limited settings are born to women with preconceptional seropositivity (Manicklal et al. 2013; Wang et al. 2011), presumably because of reactivation or primary infection with a different CMV strain. Second, diagnosis of fetal infection does not predict symptomatic disease or sequelae. Third, there is no preventive therapy currently established, with antenatal treatment options limited: ganciclovir cannot be used during pregnancy because of mutagenicity. Early phase data from an non-randomised study of intravenous CMV hyperimmunoglobulin in pregnant women with CMV positive amniotic fluid (Nigro et al. 2005) suggested a significant benefit. However, a subsequent
Stage 2 randomised clinical trial failed to replicate these results, possibly because it was underpowered (Revello et al. 2014). The results of two Phase 3 randomised clinical trials currently being performed in the United States and Europe are awaited, while the efficacy of intrapartum hyperimmune IgG as a potential treatment to prevent transmission of CMV from mother to fetus remains unresolved. Postnatal therapy with ganciclovir for 6 weeks is associated with improved hearing outcomes in congenitally infected infants (Kimberlin et al. 2003). Valganciclovir is a pro-drug of ganciclovir which is rapidly converted to ganciclovir on absorption and reduces the fetal viral load (Kimberlin et al. 2015). In the infected newborn infant it appears to deliver more reliable and consistent blood levels of ganciclovir than does the intravenous form. Several modifications to the current standard protocol for postnatal treatment are under consideration and discussed in more detail in Chapter 11 on Infectious Diseases.

Congenital Toxoplasmosis (Fig. 1.48) is currently the second most commonly recognised congenital infection but is approximately 10-fold less common than congenital CMV. Toxoplasma gondii is a ubiquitous protozoal parasite known to infect mammals, especially felines (domestic cats) and birds. Human infection occurs through ingestion of food (usually meats) contaminated by the cysts or oocysts. Maternal symptoms may be mild or absent but if present the most common presentation is lymphadenopathy sometimes with fever, resembling infectious mononucleosis. The rate of congenital infection ranges from 0.1–1.0/1000 live births, being particularly high in France. The majority of infected infants do not show symptoms at birth, with infection blood-borne from the mother to the placenta where an infection is set up and from where the parasite enters the fetal circulation. Transmission to the fetus is dependent on the timing of maternal infection during pregnancy. If maternal infection occurs during the first 10 weeks of pregnancy the rate of fetal infection is very low. After 15 weeks gestation the transmission rate rises rapidly and may be as high as 80% if the mother becomes infected in the last weeks of pregnancy. Conversely, the risk of severe congenital infection is highest between 10 and 24 weeks gestation, decreasing to term when the overall risk of infection is high but the severity mild. The net result of these opposing trends in incidence and severity is that the highest risk for early symptomatic congenital infection occurs when the mother seroconverts between 24 and 30 weeks of gestation (Dunn et al. 1999). Congenital toxoplasmosis is complicated by chorioretinitis in around 75% of infants and approximately 10% develop sensorineural hearing loss (compare to congenital CMV above) (Swisher et al. 1994). Major fetal growth restriction and preterm birth are uncommon, in unlike congenital CMV. Unlike CMV toxoplasmosis does not cause disruptions in fetal brain development, the neuropathology being mediated solely by inflammation and tissue destruction, including that caused by vasculitic thrombosis. The meningoencephalitis is often striking and multifocal, granulomatous in nature, with ocular involvement including microphthalmia and retinal scars that may resemble colobomas. Microcephaly is less common than in congenital CMV but when present implies major cerebral tissue destruction. Unlike congenital CMV macrocephaly, usually indicating hydrocephalus, commonly accompanies congenital toxoplasmosis. Intracranial calcifications are scattered throughout the brain with no regional predilection in most patients: some individuals show a basal ganglia and periventricular predominance. Calcifications may be nodular or curvilinear and a combination of the two is highly suggestive of toxoplasmosis: at autopsy the most
The common neuropathology finding is extensive parenchymal necrosis as a result of vascular involvement. These lesions are most concentrated in the cortex and basal ganglia where they may be cystic and calcified. Periventricular and periaqueductal vasculitis, leading to thrombosis and necrosis, is typical of toxoplasmosis. Lesions may rupture into the ventricular system where the high protein deposition and ependymitis (especially around the aqueduct) predispose to hydrocephalus. In some patients hydrocephalus due to aqueductal stenosis may be the only finding.

**Diagnostic testing:** The standard initial screening test is maternal serology for elevated toxoplasma-specific IgM. These titers may remain high for long periods and so ideally seroconversion or a rising titre can be demonstrated, while tests of IgG avidity are also helpful: diagnosis can be made rapidly by amniotic fluid PCR with a sensitivity of 80%. Postnatally, histological examination of the placenta will demonstrate the parasites.

**Management:** Shunting of obstructive hydrocephalus and extended courses of antitoxoplasma therapy using pyrimethamine and sulfadiazine may have a striking beneficial effect on the outcome of infants with congenital toxoplasmosis (Guerina et al. 1994; McLeod et al. 2006). In the pretreatment era more than 50% of infants with congenital toxoplasmosis developed long-term sequelae. Since the advent of postnatal treatment with pyrimethamine/sulfadiazine most infants with congenital toxoplasmosis have favourable outcomes with low risk of sensorineural hearing loss or new eye lesions due to T. gondii recrudescence (46).

**Lymphocytic choriomeningitis virus (LCMV)** is a rodent-borne arenavirus virus endemic in wild mice, the primary vector. Humans become infected through contact with infected aerosols or fomites (Sheinbergas 1976; Wright et al. 1997; Barton and Mets 2001): between 5–10% of adults in the United States are seropositive for LCMV (Bonthius et al. 2007). Although the incidence of congenital infection is presumed low congenital LCMV encephalitis is an under-recognised cause of fetal encephalitis (Bonthius, 2012; Anderson et al. 2014). The primary maternal infection is typically a mild-moderate ‘flu-like syndrome’ and most mothers of children with congenital LCMV recall an episode of fever, myalgias, malaise, pneumonitis and sometimes later an aseptic meningeal picture. The fetal infection is acquired vertically during the primary maternal infection, either transplacentally or less commonly, during birth. The effects in the fetus tend to be severe with miscarriages and fetal demise: the postnatal mortality exceeds one-third among pregnancy survivors. The LCMV is highly and selectively neurotrophic during the fetal period, especially to neuroblasts in the periventricular germinal matrices where it impairs the normally neuroproliferative activity and subsequent neuronal migration (Bonthius et al. 2002, 2007). The virus may also elicit a pronounced host-mediated inflammatory response with destructive changes resulting in subsequent areas of periventricular calcification and cysts (Fig. 1.49). Fetal LCMV infection affects only the brain and eyes causing often severe microcephaly, hydrocephalus and chorioretinitis (Wright et al. 1997; Bonthius et al. 2007). Chorioretinitis occurs in >90% of congenital LCMV infections while deafness is rare: obstructive hydrocephalus and macrocephaly may develop postnatally in infants with congenital LCMV infections (Larsen et al.
Part I  Fetal and Neonatal Neurology

1993), even in those born microcephalic. Congenital LCMV encephalitis causes cerebral and cerebellar atrophy (Fig. 1.49a) and neuronal migration disturbances, while fetal intracranial haemorrhage has also been reported (Anderson et al. 2014). As with other fetal insults the long-term manifestations are related to the gestational age at which the fetal infection is acquired (critical periods).

Diagnosis: Differentiating congenital LCMV encephalitis from that due to congenital toxoplasmosis and CMV infections may be difficult, however, the infection has several distinguishing features. Specifically, congenital LCMV infection has few if any significant extraneural findings with fetal growth restriction, rash, hepatosplenomegaly and thrombocytopenia rare: hydrops fetalis has been reported in several confirmed cases of fetal LCMV (Anderson et al. 2014; Meritet et al. 2009) with hearing loss uncommon but chorioretinitis virtually universal. The most sensitive test for recent maternal infection is an ELISA test for LCMV IgG and IGM, performed at the CDC (Lehmann-Grube et al. 1979; Enders et al. 1999). Amniocentesis with PCR testing for LCMV mRNA is useful but only during the period of viral shedding in the fetus (Cordey et al. 2011).

Treatment: No vaccine has been developed to date: ribavirin has been used to treat postnatal patients with variable success and with significant toxicity risk. Lavipiravir is an agent that has shown promise in cell culture studies but has not undergone clinical trial.

Zika Virus Associated Microcephaly

In 2015 an epidemic of Zika virus was reported in Central America and the Caribbean with some infants of infected mothers reported to have severe microcephaly (Mlakar et al. 2016; Fig. 1.50). Zika virus is an emerging mosquito-borne flavivirus originally isolated from monkeys in the Zika forest in Uganda in 1947. Many infected individuals have been reported in the Pacific Islands, Brazil and other areas of South America (Brasil et al. 2016). The infection causes dengue-like fever symptoms including fever, headache, arthralgia, myalgia and a maculopapular rash in adults,

Figure 1.50  Axial CT images of the heads of eight infants who were born with congenital microcephaly associated with intrauterine Zika Virus infection showing calcifications in band-like distributions (a, b and d) with isolated configurations (b, c, e and g), punctate configurations (b and e), and larger configurations (a, c, d and g) at the level of the corticomedullary junction (a, b, d) within the frontal, parietal, and temporal lobes, basal ganglia (c), and upper cervical spinal cord (g, arrow). In addition, there are visible signs of global cortical hypogyrarion (a–f and h), moderate to severe ventriculomegaly (a and c–f), severe global cerebellar hypoplasia (f), abnormal hypodensity of the supratentorial white matter (a, b, d and h) and encephalomalacic changes after ischaemic stroke in the vascular territory of the left middle cerebral artery (panel H, arrows). (Reproduced with permission from Hazin et al. Computed tomographic findings in microcephaly associated with Zika virus. N Engl J Med 2016; 374: 2193–5. Copyright Massachusetts Medical Society.)
while infants of infected mothers have been reported with microcephaly at birth (Hazin et al. 2016). One carefully evaluated individual was a 25-year-old young woman who had fever and rash at the end of the first trimester of pregnancy: a fetal ultrasound at 29 weeks revealed microcephaly with calcifications in the fetal brain and placenta. After the mother requested termination of pregnancy a fetal autopsy revealed microencephaly with complete agyria, multifocal dystrophic calcifications in the cortex and subcortical white matter and mild focal inflammation. The Zika virus was found in the fetal brain using reverse transcriptase-polymerase chain reaction (RT-PCR) and electron microscopy. Epidemiological evidence suggests that Zika virus associated microcephaly is emerging as a very important cause of fetal microcephaly in fetuses whose mothers live in or travel to areas where the Zika virus is endemic. A recent paper demonstrated that the Zika virus can infect human embryonic cortical neural progenitor cells in the laboratory, providing a potential mechanism by which the virus can damage the fetal brain (Tang et al. 2016).

**Fetal Brain Insults of Placental Origin**

The placenta has many different normal functions (discussed above), all of which are at risk when placental failure develops. The placenta is critical to fetal brain development from many different perspectives, including endocrine and growth factor trophic support, however the vast majority of work to date has focused on failure of placental respiratory function and nutrient supply, which forms the major focus in the section below.

**Placental Respiratory Failure**

Limitation of placental gas exchange by any mechanism may progress to placental respiratory failure or fetal asphyxia as evidenced by fetal hypoxemia and acidosis. Broadly speaking, potential mechanisms for placental respiratory failure may range from decreased utero-placental perfusion and/or oxygenation, increased diffusion distance at the villous membrane, decreased materno-fetal circulatory interface, decreased fetal oxygen carrying capacity (e.g. fetal anemia) and fetal circulatory anomalies. The fetus has a multifaceted system of compensatory responses (discussed above) activated by hypoxemia, however, these temporising responses are limited and eventually overwhelmed when hypoxemia becomes too severe, prolonged or repetitive (Mallard et al. 1992; Gunn et al. 1992). The threshold for fetal decompensation to hypoxemia can be breached by several different pathways, however, a common final pathway is the development of fetal acidaemia and haemodynamic compromise. When lactic acidosis reaches a critical threshold a cascade of events unfolds setting up the perfect storm for fetal brain injury. Specifically, circulating lactic acidosis paralyses catecholaminergic peripheral vasconstriction, causes myocardial dysfunction and abolishes cerebral autoregulation.

**Placental Ischaemic Disease**

The term placental ischaemic disease includes fetal growth restriction (FGR), placental abruption and pre-eclampsia. These conditions have a common causal origin, i.e. failure of normal placentation due to impaired trophoblast invasion. All three conditions also have a significantly increased rate of fetal and neonatal mortality and brain injury and long-term neurodevelopmental sequelae in survivors. Both placental abruption and pre-eclampsia may be complicated by FGR and the rate of adverse neurodevelopmental outcome increases for both these conditions when the fetus is also growth restricted (Ananth 2014). In placental ischaemic disease the risk of brain injury from impaired placentation function is further compounded by the significant risk of preterm birth and associated brain injury. In addition to spontaneous preterm birth the increased risk of fetal demise in all three of these conditions has increased the frequency of elective preterm delivery. In fact, these three forms of placental ischaemic disease together form the leading cause of preterm birth, accounting for well over half of preterm deliveries (Ananth and Vintzileos 2006): consequently, preterm birth related brain insults are likely to play an important role in the neurodevelopmental morbidity seen in survivors of placental ischaemic disease.

**Pre-eclampsia** is defined as the onset of hypertension, often rapidly progressive, and proteinuria after 20 weeks gestation in women without previous hypertension and proteinuria. Pre-eclampsia complicates at least 5–8% of all pregnancies worldwide, a number two-fold higher in developing countries (Sibai et al. 2005; Maynard et al. 2008). It is usually a disease of first pregnancy and other risks include in the antiphospholipid antibody syndrome (nine-fold increased risk), previous pre-eclampsia (five-fold increased risk) and diabetes (3-fold increased risk). Although the pathophysiology of pre-eclampsia remains poorly understood it is generally agreed a key step along the causative pathway is placental oxidative stress with the generation of pro-inflammatory cytokines and/or angiogenic factors that activate maternal endothelial cells. The fundamental mechanism of impaired fetal growth in pre-eclampsia is most likely fluctuating oxygenation rather than hypoxia alone: this in turn is mediated by deficient trophoblast invasion, with incomplete de-muscularisation of the spiral arteries leaving them susceptible to vasoactive influences. Consequently spontaneous constrictions in spiral arteries occur with fluctuations in utero-placental flow generating oxidative bursts into the placental circulation.

**Fetal growth restriction** (FGR) is broadly defined as failure of a fetus to achieve its inherent growth potential; however, it is difficult to establish this potential in the individual fetus. Consequently there have been multiple attempts to identify the best predictive measure. The first criterion currently used to diagnose FGR is an estimated fetal weight below the 10th centile. This definition identifies the small-for-gestational age (SGA) fetus which might be associated with a heterogeneous group of conditions including chromosomal anomalies, infection, maternal substance abuse, toxins, malnutrition and
constitutional small size. To establish the diagnosis of placental-based FGR additional criteria beyond SGA must be satisfied, including a fall-off in estimated fetal weight over time and/or other evidence of placental failure such as Doppler features of increased placental vascular resistance. It is well known from earlier studies using cord blood sampling that placenta-based FGR fetuses are at significant risk for hypoxemia, hypoglycemia, hypercapnea and acidosis, compared to normally growing fetuses (Soothill 1987; Economides 1991). The fundamental defect in FGR is reduction in terminal villous volume and surface area, a process that can start as early as the end of the first trimester. Similar to pre-villous volume and surface area, a process that can start as normally growing fetuses (Soothill 1987; Economides 1991).

The initial signs of this increased fetoplacental resistance are evidenced by reduced, absent or reversed end diastolic flow in the umbilical artery (Dubiel 2002). In the pre-terminal phase shortly preceding those in the MCA Doppler changes with decreases in ACA resistance may not be reliable. Other studies suggest anterior cerebral artery (ACA) Doppler may be a more sensitive biomarker than the MCA Doppler changes with decreases in ACA resistance preceding those in the MCA. Given that abnormal patterns in the ductus venosus herald imminent fetal demise more direct and sensitive markers of myocardial impairment are being pursued (Benevides-Serralde et al. 2011). Power Doppler studies in FGR (Bartha 2009) have shown an early increase in frontal lobe perfusion, followed by a pronounced decrease which coincides with an increased perfusion to the deep grey matter structures (Hernandez-Andrade 2008). In the pre-terminal phase shortly before fetal demise MCA resistance may ‘normalise’ even though placental resistance remains high (Man 1991; Rizzo 1994; Weiner 1994; Mari and Deter 1992; Dubiel 2002): this paradoxical pseudo-normalisation occurs because of cardiac failure and decreased cardiac output, coinciding with central venous abnormalities. In some studies this ACA resistance remains decreased even after MCA-PI normalises, suggesting frontal lobe ‘sparing’ persists longest (Dubiel 2002).

Although a major factor in the consequences of FGR, placenta-based hypoxemia is one of many disturbances occurring in this progressive multisystem disorder. Significant impairment of placental amino acid transport develops even in the absence of significant hypoxemia, acidemia or Doppler changes. Glucose metabolism is disturbed and since gluconeogenesis is not an adaptive mechanism in FGR the fetus attempts to meet glucose requirements by increasing glucose...
transport. However despite this the growth-restricted fetus has reduced circulating glucose despite normal maternal levels, a difference that increases as FGR progresses. Placental failure also decreases the enzyme 11β-HSD-2, which normally inactivates noxious cortisone to inactive cortisone levels in the fetus. The hypoxemia associated with FGR increases erythropoietin release, thereby increasing the circulating red cell mass.

Management: Preterm FGR is a progressive disease for which there is currently no effective intervention besides delivery, often at the risk of preterm birth. The critical challenge in preterm FGR is the safe prolongation of pregnancy, the risks of prematurity being balanced against the risk of fetal demise when delivery is delayed. Term FGR presents in the third trimester and has subtler signs of deterioration with minimal or absent Doppler features. Here the major challenge is timely detection of FGR since failure to recognise term FGR may account for over 50% of unexplained still-births near term (Froen 2004). The optimal technique for detection of imminent demise (fetal heart rate, biophysical profile or Doppler) remains controversial.

Prognosis: FGR fetuses have an 8-fold higher perinatal mortality than appropriately grown fetuses. In addition a broad spectrum of neurodevelopmental sequelae may occur, from cerebral destructive injury to structural and functional developmental disruption, as well as adverse fetal programming that manifests with neuropsychiatric conditions later in life. Those neurological complications presenting early in fetal and neonatal life usually have abnormal brain imaging while those with later-onset presentation such as autism, attentional disturbances, learning differences and schizophrenia (Geddes 1999) usually have normal conventional brain imaging. More advanced quantitative MRI studies have provided in vivo evidence that FGR is associated with impaired brain development in the fetus, including reduced cerebral cortical volume (Tolsa 2004), reduced hippocampal volume (Lodygensky et al. 2008) and delayed white matter maturation (Huppi 2004) which may underlie the high rate of cognitive and memory dysfunction in these fetuses (Huppi 2004). Even though preterm FGR with abnormal umbilical artery Doppler studies is the less common form of the neurodevelopmental morbidity described has been from this group. However, even with normal umbilical artery Doppler measures FGR may be associated with abnormal neurodevelopmental outcomes (Sanz-Cortes et al. 2010; Figueras et al. 2008; Figueras et al. 2009; Leitner et al. 2007): in these fetuses magnetic resonance spectroscopy (MRS) and diffusion weighted imaging studies have shown important microstructural and metabolic differences from control AGA fetuses (Sanz-Cortes et al. 2010). Neonatal complications in FGR infants born closer to term include an increased risk of perinatal asphyxia, neonatal encephalopathy and seizures. However, neonatal outcomes are still primarily determined by effect of preterm birth, with the impact of preterm birth overriding that of deteriorating fetal status until the late second trimester (Thornton et al. 2004).

Twin pregnancies and fetal brain injury
Twin pregnancies are associated with increased mortality and morbidity, including neurological impairment, especially true for monochorionic twins who share a single placenta. Potential mechanisms of fetal brain injury in monochorionic twins are hypoxemia, ischaemia, cardiac failure, anaemia-polyhydramnios as well as, in survivors of twin demise, embolic complications, vaso-occlusive injury and inflammatory injury (Blair and Nelson 2015; Hoffmann et al. 2013; Lopriore et al. 2013; Hack et al. 2008).

Monochorionic twin pregnancies are at significant risk of fetal complications including selective fetal growth restriction, twin-twin transfusion syndrome and twin anemia polyhydramnios sequence, all of which are associated with neurological sequelae in survivors. Factors that determine the risk for and type of complication in each individual include unequal placental sharing and unbalanced vascular anastomotic blood flow. Vascular anastomoses are almost universally present between the two fetuses and may be arterio-arterial (A-A), arterio-venous (A-VA) or veno-venous (V-VA). Their number, size and flow direction varies significantly between monochorionic placentas. The direction of blood flow across these anastomoses can change, as resistances and pressures in the two circulations alter, with the anastomoses usually acting to balance out perfusion between monochorionic twins. Arteriovenous anastomoses are deep and unidirectional with a single cotyledon perfused by an artery of one twin and drained by a vein of the other twin. Both A-AA and V-VA are superficial and can direct blood in either direction, playing an important compensatory role when there are imbalances in volume or pressure in one fetus. The risk of fetal brain injury increases significantly if there is co-twin demise, but can occur even if both twins survive (Szymonowicz et al. 1986; Enbom 1985; Saunders et al. 1992; Bejar et al. 1990; Grafe 1993). Brain injury in the surviving twin is mediated primarily by the acute blood volume overload when the co-twin dies: necrotic thromboembolism or disseminated intravascular coagulation triggered by tissue thromboplastin from the dead twin may exacerbate injury.

Selective Fetal Growth Restriction (sFGR) in monochorionic twins develops in 11–14% of such pregnancies. The diagnosis of sFGR is made when the smaller twin is below the 10th centile for expected gestational age (Vályi et al. 2010). The primary determinant of fetal growth in sFGR is the proportion of placental exchange surface available to each fetus and the efficacy with which shared collateral vessels act to compensate
for any discrepancy. Multiple collaterals and larger intertwin blood flow exchange tend to lead to better outcomes than those with few connections. The placental arterial anastomoses of such individuals are large and even a brief transient period of haemodynamic imbalance such as bradycardia or hypotension in the smaller twin may cause it to experience lethal volume overload, with hypovolemia and cerebral hypoperfusion in the larger twin. Compared to other forms of mono- or dichorionic twin pregnancy the incidence of fetal demise (20%) and cerebral white matter injury is significantly higher in sFGR twins. After demise of a smaller twin mortality of the larger twin increases to 25–30% while up to 30% of survivors sustain brain injury (Valsky et al. 2010). To date the best biomarker for management and prognosis in monochorionic twin pregnancies with sFGR is the uterine artery Doppler pattern in the sFGR twin where different patterns have been described and are reviewed in detail elsewhere (Gratacos et al. 2004b). The development of absent or reversed diastolic flow (AREDV) in the umbilical artery of the smaller twin, which occurs in 40% of sFGR patients, is an important risk factor for fetal demise and brain injury (Gratacos et al. 2004b). Importantly, this brain injury occurs significantly more in the larger twin even if the smaller twin survives: in fact, the incidence of brain injury in normally grown co-twins of sFGR twins with AREDV approaches 40% (Gratacos et al. 2004b). Other risk factors for brain injury in monochorionic twins with sFGR are the need for preterm delivery for many patients as well as the high risk of acute feto-fetal transfusions with brain injury in the larger twin (Gratacos et al. 2004a, 2007; Ishii et al. 2009).

**Twin-twin transfusion syndrome (TTTS)** complicates approximately 10–15% of all monochorionic twin pregnancies. Untreated TTTS has a perinatal mortality of over 80% (Lewi et al. 2008a, b; Denbow et al. 1998) with a 15–20% risk of neurological injury in survivors (Lopriore et al. 2007; Crombleholme 2012). Factors predisposing to this complication include evidence of circulatory disequilibrium between the twins and unidirectional flow in deep A-VA not countered by sufficient superficial A-AA (Denbow et al. 2000; Taylor et al. 2000). Superficial A-AA on the chorionic plate surface are a good biomarker for the development and severity of TTTS; absence of such A-AA confers a 78% risk of TTTS (Denbow et al. 2000). With loss of circulatory equilibrium the recipient twin develops hypervolemia, polyuria and polyhydramnios while the opposite features develop in the donor twin. The TTTS has a multisystem impact in the fetus, especially on the heart and kidneys: volume overload in the recipient leads to polyuria and polyhydramnios as well as myocardial hypertrophy, depressed myocardial function, abnormal venous Doppler measures and tricuspid regurgitation (TTTS cardiomyopathy), with fetal hydrops and demise ultimately occurring. The donor twin develops renal atrophy, a small heart and bladder, oliguria and oligohydramnios, which if especially severe can lead to a ‘stuck twin’ situation with amniotic membranes wrapped around the growth-restricted fetus.

**Management of TTTS** is guided by multilevel staging schemes of severity (Quintero et al. 1999; Villa et al. 2014). Current treatment options include conservative management through amnioreduction (percutaneous needle removal of amniotic fluid) to reduce polyhydramnios and the risk of preterm labour. More invasive approaches include fetoscopic laser surgery aimed at occluding anastomoses to improve circulatory balance or selective feticide by cord occlusion, usually of the recipient fetus. Review of previous studies show that after amnioreduction overall mortality ranges from 43% to 77% (Rossi and D’Addario 2008; Mari et al. 2001; Gray et al. 2006; Li et al. 2011a) with major neurodevelopmental impairment in 14–26% of survivors (Lopriore et al. 2003; Frusca et al. 2003). In a recent report survivors of TTTS treated with amnioreduction had neurodevelopmental impairment in 30% while cranial ultrasound abnormalities were present in over 50% (Li et al. 2011a). Conversely, mortality after fetoscopic laser surgery ranges from 38% to 81% (Rossi and D’Addario 2008), however, more recent advances in laser surgery in TTTS have been associated

Brain ischaemia can occur in the donor and circulatory overload and haemorrhage in the recipient.

Brain lesions are more common in the recipient than the donor twin and include:

- Hydranencephaly
- Parenencephaly
- Polymicrogyria or mild cortical thinning
- Bilateral or unilateral ventriculomegaly
- Germinal matrix haemorrhage
- Periventricular leukomalacia (PVL)
- Reduction in volume of cerebral cortex or cerebellum
- Cerebellar malformation including Dandy-Walker malformation

The development of absent or reversed diastolic flow (AREDV) in the umbilical artery of the smaller twin, which occurs in 40% of sFGR patients, is an important risk factor for fetal demise and brain injury (Gratacos et al. 2004b). Importantly, this brain injury occurs significantly more in the larger twin even if the smaller twin survives: in fact, the incidence of brain injury in normally grown co-twins of sFGR twins with AREDV approaches 40% (Gratacos et al. 2004b). Other risk factors for brain injury in monochorionic twins with sFGR are the need for preterm delivery for many patients as well as the high risk of acute feto-fetal transfusions with brain injury in the larger twin (Gratacos et al. 2004a, 2007; Ishii et al. 2009).
with improving survival and neurological outcome: in the largest reported study major neurodevelopmental impairment was seen in 18% of survivors at 2 years of age (Lopriore et al. 2009). Overall, the risk of adverse neurological outcome in TTTS is high regardless of treatment: this is related to the fetal haemodynamic and haematological imbalances (Haverkamp et al. 2001) and the risks of preterm birth (Lutthi et al. 2004) as well as low birthweight (Frusca et al. 2003). In fact, the outcome for TTTS appears vastly improved when both fetuses are born alive after 27 weeks (Mari et al. 2000, 2001). Therefore, the central goal for management of TTTS should be prolongation of pregnancy (Li et al. 2011a).

Twin Anaemia Polyhydramnios Sequence (TAPS) results when slow twin-twin blood transfusions occur through very small placental anastomoses in monochorionic twin pregnancies, either spontaneously or after laser therapy for TTTS. TAPS is characterised by large haemoglobin differences but no significant amniotic fluid differences. Severe brain injury and fetal demise may develop as a consequence of polycythaemia and hyperviscosity (Lopriore et al. 2013). In monochorionic twin pregnancies widely divergent peak systolic velocities on middle cerebral artery Doppler should suggest the diagnosis of TAPS, velocities being high in the anemic donor and low in the polycythaemic recipient.

Fetal Brain Insults of Fetal Origin

Fetomaternal haemorrhage with transfer of small amounts of fetal blood to the maternal circulation is likely to occur in most pregnancies. The neurological consequences for the fetus depend on the acuity and volumes of blood transferred. Fetomaternal haemorrhage results from disruption of the placental trophoblast and in most patients the aetiology remains unknown: a decrease or loss of fetal movements is the most common presentation (Giacosa 1997). Small amounts of transfusion are invoked in conditions such as alloimmunisation in Rh (–) mothers (with haemolysis, anemia and jaundice in the fetus) and alloimmune thrombocytopenia. Large transfusions, especially when acute, may result in fetal hypovolemia, neurological injury and fetal demise (Wylie 2010). Chronic fetomaternal haemorrhage may result in fetal anemia and decreased oxygen carrying capacity with subsequent end-organ injury, especially in the context of sudden superimposed stressors such as complicated labour. Chronic low-grade fetomaternal haemorrhage may lead to fetal anemia with a characteristic increase in the peak systolic Doppler velocity in the middle cerebral artery. The standard Kleihauer-Betke test has limitations but remains the first line diagnostic test: treatment of fetal anemia is complex and may require repeated percutaneous fetal blood transfusions.

Brain injury secondary to fetal malformations. Certain fetal malformations may lead to secondary fetal brain injury or developmental anomalies, especially conditions that cause disturbances in the fetal circulation and oxygenation. Certain cardiac malformations, most notably transposition of the great arteries and hypoplastic left heart syndrome, may be associated with hypoxemia and/or hypoperfusion of the fetal brain. Fetal imaging with Doppler and MRI studies have shown decreased cerebral vascular resistance (presumably compensatory) (Donofrio et al. 2003; Limperopoulos et al. 2010) as well as cerebral lactate (suggestive of anaerobic metabolism) (Limperopoulos et al. 2010) in these conditions. Over the course of the third trimester there is delay in sulcal-gyral development (Clouchoux et al. 2012a) and a fall-off in volumetric brain growth (Limperopoulos et al. 2010) in these fetuses. Large congenital diaphragmatic hernias may interfere with left ventricular function and impede cerebral venous drainage, thereby exposing the fetal brain to risk of hypoperfusion-hypoxia.

Progressive fetal hydrocephalus is a risk factor for acquired periventricular parenchymal injury due to either mechanical stress on axons or impaired regional perfusion (Del Bigio et al. 1994; Guzzetta et al. 1995). In addition, certain vascular lesions may cause high output cardiac failure in the fetus with secondary effects on fetal cerebral perfusion: examples of such lesions are large, vascular sacrococcygeal teratomas and vein of Galen malformations.

The Intrapartum Period

Tolerance of Labour: Impaired exchange of critical substrates between the maternal and fetal circulations may occur during labour. The contractile forces of normal labour may interrupt, usually briefly, both uteroplacental and fetal placental circulations. Myometrial contractions compress uterine artery branches especially the spiral arteries, decreasing perfusion to the intervillous spaces, while increased intrauterine pressure may compress the umbilical vein and artery, especially after membranes are ruptured. By definition these decreases in perfusion impair materno-fetal gas exchange making labour an intrinsically asphyxiating process. The impact on the fetal brain from these systemic asphyxiating insults depends to a large extent on the integrity of compensatory mechanisms aimed at maintaining preferential cerebral supply of oxygen and nutrients (see above).

That the vast majority of fetuses survive the insults of labour apparently unscathed is due in large part to the adaptive haemodynamic responses activated during the transient fetal hypoxia associated with uterine contractions. The ability of the fetus to withstand the rigors of labour depends on both the integrity of these compensatory fetal responses as well as the nature of the asphyxial insult. In a small percentage of patients these adaptive fetal mechanisms are overwhelmed because of preceding placental and/or fetal compromise or dysfunctional labour or both (Low 1997). With collapse of these protective responses the fetus becomes exposed to brain insults and potential brain injury: the consequences of such insults range from transient neonatal encephalopathy to lifelong neurological complications (Volpe 2001) the most prevalent of which are CP epilepsy and cognitive impairment.

The importance of identifying the fetus likely to be intolerant of labour, or to identify when such intolerance develops...
during labour, relates to the importance of timely responses to prevent or limit brain injury as a consequence. A multitude of agents have shown neuroprotective efficacy in experimental models where the insult is timed and interventions can occur before, during or very soon after such insults; however, the vast majority of these agents have failed in human clinical trials. One important reason for this is our current inability to anticipate or detect brain insults within the therapeutic window of these neuroprotective agents.

The initial events during the development of intrapartum asphyxia are fetal hypoxemia and hypercarbia. These phenomena are normally transient, waxing and waning with contractions; however, if contractions are sustained, frequently repeated without ‘recovery’ or compensatory mechanisms compromised hypoxemia will lead to metabolic acidosis. Intrauterine asphyxia may be considered pathological when impaired materno-fetal gas exchange circulations leads to anaerobic cellular metabolism and the accumulation of lactate, ‘significant’ metabolic acidosis, causing eventual energy failure in the fetus. Although the criteria for diagnosing significant metabolic acidosis in fetal asphyxia remain an open debate the commonly used clinical threshold is an umbilical artery pH of 7.00 or below, with a base deficit above 12mmol/L (Low et al. 1997; Gilstrap et al. 1989; Goldaber et al. 1991; American College of Obstetricians and Gynecologists 2014). Although fetal asphyxia as defined by these clinical criteria complicates around 2% of births (Low 1997; Low et al. 1997) the insult is usually mild and the fetal impact minimal (Low 1997; Low et al. 1997). For reasons discussed below these diagnostic criteria for asphyxia are in isolation, at best, weak prognostic indicators of long-term neurological outcome (Ruth and Raivio 1988; Fee et al. 1990). In only about 0.4% of infants is the asphyxial insult severe enough to cause at least transient organ (including brain) dysfunction (Low 1997; Low et al. 1997) with only 0.1% of live births associated with asphyxial brain injury and irreversible neurological sequelae (Low et al. 2001).

Neither fetal asphyxia nor the ensuing brain in term infants the severity of neonatal encephalopathy after asphyxia is often predictive of later neurological disability, as described in the 2014 report of the American College of obstetricians and Gynecologists. Injury is mediated by a single mechanism: instead, the potential pathways leading to these pathological sequences are multiple (du Plessis and Johnston 1997; Johnston et al. 2001). What follows is a conceptual overview of the factors involved in the asphyxial insult, the adaptive responses of the fetus to preserve cerebral oxygenation and the consequences of eventual failure of these compensatory mechanisms.

Broadly speaking, fetal tissue hypoxia may result from reduced circulating arterial oxygen content (i.e. hypoxic-hypoxia or anemic-hypoxia) or inadequate tissue perfusion (ischaemic-hypoxia). These mechanisms may originate in the mother, the uteroplacental unit, the fetoplacental unit or the fetus itself. Maternal causes of fetal asphyxia include maternal hypotension or cardiac arrest, maternal pre-eclampsia or myometrial hypercontractility during labour. All these conditions cause a decrease in uterine perfusion, leading to ischaemic hypoxia in the placental intervillous spaces and ultimately hypoxic-hypoxia in the fetus (Brinkman et al. 1974). Placental causes of fetal asphyxia include placental abruption, placenta previa, vasa previa or feto-maternal haemorrhage, all of which may cause fetal hypovolemic cardiac failure and rapid ischaemic-hypoxia. Other causes, such as twin-to-twin transfusion in monochorionic twins, may result in more gradual fetal anemic hypoxia. Occlusion of a malpositioned umbilical cord may cause relatively brief but repeated insults during uterine contractions; conversely, nuchal entwining of the cord may cause prolonged, variable compression, while cord prolapse may cause severe and sustained compression. Fetal causes include anemia (e.g. Rh-incompatibility, parvovirus infection) leading to anemic-hypoxia or certain congenital malformations such as congenital heart disease, in which circulatory disturbances may result in cerebral hypoperfusion or hypoxemia.

**Cellular Mechanisms of Intrapartum Hypoxic–Ischaemic Cerebral Injury**

The overall oxygen demand of the immature brain is significantly lower than that of the mature brain (Altman et al. 1988; Altman et al. 1993). However, although the global cerebral oxygen demand is low regions of most active maturation at a particular gestational age have particularly high oxygen demands, necessary to support the activity of enzymes critical for neuronal development, such as those involved in ion homeostasis (e.g. Na K-ATPase) (Mishra et al. 1988) and oxidative metabolism (Chugani et al. 1987; Clark 1994). These regions of elevated oxygen metabolism are particularly vulnerable to hypoxia: during fetal asphyxia failure to satisfy these regional energy demands leads to the rapid depletion of available energy substrate and unleashes cellular processes of injury and the cell death cascade.

The excitatory neurotransmitter glutamate plays an essential role in normal brain development (Johnston et al. 2001; McDonald and Johnson 1990). Through action at specific receptors on the neuronal membrane glutamate is critical for maturational processes such as neuronal differentiation dendritic arborisation, synapse formation and plasticity. Normal activation of these glutamate receptors, particularly the N-methyl-D-aspartate (NMDA) receptors, triggers the highly regulated passage of calcium through the receptor ionophores, thereby providing critical trophic support for neuronal development. The normal control of calcium conductance through the ionophores of these NMDA receptors is dependent upon regulation of the neuronal membrane potential by energy-dependent ion pumps. In regions of particularly active neuronal development the glutamate system is ‘primed’ in several ways to facilitate the cytosolic calcium influx including a regional increase in glutamate receptor density and the enhanced calcium conductivity of these immature receptors.

When cerebral energy failure develops in fetal asphyxia the tight regulation of this glutamate system is lost, causing massive pre-synaptic glutamate release and decreased
glutamate reuptake: this results in toxic levels of glutamate accumulating in the synaptic cleft (Johnston et al. 1992; Riikonen et al. 1992). The combination of sustained glutamate receptor activation and neuronal membrane depolarisation maintains glutamate calcium channels open to a massive, uncontrolled influx of calcium into the neuronal cytosol where potentially lethal processes of cellular injury are activated. The dichotomous roles of glutamate in normal brain development and in ‘excitotoxic’ injury during hypoxia-ischaemia help to explain the distribution of brain injury in fetal asphyxia. Glucose metabolism plays a complex role in hypoxic-ischaemic brain injury. During the early phases of asphyxia failure of oxidative metabolism with a persistence of cerebral glucose supply activates glycolysis and lactate production. The accumulation of lactate during cerebral hypoxia-ischaemia has a biphasic effect on the immature brain: in animal models lactate accumulation has an initial beneficial effect in part because of the role as an alternative fuel source in the immature brain (Vannucci, Bruchlaker, et al. 1996) however in studies with sustained high levels of lactic acidosis, deleterious processes are initiated whether the levels of cerebral lactate developing during asphyxia remains controversial. Glucose is critical for the reuptake by astrogial cells of glutamate from the extracellular space. (Magistretti 1999) thus, hypoglycemia may trigger or exacerbate excitotoxic brain injury. During periods of prolonged asphyxia exhaustion of fetal hepatic glycogen stores may result in hypoglycemia: the resulting combination of energy failure (due to hypoxia and hypoglycemia) and accumulation of extracellular glutamate may lead to profound cerebral injury.

**Topographic Patterns of Brain Injury During Fetal Asphyxia:** Although the critical insult during fetal asphyxia, i.e. cerebral hypoperfusion, is typically generalised the topography of the resulting brain injury tends to be focal or regional. The regional distribution of brain injury is determined by many factors including gestational age (i.e. level of cerebral and vascular development) and the nature (intensity and duration) of the insult. The relationship between gestational age and the topography of brain injury is determined in large part by the regional differences in brain maturation (and thus regional differences in metabolism) at the time of insult. The specific regions of brain injury in turn determine the clinical picture of subsequent neurological deficits in survivors and although the relationship between insult, injury, and outcome remains only partially understood techniques such as brain MRI have provided important insights (discussed below).

At a tissue level two broad types of hypoxic–ischaemic brain injury can be distinguished in the asphyxiated newborn-infant, i.e. selective cellular injury and pancellular necrosis (infarction). In each infant the type of injury and the distribution of such are determined by factors such as the gestational age and the intensity, duration and number of insults. Although any cell type may be injured by hypoxia-ischaemia certain cell types are selectively vulnerable at different gestational ages. In the preterm fetus the immature premyelinating oligodendrocyte (Back et al. 2001) is particularly vulnerable to selective cellular injury while at term gestation selective cellular injury tends to be mainly neuronal although in regions of active myelination the mature oligodendrocyte is also vulnerable. The regional distribution of selective cellular injury (neuronal and oligodendrocyte) may be categorised into several broad patterns. At term, the most actively maturing (and therefore most vulnerable) neurons are in the basilar ganglia and thalamus, brainstem nuclei, hippocampus and regions of the neocortex, especially the peri-rolandic and visual cortices (Maller et al. 1998). Within the cortex neuronal injury is most severe in the deeper layers particularly in the depths of the sulci as discussed above, the vulnerability of these areas of intense regional maturation (Piggott 1993) relates to their high glutamate-receptor density and reactivity as well as the high metabolic demands of neuronal maturation and axon myelination.

The regional distribution of cerebral infarction that occurs during global cerebral hypoperfusion is also determined by the maturational state of the cerebral vasculature. These regions of infarction tend to develop in the watershed territories between the cerebral arterial end-zones. In the term infant the major watershed regions are in the end-zones between the anterior, middle and posterior cerebral artery territories of supply; consequently infarction develops in the parasagittal regions along the superolateral convexity of the cerebral hemispheres.

Perinatal asphyxia may also be complicated by vasocoective insults and infarction in the territories of arterial supply or venous drainage (see Chapter 2). Arterial occlusion or stroke is more common in the term infant and usually involves the middle cerebral arteries, particularly the left. Venous occlusion usually occurs in the dural veins most commonly in the posterior part of the superior sagittal sinus and less commonly in the surface cortical veins or deep venous system. Although any type of infarction is susceptible to haemorrhagic transformation this is more typical of venous infarction: these vasocoective injuries are discussed in detail elsewhere.

The other major determinant of the topography of brain injury in fetal asphyxia is the insult ‘dose’ which is in turn determined by the intensity and duration of the insult. The intensity of asphyxial insults may be divided broadly into partial or severe insults: prolonged partial insults at term tend to concentrate injury in the parasagittal watershed areas of cortex and subcortical white matter with relative sparing of the deep grey regions. This pattern of parasagittal cerebral injury has been well described in a term primate model of prolonged partial asphyxia.

With severe asphyxia the regional distribution of injury is determined by the duration of insult. Regardless of gestational age infants surviving prolonged and severe circulatory collapse (e.g. 20–30 minutes or more) develop diffuse rather than regional cerebral injury, with devastating neurological sequelae. Conversely, with severe insults of brief duration gestational age does influence the distribution of cerebral injury. At term such brief but severe insults tend to concentrate neuronal injury...
Fetal and Neonatal Neurology

Part I

in the basal ganglia, thalamus, hippocampus, sensorimotor cortex and white matter injury in the corticospinal tracts from the sensorimotor cortex to the internal capsule, as well as the optic radiations. Interestingly, in fetal sheep basal ganglia injury may also follow repeated brief insults while prolonged partial insults cause hippocampal injury. These neuropathologic patterns of injury were initially described at autopsy but can now be detected by neuroimaging studies, especially MRI.

FETAL NEURODIAGNOSTIC TECHNIQUES

Prenatal Screening Tests

As part of prenatal screening programmes maternal serum AFP performed between 16 and 18 weeks of gestation is used to screen for neural tube defects, from anencephaly to spina bifida. However, maternal serum alpha-fetoprotein may be falsely elevated in twin pregnancies, abdominal wall defects (omphalocele, gastroschisis) and duodenal atresia, as well as falsely decreased in insulin-dependent diabetes and maternal obesity. Amniotic fluid measures of AFP are highly sensitive for anencephaly and open neural tube defects and can be further enhanced by measures of acetylcholinesterase which is primarily neuronal in origin.

Prenatal Genetic Testing

Cytogenetic studies on fetal (amniocentesis) or chorionic villous sampling cells have been in practice for many years; however, advances in understanding of the genome and newer technologies have significantly increased the utility of this approach for establishing or confirming a specific genetic diagnosis. Indications for cytogenetic testing are several and the specific test may be determined by the phenotypic features on fetal imaging or the level of risk based on the maternal and family history. The earliest and still the most common indication for chromosomal studies is to exclude Down syndrome while the sampling of genetic material for cytogenetic studies may be achieved through amniocentesis, CVS and more recently cell-free fetal DNA from maternal blood. Full karyotype analysis remains the most common cytogenetic technique; however, karyotyping has limitations including long turnaround time, labour intensity and cost: the delayed diagnosis of 1 to 2 weeks is an issue if decisions about continuation of pregnancy need to be made urgently. Fluorescent in situ hybridisation (FISH) has a much faster turnaround (24–48 hours) and provides a provisional chromosome ‘count’ however definitive testing still requires formal karyotyping. The FISH technique can also be performed when specific chromosomal microdeletions are suspected on the basis of family history or phenotype. Microarray analysis is an extension of the FISH technique that allows more detailed examination of specific regions of the genome. The field of neurogenetics, in particular, has benefited enormously over the last decade from the large body of integrated genomic data linking brain malformations to specific gene loci: the advance in microarray-based testing, such as microarray-comparative genomic hybridisation, applied to the genome-wide study of specific neurogenetic disorders, have identified the submicroscopic chromosomal loci for many of these conditions. In addition, different genetic mutations may be associated with a specific malformation category but allow subtyping and more refined prediction of outcome: examples include the holoprosencephaly, lissencephaly and callosal agenesis spectra, all of which are discussed in more detail above.

Maternofetal trafficking and non-invasive fetal testing: Despite the commonly held belief that the maternal and fetal circulations are separate bidirectional cell trafficking occurs and fetal cells can be found in the maternal tissues and vice versa. Earlier the focus was on extracting DNA from nucleated fetal red blood cells but the number of intact fetal cells is markedly less than maternal cells, impeding this approach. The more recent focus on cell-free fetal DNA (cffDNA) in the circulation of the mother has created and exciting new non-invasive approach to fetal testing.

Circulating cell free DNA in the maternal serum contains both maternal and fetal components, with the fetal fraction increasing to as high as 50% with normal gestation (Ferres et al. 2014; Fan et al. 2012) and increasing further in conditions such as pre-eclampsia: cffDNA can also be amplified using polymerase chain reaction (PCR). Such cffDNA is now thought to arise primarily from placental trophoblastic cells and less so from fetal haematopoietic cells. This non-invasive prenatal testing approach has already entered the clinical arena although it is currently confined to testing for aneuploidy, (especially the trisomies) and sex in patients where sex-linked genetic syndromes are suspected (Ferres et al. 2014). Although cffDNA testing is not diagnostic for the aneuploides the very high specificity has already reduced the number of invasive procedures like amniocentesis or chorionic villus sampling, which are not without risk. This approach has exciting potential for more expanded testing in future, such as the study of fetal mRNA of placent al origin in the maternal circulation (Poon et al. 2000; Ng et al. 2003) and testing for duplications and microdeletions in conditions such as Prader-Willi/Angelman syndrome (15q11–q13), Miller-Dieker syndrome (17p13.3) and Di George syndrome (22q11.2). When specific chromosomal regions are of interest more focused or targeted sequencing allows more rapid and less costly analysis. Epigenetic changes describe the environmental effects on gene function, without changing the DNA sequence: these changes are heritable and affect gene expression by turning genes on or off. Of great interest is the potential to detect epigenetic markers, including DNA methylation, histone modifications and genomic imprinting, on the fragments of cffDNA. Fetal microRNA (miRNA) can also be detected in the maternal serum; miRNA are small non-coding RNA molecules which function in RNA silencing and...
post-transcriptional regulation of gene expression. A specific group of miRNAs called epi-miRNA can directly target the effectors of epigenetic mechanisms and alter gene expression. This approach holds great promise for the future ability to detect the impact of environmentally mediated phenotypic plasticity of not only the fetus but also the placenta as a result of influences such as stress, toxins, inflammation or conditions such as maternal diabetes or pre-eclampsia. Preliminary studies have suggested that hypoxia-induced fetal RNA transcripts in the maternal circulation can be quantified and that these correlate with fetal hypoxic status (Whitehead et al. 2013).

**FETAL NEUROIMAGING**

**Fetal Ultrasound Imaging**

Antenatal ultrasound revolutionised the field of fetal medicine over four decades ago. This prolonged experience with fetal ultrasound has provided a well-established body of normative biometric data, including measures of head circumference, biparietal diameter and ventricular size. Despite the more recent advent of MRI, fetal ultrasound remains the first-line screening modality choice for the fetal brain. Fetal ultrasound has undergone major advances in both image quality and application: imaging quality has improved significantly with development of high-frequency, three-dimensional transducers. Transvaginal fetal ultrasound has overcome some of the limitations of transabdominal ultrasound (see below). Fetal Doppler ultrasound has enabled evaluation of the fetal circulation including fetal cerebral haemodynamics, such as the autoregulatory ‘brain-sparing’ response to hypoxemia in fetal growth restriction and certain fetal heart lesions (Baschat et al. 2001; Donofrio et al. 2003). Three-dimensional ultrasound has many potential applications including volumetric measurements; however it is primarily used for determining the extent of craniofacial and skeletal disorders (Merz et al. 2012; Merz and Abramowicz, 2012; Chen et al. 2005; Cassart et al. 2007) as well as providing surface rendering of the fetus. Four-dimensional ultrasound is not widely used but has opened windows of opportunity for the real-time assessment of fetal movements and behaviour (Kurjak et al. 2012; Sato et al. 2014).

Standard screening protocols for the timing and level of fetal ultrasound vary regionally. First trimester fetal ultrasound is used to confirm the presence of a beating-heart fetus and establish gestational age. In addition first trimester ultrasound indices (e.g. the nuchal translucency) are part of a panel of routine screening measures which together with maternal biochemistry screening serve to identify risk for aneuploidies and major anomalies. In certain centres first trimester is being used to provide earlier diagnosis of specific conditions such as congenital heart disease (Persico et al. 2011; Johnson and Simpson 2007). Later, usually between 18 and 22 weeks when most major anomalies can be detected, a more detailed anatomic survey is performed: a normal first trimester ultrasound should not replace this 18–22 week anatomy scan. Ultrasound also forms part of integrated fetal testing panels such as the biophysical profile, used for monitoring high-risk pregnancies.

Antenatal testing by ultrasound includes Doppler measurements of blood flow impedance in the different tissue types. Doppler ultrasound is an important tool for following the progression of diseases such as fetal growth restriction and polyhydramnios. Both fetal ultrasound and Doppler are used in high-risk patients as part of the biophysical profile and non-stress testing.

**Fetal Brain MRI**

Because of superior soft tissue resolution MRI has become the principal tool for visualising brain structure. Adaptation of MRI to the fetal brain has played a major role in the advance of fetal neurology as a discipline: fetal MRI offers three-dimensional resolution, multiplanar imaging capabilities, large field of view and robust image quality. Overcoming the obvious challenges of imaging the fetus, particularly spontaneous fetal movements and maternal breathing, required development of ultrafast sequences that minimise motion artifact. The development of ultrafast T2-weighted sequences and improved MRI hardware enabled acquisition of single T2-weighted slices in less than one second, eliminating the need for sedation (Huisman et al. 2002; Glenn 2009). These sequences provide superb contrast between tissue and cerebrospinal fluid, especially useful for assessing cortical development (Levine 1996). T1-weighted inversion recovery and proton density sequences can be used to detect hyperintense lesions such as haemorrhage, lipoma, subependymal nodules or calcifications and myelination patterns (Girard et al. 2006a; Glenn 2009); however, T1-weighted images of the fetal brain are more difficult, especially before the end of the second trimester, primarily because of their longer acquisition times which makes them prone to motion artifact. This limitation reduces the ability to detect haemorrhage and calcification by fetal MRI. More recently, T2* sequences have been used to detect blood-breakdown products. Susceptibility-weighted MRI is sensitive to blood, blood products and calcification and, therefore, might provide important information about acquired disruptive aetiology. Diffusion weighted imaging using single-shot, echo-planar diffusion imaging can be acquired in less than 15–20 seconds and assist in identifying destructive brain lesions. Diffusion weighted imaging is used to identify focal areas of reduced or increased diffusion following acute ischaemic injury (Righini et al. 2003; Schneider et al. 2007; Schneider et al. 2009): in addition, fetal DWI has been used to identify delayed brain development and decreased microstructural organisation in high-risk groups such as small-for-gestational-age fetuses (Sanz-Cortes et al. 2010). Diffusion tensor imaging (DTI) assesses white matter microstructural architecture (Basser et al. 1994) by evaluating axonal/fibre formation and connectivity in the developing
Choline, which reflects membrane synthesis, degradation and indicator of cerebral cellular energy metabolism and

Brain (Huppi et al. 1998; Berman et al. 2005; Partridge et al. 2005; Bui et al. 2006; Anjari et al. 2007; Dubois et al. 2008; Huang 2010) however challenges related to fetal
tion have delayed the clinical application of fetal DTI. Proton MRS (1H-MRS) in the fetal brain is technically dif-

The ability of 1H-MRS to measure metabolic substrates has the potential to elucidate metabolic development of the fetal brain in vivo. For example, it provides semi-quantitative measures of N-acetyl aspartate (NAA), a neuroaxonal marker reflecting development of dendrites and synapses, oligodendrocyte proliferation and differentiation, creatine an indicator of cerebral cellular energy metabolism and choline, which reflects membrane synthesis, degradation and myelination. In addition, 1H-MRS can identify a lactate peak suggestive of anaerobic metabolism (Girard et al. 2006b; Limperopoulos and Clouchoux 2009), although this is debated.

As the principal diagnostic modality for detecting parenchymal brain lesions (both dysgenetic and acquired) in the fetus MRI plays a critical role in fetal counselling. In countries where pregnancy termination is legal the outer gestational age for these procedures is often around 22–24 weeks gestation. However many critical processes of brain and especially cortical development are far from complete at this stage, leaving uncertainty about suspected but subtle cortical anomalies. When fetal brain status is likely to impact on important inter-

Advanced Quantitative MRI techniques have become well-established tools for the study of the postnatal brain. Despite significant challenges of bringing some of these techn-

Three-dimensional volumetric MRI has been enabled by combined motion correction algorithms and 3-D reconstruction techniques developed specifically for fetal MRI (Rousseau et al. 2006; Jiang et al. 2007; Kim et al. 2010): this approach allows measurement of global and regional brain growth and provides previously unavailable in vivo fetal brain growth curves (Habas et al. 2010; Clouchoux et al. 2011; Rajagopal et al. 2011). Similarly, studies are providing the first description of gyral development in the human fetal brain during the critical period of rapid cortical development in the second and third trimester (Clouchoux et al. 2011; Habas et al. 2011).

Fetal brain MRI versus ultrasound, strengths and weaknesses. Fetal ultrasound and MRI techniques each have unique

Strengths and weaknesses and should be be used in a complementary manner when evaluating the fetal brain (Levine 2001; Levine 2002; Pugash et al. 2008). Fetal ultrasound is non-invasive, relatively inexpensive, easily repeatable and allows real-time exploration of the fetus, features that make it the preferred technique for monitoring change such as the size of lesions including fetal ventriculomegaly. However, although ultrasound will remain the screening modality of choice, MRI is the diagnostic modality when abnormalities are noted by ultrasound. Echogenicity increases at the interface between fluids and membranes: for this reason ultrasound may better detect thin structures such as the walls of cystic lesions (e.g. Blake’s pouch cysts, arachnoid cysts, choroid plexus cysts) than MRI. Ultrasound is also better at iden-

Fetal MRI is particularly valuable for delineating lamination of the cerebral mantle in the second trimester and gyral-sulcal development in the third trimester cerebral cortex. Between 20 and 28 weeks gestation the cortical mantle has a multilayered appearance on MRI (Girard and Raybaud 1992; Girard et al. 1995; Chong et al. 1996; Brisse et al. 1997; Kostovic et al. 2002; Garel et al. 2003; Garel 2004; Prayer et al. 2006) which represents the ventricular, periventricular, subventricular, intermediate and subplate zones, as well as cortical plate of the developing fetal brain (Kostovic et al. 2002; Rados et al. 2006). In the third trimester the emergence of sulci and gyri follows a consistent spatial and temporal programme. MRI best detects disturbances in cortical development (e.g. lissencephalies and polymicrogyria) (Glenn et al. 2005) as well as subependymal lesions (e.g. tubers, heterotopias and cysts). Bone attenuates the ultrasound signal causing acoustic shadowing which makes MRI superior for delineating posterior fossa structures, especially the vermis and brainstem. Furthermore, calcification of the calvarium in the third trimester and maternal pelvic bones obscures visualisation of the fetal brain by ultrasound (Glenn and Barkovich 2006): although adipose tissue degrades both ultrasound and MRI signals, the former is more compromised. These limitations can be reduced by transvaginal and high-frequency ultrasound transducers: as discussed above, fetal motion has been a major challenge for the advance of fetal MRI but not
for fetal ultrasound. Abnormalities in amniotic fluid volume present different challenges to the two techniques: the increased range of fetal movements makes motion artifact particularly challenging for MRI in patients affected by polyhydramnios, until the fetal head becomes stabilised by the maternal pelvis in late gestation. Conversely, oligohydramnios limits the resolution of ultrasound but not MRI, with contraindications to MRI including ferromagnetic implanted devices and certain tattoo materials, as well as maternal claustrophobia.

NON-INVASIVE TECHNIQUES FOR MONITORING FETAL HYPOXEMIA AND ACIDOSIS

Direct percutaneous needle sampling of fetal cord blood was performed more commonly in the past and provided valuable insights into the development of fetal hypoxemia and acidosis in conditions such as placental-based fetal growth restriction (Nicolaides et al. 1986). In recent years an integrated panel of non-invasive tests have largely replaced cord blood sampling in the monitoring of conditions at high risk for fetal compromise. The fetus can usually tolerate moderate chronic hypoxemia for long periods of time without collapse (Longo and Pearce 1991; Pearce 2006); however, chronic fetal hypoxemia increases the risk of fetal demise, intrapartum metabolic acidosis and long-term neurodevelopmental impairment. Antepartum hypoxemia reaches a critical risk threshold for catastrophic fetal decompensation and ultimately demise when fetal hypoxemia progresses to metabolic acidosis (Turan et al. 2008a, b; Manning 2009) Turan et al. 2008b; Manning 2009). ‘Significant’ fetal academia has been strongly associated with perinatal mortality and morbidity including neurological adverse outcomes. Early-onset FGR is associated with significant risk for preterm birth, both spontaneous or elective while preterm infants born acidic are at significantly higher risk of adverse neurological outcome and perinatal demise (Locatelli et al. 2010; Baschat et al. 2007). The panel of diagnostic modalities used to monitor these patients for signs of decompenation combines and integrates the strengths of fetal ultrasound, heart rate and Doppler ultrasound to obtain scores, such as the biophysical profile score (BPS).

Fetal heart rate analysis is used for the fetal non-stress test and is part of BPS. The fetal heart rate is used as a downstream surrogate for brainstem and hypothalamic autonomic systems of cardiovascular control, systems that are sensitive to hypoxemia (Baser et al. 1992). In current practice the FHR is assessed by visual inspection for baseline rate, accelerations and decelerations however these are influenced by a number of other factors including the maturational and behavioural state of the fetus. The non-stress test (NST) links fetal movements to heart rate accelerations and is one of the most sensitive tests for fetal hypoxemia. A normal NST must show at least two accelerations within 20 minutes as well as a normal fetal heart rate and variability: absence of accelerations is considered a non-reactive NST. Elsewhere, while a reactive NST is reassuring for the absence of fetal hypoxemia a non-reactive NST has poor specificity. Studies in fetal sheep have shown a progressive loss of FHR variability with increasing fetal acidemia, reflecting a loss of normal autonomic influence on the heart rhythm. A more detailed review of the basis for FHR testing can be found elsewhere (Bennet and Gunn 2009).

The biophysical profile (BPS) uses a multivariable approach assigning a score between zero and two points for each of five fetal variables with a maximally reassuring score of 10 points. The five modalities assessed are breathing movements, body movements, tone/posture, heart rate and variability and amniotic fluid assessment. A score of 8 or more is associated with a very low incidence of acidemia (pH<7.25) (Manning et al. 1993). Fetal breathing movements are suppressed early in the development of hypoxemia. Fetal tone is assessed largely by posture and only valid when there are at least some fetal movements during the study: absent fetal tone correlates strongly with fetal acidosis. During a BPS study fetal movements eliciting an acceleration of heart rate are reassuring whereas lack of accelerations or decelerations associated with fetal movements is considered non-reassuring.

Amniotic fluid volume decreases when circulatory centralisation in the hypoxic fetus leads to redistribution of perfusion away from the kidneys; however, the relationship with acidosis is not clear.

The fetal behavioural variables of fetal tone, movement and breathing activity are centrally mediated and can be studied by fetal ultrasound: progressive fetal hypoxemia and acidemia have fairly predictable effects on these behaviours (Ribbert et al. 1993). Fetal breathing movements decrease first but loss of gross body movements and tone are the most consistent predictor of fetal acidemia and usually cease at a pH around 7.10 (Vintzileos et al. 1991). The response of fetal behaviours to progressive hypoxemia appears to be hierarchical with FHR variability disappearing first, followed by respiratory activity and then loss of fetal movements.

Doppler ultrasound, which measures velocity and resistance of regional blood flow, has become a powerful technique for monitoring the progression of conditions such as placental failure and other conditions with fetal circulatory impact (e.g. fetal heart lesions). Doppler studies of the maternal uterine arteries are used to diagnose and monitor abnormal implantation (e.g. pre-eclampsia) in which failure of spiral artery conversion (see above) causes increased resistance evidenced by an abnormal diastolic ‘notch’. Changes in the fetal circulation are mediated by increasing resistance in the umbilico-placental circulation and the resulting hypoxemia-acidemia. Cardiac afterload and output of the ventricles are affected differently because of the parallel arrangement of the fetal circulation (Baschat 2003): changes in right ventricular afterload are measured by changing resistance in the umbilical or descending aorta, while changes in left ventricular afterload are detected in the
carotid or middle cerebral artery (MCA) resistance. Doppler measures of these changes allow assessment of circulatory redistribution.

These changes progress in a fairly predictable sequence through the different fetal vascular beds, starting with increasing umbilical artery resistance and followed by decreased middle cerebral artery resistance, the so-called ‘brain sparing’ effect described in 1986 by Wladimiroff (Wladimiroff et al. 1986). These resistance changes have opposite effects on the cardiac ventricles decreasing left ventricular afterload, while increasing right (systemic) ventricular afterload which manifests as reversal of flow across the aortic isthmus (Fournon et al. 1999). As right heart function deteriorates abnormal flow patterns appear in the fetal venous system, including preterminal development of abnormal ductus venous waveforms (Rizzo et al. 1992; Hecher et al. 1995). These late venous changes coincide with the loss of fetal heart rate variability (Hecher et al. 2001): the left ventricular output also increases with increasing peak systolic velocity (Mari et al. 2007; al-Ghazali et al. 1989). Finally, with development of myocardial compromise and tricuspid dysfunction two ominous signs of imminent fetal demise appear, namely a sudden decrease in the MCA peak systolic velocity and pseudo-normalisation of MCA resistance (Senat et al. 2000).

The MCA is widely used as the site for measuring cerebral resistance but this practice has been questioned. Brain perfusion changes may be regionally heterogeneous and change during the progressive hypoxemia of placental failure. Several authors have suggested that the anterior cerebral artery resistance may be more sensitive, showing earlier vasodilation (Figueroa-Diesel et al. 2007; Dubiel et al. 2002; Benavides-Serralde et al. 2011; Benavides-Serralde et al. 2010). In addition, evidence of abnormal brain development measured by fetal MRI and MRS has been described in growth restricted infants despite normal MCA Doppler measurements (Sanz-Cortes et al. 2010). Newer techniques such as 3D-power Doppler analysis give a more comprehensive assessment of the fetal cerebral circulation (Bartha et al. 2009; Chang et al. 2003) and in fetal growth restriction appears to be more sensitive than MCA resistance alone (Bartha et al. 2009).

During the period of circulatory compensation and redistribution, the opposite systemic and cerebral resistance changes may occur concurrently. For this reason a cerebroplacental ratio (CPR; the ratio of cerebral resistance divided by uterine artery resistance) has been developed to track the circulatory changes. Changes in CPR are thought to reflect both ‘forced centralisation’ because of increased placental resistance and hypoxemia-induced vasodilation in the MCA (Baschat et al. 2002; al-Ghazali et al. 1989). Animal studies show that CPR is more sensitive to acute hypoxemia and better predictor of adverse outcome than the individual MCA or uterine artery resistances (Harrington et al. 1999; Bahado-Singh et al. 1999).

THE FETAL NEUROLOGICAL EXAMINATION – A WORK IN PROGRESS

The inaccessibility of the fetus to conventional neurological examination was until recently a fundamental obstacle to the development of fetal neurology as a discipline. Advances in neonatal critical care over the past five decades have resulted in major decreases in mortality among extremely preterm infants born at the brink of viability. This in turn allowed direct observation and study of the nervous system over an ex utero period equivalent to the late second and third trimesters of pregnancy. Unfortunately, these advances in survival came at the expense of significant neurodevelopmental burden among survivors. Recognition of this growing population of neurodevelopmentally impaired ex-preterm children activated a major movement to understand preterm birth-related brain injury and contributed significantly to the development of neonatal neurology as its subspeciality. Although these extremely preterm infants encounter a significantly different milieu from that experienced by normal, thriving in-utero fetuses they have provided an unprecedented window for understanding the immature brain and a vulnerability to injury. The large body of clinical and laboratory data amassed over time has provided an invaluable platform for understanding the in utero structural and functional development of the fetal brain. Many of the tools that facilitated the advance of neonatal neurology, especially neuroimaging, have been adapted to provide unprecedented access to the fetal brain.

The neurologist now has increasingly powerful imaging tools with which to examine the structural development of the fetal nervous system. First, fetal ultrasound and more recently fetal MRI have allowed detection of lesions with increasing resolution. The emergence of quantitative MRI for the fetal brain promises to take imaging beyond ‘pattern recognition’ and subjective lesion detection to more precise continuous measures of brain development (Limperopoulos et al. 2010; Limperopoulos and Clouchoux 2009). These techniques will allow close monitoring of global and regional volumetric development, microarchitectural fibre tract development and cortical gyration patterns (Clouchoux et al. 2012a; Mitter et al. 2011). Likewise, MRS has the potential to track patterns of important fetal brain substances (such as choline, creatine and N-acetyl aspartate) as well as the emergence of lactate, a potential marker of anaerobic metabolism (Berger-Kulemann et al. 2012). Doppler ultrasound has long been used by obstetricians to monitor the fetal circulation and measurements of resistance in the middle cerebral arteries are now routinely used to detect fetal ‘brain sparing’ in situations with potential fetal hypoxemia or hypoperfusion (Baschat et al. 2001).

Evaluation of fetal neurological function is less advanced than imaging of the fetal CNS anatomy. Crude measures of neurological function in high-risk patients include fetal movement counts, the development of polyhydramnios and assessment of fetal ‘tone’ in the biophysical profile (Manning 2009).
Direct observation of fetal movements including facial, ocular, oral and breathing movements by 3D and 4D ultrasound permits a gross evaluation of fetal motor activity and behavioural state (Kurjak et al. 2005) but these techniques have not been widely incorporated into clinical practice. An important gap in our diagnostic armamentarium is the lack of a readily accessible technique for measuring electrocortical activity: a small number of centres have been able to record electrocortical activity from the maternal abdomen using fetal magnetoencephalography (Lowery et al. 2006) but at the present time this is an expensive, time-consuming and complex technique. Special frequency- and time-domain approaches to fetal heart rate variability may provide a window into the fetal autonomic system (Van Laar et al. 2008). For obvious reasons examination of the peripheral nervous system is currently not possible.

Resting state studies of fetal brain connectivity are being explored in research centres, based on the blood-oxygen-level dependent technique of MRI (Ferrazzi et al. 2014). Evoked responses have been used to test special senses in the fetus, including auditory evoked responses to a vibroacoustic stimulus as well as visual evoked responses to bright light projected across the abdomen of the mother (Lowery et al. 2006). An interesting approach to assess the fetal ability to mount an inhibitory influence from the cerebrum to the brainstem and spine is the testing for habituation during repeated sensory stimuli (Leader 1995): such tests require careful assessment of fetal behavioural state since this might significantly influence the results.

While there are major voids to be filled, particularly in evaluating neurological function in utero, these new insights and the advances in fetal diagnostics provide the neurologist with important tools to begin meaningful assessment of the fetal nervous system. This is done in close collaboration with fetal imaging specialists, obstetricians, perinatologists and fetal nervous system. This is done in close collaboration with the advances in fetal diagnostics provide the neurologist evaluating neurological function in utero, these new insights significantly influence the results.

Careful assessment of fetal behavioural state since this might significantly influence the results.

While there are major voids to be filled, particularly in evaluating neurological function in utero, these new insights and the advances in fetal diagnostics provide the neurologist with important tools to begin meaningful assessment of the fetal nervous system. This is done in close collaboration with fetal imaging specialists, obstetricians, perinatologists and geneticists among others: in some centres special fetal neuroradiology expertise has developed. Neurologists providing fetal counseling will need to develop an in-depth understanding of the normal and abnormal fetal milieu to include an understanding of maternal, placental and fetal conditions that may adversely affect the developing brain. Techniques previously developed by obstetricians and perinatologists to assess fetal well-being have included components that assess the fetal nervous system, as it is imperative that neurologists involved in fetal counseling become informed about the strengths and limitations of studies performed by the multidisciplinary fetal care team. Obstetricians in most developed countries perform routine screening tests at specific gestational ages, including the first trimester for accurate ultrasound dating of the pregnancy and to screen for aneuploidy and again toward midgestation when more detailed ‘anatomy’ ultrasound is performed. The technique of non-invasive prenatal testing performed on fetal genetic material obtained from the maternal circulation is in the early stages but has the potential to provide unprecedented insights into the genomic and epigenomic origins of fetal conditions. Tests for neural tube defects may be performed on maternal serum and confirmed by amniocentesis with tests of alpha-fetoprotein and cholinesterase levels: likewise, in patients affected by suspected fetal encephalitis special maternal serology studies, possibly followed by more direct testing in the amniotic fluid, may be performed. In high-risk pregnancies obstetricians and perinatologists utilise repeated tests such as the biophysical profile and the NST to monitor fetal well-being. The assimilation of this battery of neurodiagnostic techniques into the ‘toolbag’ of the neurologist permits not just the ability to counsel parents-to-be about diagnosis and prognosis but also allows for the development of rational plans for preventive brain-oriented care of the high-risk transitional period.

Neurological Diseases in the Perinatal Period

Miriam Martinez-Biarge and Linda S de Vries

This chapter deals with the period that extends from the onset of labour – covering abnormal intrapartum events – to the end of the neonatal period, conventionally limited to the first 28 days after birth. Most of the neurological problems of this period arise during the first 10 days after birth. Intracranial haemorrhages and hypoxia–ischaemia dominate the neurology of the perinatal period, although it must be emphasised that they do not account for all the neurological problems of this period and that their predominance should not lead one to miss other important diagnoses such as metabolic and neuromuscular diseases, which are discussed in Chapters 9 and Chapters 24–26 respectively.

The pre- and perinatal periods are nowadays more often considered as a continuum rather than two separate entities. Indeed, prenatal factors such as fetal growth restriction, prenatal hypoxia of whatever origin, prenatal inflammation and preterm birth all play a considerable role in the determination of many perinatal disorders. The response of the central nervous system (CNS) to the stress of the birth process and adaptation to extrauterine challenges are also important.

The two major pathological conditions encountered in the perinatal period – haemorrhage and hypoxia–ischaemia – are not totally separate entities. They often coexist, and they share some common causes and precipitating factors. However, other mechanisms such as mechanical trauma or coagulopathies can provoke haemorrhage without hypoxia, and the pathology and mechanisms are sufficiently different to warrant separate description.

INTRACRANIAL HAEMORRHAGE IN THE TERM INFANT

The epidemiology of intracranial haemorrhage (ICH) in the term infant has changed considerably over the past three decades. The incidence of traumatic haemorrhage, mainly subdural in location, has markedly decreased as a result of improvement in obstetric practices.

Some of these ICHs are related to a complicated and often assisted delivery. Using routine magnetic resonance imaging (MRI) in a group of asymptomatic infants, subdural and subarachnoid haemorrhages were, however, not an uncommon finding (Whitby et al. 2004). Intraparenchymal haemorrhage is also occasionally traumatic in origin (Brouwer et al. 2010) but this type of lesion has also been detected on antenatal imaging, in some cases related to alloimmune thrombocytopenia or a mutation in the COL4A1 gene (de Vries et al. 2009). Spontaneous intraparenchymal haemorrhage of unknown cause has also been reported (Sandberg et al. 2001 Cole et al 2017). Intraparenchymal haemorrhage, especially thalamic haemorrhage, may be due to cerebral sinovenous thrombosis (CSVT) in association with intraventricular haemorrhage (IVH) (Wu et al. 2003). A germinal matrix–IVH (GMH-IVH) in term infants is uncommon. There is some dispute about the site of origin (Pagano et al. 1990). Most consider that these haemorrhages originate from the choroid plexus.

SUBDURAL HAEMORRHAGE

Pathogenesis

Subdural haemorrhage may result from the following: a tentorial tear with rupture of the straight sinus or the vein of Galen, or smaller afferent veins; occipital osteodiastasis with damage to the occipital sinus or cerebellar veins; a tear of the falx with involvement of the inferior sagittal sinus; or injury to the bridging veins between either the convexity of the hemispheres and the superior sagittal sinus, or the transverse or sigmoid sinus and the base of the brain (Govaert 1993; Volpe 2008). In the first two situations, the haemorrhage occurs in the posterior fossa, whereas in the other patients it is supratentorial, located adjacent to the convexity in case of injury to the bridging veins and the hemispheric fissure in falx laceration, and at the base of the brain with rupture of the veins draining into the lateral sinus.
Towner et al. (1999) looked at the effect of the mode of delivery in nulliparous women on neonatal intracranial injury. Rupture of the veins is caused by excessive head moulding in vertex presentation or excessive traction on the head presenting last in a breech presentation (Pape and Wigglesworth 1979). Towner et al. (1999) found that the rate of ICH was higher among infants delivered by ventouse extraction, forceps or Caesarean section during labour than among infants delivered spontaneously, but the rate among infants delivered by Caesarean section before labour was not higher, suggesting that the common risk factor for haemorrhage is abnormal labour. Recent MRI studies have shown that, when MRI is used routinely in term infants, a subdural haemorrhage, which tends to be small, was noted as a common finding (Whitby et al. 2004). In a study by Looney et al. (2007) a symptomatic ICH was found in 26% of 97 neonates following vaginal birth and in a study by Rooks et al. (2008), 46 of 101 asymptomatic infants showed a subdural haemorrhage, which tended to be small. According to these two studies the subdural haemorrhages will resolve within 4 weeks' and all had resolved by 3 months. They occur mostly in the posterior fossa or over the occipital lobes near the tentorium. This is in contrast to infants with non-accidental injury, who have subdural haematomas that are generally located in the interhemispheric fissure or over the cerebral convexities. Retinal haemorrhages are also often seen (20%–40%) in newborn infants and red blood cells are often found in their cerebrospinal fluid (CSF), all suggestive of mild trauma after vaginal birth (Holden et al. 1999).

Clinical Manifestations of Subdural Haemorrhage

The clinical features are variable depending on the location and acuteness of the haemorrhage. In acute cases of posterior fossa haemorrhage, there can be massive bleeding with compression of vital brainstem structures, manifested by stupor or coma, nuchal rigidity, opisthotonus, eye deviation, bradycardia and apnoeic spells. Seizures occur in 36% of cases (Govaert 1993). A tense fontanelle, generalised hypotonia or hypertonia, skew eye deviation, facial palsy and unequal pupils may be observed. Of the 90 infants reviewed by Govaert (1993), a fatal outcome occurred in 15 unoperated and three operated cases. Sequelae include hydrocephalus, but outflow obstruction can be temporary and managed by insertion of a subcutaneous reservoir into the lateral ventricle. In subacute cases, the onset of neurological symptoms is delayed for 12 hours or more. Irritability, stupor, a bulging fontanelle and respiratory irregularities may suggest the diagnosis. Diagnosis by ultrasound is possible, provided that the collection is large enough. Computed tomography (CT) and especially MRI give a better definition of the size and exact localisation of the haematoma, and MRI will give the best appreciation of associated ischaemia (Govaert 1993; Sandberg et al. 2001). Surgical treatment is effective but adhesions may evolve with development of hydrocephalus, requiring shunt insertion. In a study by Blauwhonne et al. (2013), 11 of 16 infants required neurosurgical interventions, with nine presenting within the first 24 hours with symptoms of brainstem dysfunction. One should also consider performing percutaneous needle aspiration.
to relieve the midline shift caused by the subdural haemorrhage, which was successfully performed in five of seven infants who required surgical decompression of the clot (Vinchon et al. 2005). Successful needle aspiration was also performed in two infants with haemophilia A (Peyre et al. 2008).

Supratentorial haematoma of the convexity does not usually produce an immediate dramatic clinical picture. In typical patients, focal seizures or asymmetry in tone, or both, occur on the second or third day after birth (Sandberg et al. 2001). The occurrence of a third cranial nerve palsy manifested by a dilated, non-reactive pupil on the side of the haematoma is characteristic. Minor subdural haematomas over the convexity may give only minimal clinical signs (Whitby et al. 2004). In cases of a subdural haemorrhage, the CSF is usually bloody. Lumbar punctures should no longer be used for the diagnosis of ICH, in view of the different imaging techniques now available.

Basal subdural haemorrhage caused by lateral tentorial injury results in collection of blood underneath the temporal lobe and/or occipital lobes. Govaert (1993) reviewed 21 cases confirmed by CT, which presented in a similar way to convexity haematomas. Such instances are sometimes associated with arterial ischemic stroke caused by compression of the middle cerebral artery (Govaert et al. 1992a). Similar cases have been reported involving the posterior cerebral artery (van der Aa et al. 2013a).

**Neurodevelopmental Outcome**

Outcome data tend to involve cohorts with a combination of different types of haemorrhages (supra- and infratentorial, subdural and intraparenchymal). Data is limited and the children have often been assessed at a young age. Taking this into account, outcome has been reported to be better than expected (Jhawar et al. 2005; Brouwer et al. 2010). Jhawar et al. (2005) studied 66 infants and reported that, overall, 57% of infants had no physical or cognitive deficits at follow-up. The most favourable outcomes occurred among those with subdural haemorrhage (80% had no disability). Brouwer et al. (2010) studied 53 infants and reported a mortality rate of 25% and a cerebral palsy (CP) rate of 8.6% among survivors. Of the 34 survivors without CP (88.2%), however, 30 had an early normal neurodevelopmental outcome in spite of often large, intraparenchymal haemorrhages. In the study of Blauwblomme et al. (2013) only two infants required a ventriculoperitoneal shunt and, with a mean follow-up of 7.8 years, two of their 16 infants showed a mild developmental delay and 1 had severe developmental delay.

**INTRACEREBELLAR HAEOMRHRAGE**

Intracerebellar haemorrhage has many features in common with a subdural haematoma in the posterior fossa. Its mechanism is different and it seems to be related to hypoxia and ischaemia rather than to mechanical trauma, although it may be caused by occipital osteodiastasis or traumatic cerebellar injury (De Campo 1989). Neurological manifestations are generally overshadowed by symptoms and signs of hypoxia–ischaemia or respiratory distress. Apnoea, bradycardia and a fall in haematocrit are frequent features. Obstructive hydrocephalus is common even after surgical evacuation of the collection, and may be associated with the development of a cerebellar cyst communicating with the fourth ventricle (Huang and Shen 1991). Clinically, cerebellar dysfunction may be seen as sequelae (Williamson et al. 1985). Cerebellar haemorrhage has also been seen as a complication of extracorporeal membrane oxygenation (Bulas et al. 1991), coagulopathy and in some infants with organic acidurias (Dave et al. 1984) (Fig. 2.2).
has also been reported in uncomplicated vaginal deliveries (Sandberg et al. 2001; Brouwer et al. 2010). Clotting defects and especially neonatal allo- and rarely isoimmune thrombocytopenia, may play an auxiliary role (Berkowitz et al. 2006). The symptomatology resembles that of a subdural haematoma (Govaert 1993), with a symptom-free period of sometimes more than 24 hours, followed by focal signs and symptoms of raised intracranial pressure. Variable focal signs depend on the lobe involved and may include convulsions, asymmetry in tone and ocular signs. Surgical evacuation is indicated when symptoms of increased intracranial pressure are present, associated with a midline shift on neuroimaging (see Fig. 2.1). A residual cavity in the brain may not cause any symptoms or may be associated with a focal deficit (Brouwer et al. 2010). A similar picture may be seen with haemorrhagic brain infarction (Bruno et al. 2014, Cole et al. 2017).

Haemorrhagic disease of the newborn should no longer be seen with prophylactic administration of vitamin K, but is still reported in the literature in countries where prophylaxis is not yet common practice or in infants with specific problems such as α1-antitrypsin deficiency, Alagille syndrome and other problems leading to malabsorption of orally administered vitamin K (Vorstman et al. 2003; Danielsson et al. 2004; Ijland et al. 2008; Yilmaz et al. 2009). Differences in vitamin K prophylaxis regimens have shown that a daily dose of 25mcg vitamin K fails to prevent haemorrhages in apparently healthy infants with unrecognised cholestasis because of biliary atresia. Oral prophylaxis of 1mg weekly offered significantly better protection to these infants and was of similar efficacy to 2mg of intramuscular prophylaxis at birth (van Hasselt et al. 2008).

Other coagulation disorders may be responsible for severe ICH in the neonatal period. Haemophilia can cause subdural intraparenchymal haemorrhage, subgaleal haemorrhage or IVH (Chalmers 2004).

Brainstem haemorrhage is rarely of traumatic origin. At least one patient with spontaneous brainstem haemorrhage, with diaphragmatic paralysis and lower cranial nerve involvement, is on record (Blazer et al. 1989).

**THALAMIC HAEMORRHAGE**

Thalamic haemorrhage (Fig. 2.3) is a rare form of neonatal intraparenchymal haemorrhage (Trounce et al. 1985; de Vries et al. 1992b). The haemorrhage can be associated with an IVH (Roland et al. 1990; Govaert 1993; Monteiro et al. 2001; Wu et al. 2003) or limited to the thalamus and neighbouring structures. It was first shown by Wu et al. (2003) that a sinus venous thrombosis should be suspected when the thalamic haemorrhage is associated with an IVH. With increased use of MRI and MR venography (MRV) the association of a thalamic haemorrhage caused by a thrombosis of the straight sinus is now well recognised (Kersbergen et al. 2013) (Fig. 2.3). Some venous congestion in the periventricular white matter or even venous infarction can be present on the side of the thalamic haemorrhage. With power Doppler through the anterior, posterior, and mastoid fontanelle, or with better imaging such as CTV or MRV, one can confirm the sinus venous thrombosis. Once confirmed, some will consider the use of anticoagulants, usually low-molecular-weight heparin, but others are less inclined to treat in the presence of an associated parenchymal haemorrhage (Jordan et al. 2010; Moharir et al. 2010). Although the course may appear favourable in early infancy, Monteiro et al. (2001) reported that epilepsy with continuous spike waves during sleep (ESES) was related to primary neonatal thalamic

---

**Figure 2.3** Thalamic haemorrhage associated with cerebrospinosinous thrombosis. Axial T2-weighted sequence (a) shows a small amount of intraventricular blood, and a large haemorrhage in the right thalamus, which has almost completely resolved on the repeat MRI, performed at 3 months and (b) venous congestion and punctate lesions in the right periventricular white matter. The inversion recovery sequence at 3 months (c) shows an elongated area of low signal intensity, which is still visible on the FLAIR sequence performed at 7 years. Also noted is the increased signal intensity in the periventricular white matter on the right (right). The patient had febrile seizures, but had an otherwise normal outcome at 5 years.
haemorrhage. In a review of the literature they reported occurrence of epilepsy in 13 of 28 infants. Kersbergen et al. (2013) were able to confirm this observation in 15 infants with a thalamic haemorrhage associated with a thrombosis of the straight sinus. Of the 15 infants, three developed ESES (spike and wave index [SWI] >85%) between age 2 and 9 years, a further two children had ESES spectrum disorder (SWI between 50% and 85%), and in two more significant sleep-induced epileptiform activity (SIEA) was noted (SWI between 25% and 50%). Two other children were diagnosed with focal epilepsy, in the absence of sleep-induced epileptiform EEG abnormalities. A routine sleep EEG is therefore recommended in infants with a thalamic haemorrhage to make the diagnosis before a decline in cognitive and language performance occurs. Unilateral thalamic haemorrhage should not be confused with the more severe condition of bilateral thalamic and basal ganglia involvement in term infants with ‘near-total acute asphyxia’ (Barkovich 1992; Rutherford et al. 1995; Miller et al. 2005), which can in rare cases also be haemorrhagic (Kreusser et al. 1984).

**PRIMARY SUBARACHNOID HAEMORRHAGE**

It is common to see haemorrhage within the subarachnoid space, not as an extension from an intraventricular, subdural or intraparenchymal haemorrhage, based on the fact that bloody or xanthochromic CSF is frequently found when performing a lumbar puncture during the first few days after birth. A significant subarachnoid haemorrhage, also visible on CT or MRI, is much less common. Subarachnoid haemorrhage can be either traumatic or related to asphyxia. These were found, respectively, in 16 and 17 of 48 cases reported by Govaert (1993), whereas 10 cases remained of undetermined origin.

Clinical manifestations are often lacking. In some, irritability and seizures, occasionally presenting as apnoeic spells, are noted, typically on the second day after birth in otherwise well infants (Volpe 2008). Limited outcome data are variable. According to Palmer and Donn (1991), only 50% of the infants were neurologically normal, regardless of whether the presumed aetiology was hypoxic–ischaemic or traumatic. Others report a favourable outcome, although development of posthaemorrhagic ventricular dilatation can occur. Diagnosis is difficult using ultrasound unless the posterolateral window is used. MRI is a better imaging modality, showing blood in the posterior interhemispheric fissure and the region of the vein of Galen, and on the tentorium (Paneth et al. 1994). These studies were performed using ultrasound or CT; associated hypoxic–ischaemic lesions may not have been noticed and may have played an important role in the outcome.

**EPIDURAL HAEMATOMA AND RARE TYPES OF NEONATAL INTRACRANIAL HAEMORRHAGE**

Epidural haematoma is a rare condition in newborn infants and is usually caused by mechanical trauma during or sometimes after delivery, by a fall at home or out of an incubator in the neonatal intensive care unit (Vachharajani and Mathur 2002).

Cephalhaematoma is commonly associated and communicates with the extradural blood collection through a skull fracture. Signs of progressive CNS dysfunction are usually delayed and may be absent altogether. Ultrasonography is not very helpful, and the diagnosis is usually made by CT or MRI. Surgical evacuation is sometimes indicated but needle aspiration of the epidural haematoma has also been reported (Vachharajani and Mathur 2002). The collection tends to rapidly liquefy, leading to a differential density. Conservative treatment is possible in asymptomatic infants and those with just mild symptoms.

Other rare types of haemorrhage in the newborn infant include subgaleal haemorrhage with extensive blood loss (Kilani and Wetmore 2006; Swanson et al. 2012), haemorrhages related to vascular malformations such as Osler–Weber–Rendu (Morgan et al. 2002; Delaney et al. 2012), the vein of Galen (Chapter 15) and congenital tumours.

**Pathogenesis**

This type of haemorrhage is especially common in the very low-birthweight infant. Germinal matrix-intraventricular haemorrhage (GMH-IVH) mainly occurs within the first 3 days after delivery and is rarely noted to develop beyond the first week after birth, in contrast with white matter injury (see below). The haemorrhage develops in the germinal matrix and may subsequently rupture into the lateral ventricle. IVH is less common in the term infant and is then more likely to start off in the choroid plexus, rather than the germinal matrix, which has shown almost complete involution at term equivalent age. With routine use of cranial ultrasonography, the incidence could be assessed and was approximately 40% in the early 1980s, and has decreased to about 20% in the 1990s (Papile et al. 1978; Heuchan et al. 2002; Horbar et al. 2002). Less mature infants are more at risk of developing a haemorrhage, and it was shown by Perlman and Volpe (1986) that 60% of infants weighing <1000g at birth developed GMH-IVH, compared with only 20% of larger very low birth weight infants (Fig. 2.4). In a more recent study by Horbar et al. (2012), only the change in severe GMH-IVH grades III and IV was reported for preterm infants with a birthweight of 500–1500g. The decrease in severe IVH was of borderline statistical significance (P = 0.04) and stabilised at around 6%.
In a population-based study in France, a decline from 24.9% in 2005 to 12.4% in 2010 was reported, but the decrease was only significant for grade I haemorrhage (Pinto Cardoso et al. 2013). The average incidence for intraparenchymal haemorrhage reported in the literature is between 5% and 11% (de Vries et al. 2004). A lower incidence of 3% was reported in a French population-based cohort (Larroque et al. 2003). No statistically significant decline was noted in our own population for severe GMH-IVH, between 1991 and 2006, but a significant decline was seen for cystic periventricular leukomalacia (c-PVL) (Groenendaal et al. 2010).

The precise nature and origin of GMH-IVH remains uncertain. Although some groups have suggested that the capillaries in the germinal matrix do not rupture easily, others have claimed that this can result from the fact that the vessels are immature in a structure with little evidence of basement membrane protein (Grunnet 1989). Pape and Wigglesworth (1979) suggested from their injection studies that capillary bleeding was more prominent than terminal vein rupture. Anatomical analysis of the developing cerebral vasculature was unable to show precapillary arteriole-to-venous shunts (Anstrom et al. 2002). Most instances of GMH-IVH in preterm infants originate in the subependymal germinal matrix, the highly cellular area that gives rise to neurons and glia and involutes before term. In infants <28 weeks’ gestational age, haemorrhage is often located in that part of the matrix overlying the body of the caudate nucleus, whereas in those >28 weeks’ it more commonly overlies the head of the caudate (Anstrom 2002; Del Bigio 2011). Haemorrhages usually arise in the region of the germinal matrix. The venous architecture can be visualised with a recently introduced MRI sequence, susceptibility weighted imaging (SWI) (Tortora et al. 2016). IVH results when the ependyma ruptures. Parenchymal haemorrhage, still often referred to as grade IV haemorrhage, was initially considered to be an extension of the haemorrhage with rupture of the ependyma. It is now considered more likely to be due to impaired drainage of the medullary white matter veins (Takashima et al. 1986; Gould et al. 1987), and the terms ‘venous infarction’ and ‘periventricular haemorrhagic infarction’ (PVHI) appear to be more appropriate. Various grading systems have been devised (Papile et al. 1978; Volpe 2008). The grading system according to Volpe is shown in Table 2.1. It is preferable to use a separate notation for associated (haemorrhagic) lesions in the white matter, rather than the term ‘grade IV haemorrhage’. A PVHI is often noted to develop following an IVH, which may lead to impaired venous drainage into the terminal vein. The lesion is mostly unilateral and on the side of the IVH. It is important to note both the site and the extent of the lesion (Rademaker et al. 1994; de Vries et al. 2001; Bassan et al. 2006). Most of the parenchymal lesions will develop in the parietal white matter, but some occur in the frontal white matter or the germinal matrix of the temporal white matter (Soltirovska Salamon et al. 2013). (Fig. 2.5).
Other associated lesions that have mainly been diagnosed at post-mortem examination include pontine neuronal necrosis, encountered in 46% of cases, which were associated with pontosubicular necrosis in 20% (Armstrong et al. 1987).

Risk Factors

Risk factors can be prenatal, intrapartum or neonatal in origin.

Prenatal Risk Factors

Histological signs of amniotic infection have been shown to increase the risk of GMH-IVH. Increased serum levels of interleukin (IL)-1β, IL-6 and IL-8 have been found to be associated with severe IVH in extremely preterm infants (Yanowitz et al. 2002; Heep et al. 2003; Tauscher et al. 2003). In the study by Yanowitz et al. (2002), a correlation was shown between blood cytokine concentrations and altered haemodynamic function with cord blood IL-6 concentration correlating inversely with newborn systolic, mean and diastolic blood pressures. Maternal pre-eclampsia has been associated with a reduced risk of GMH-IVH (Shankaran et al. 1996; Gagliardi et al. 2013). The protective effect appears to be due to enhanced in utero maturation of the fetus. Administration of antenatal corticosteroids is, according to several studies, the most important protective factor against the development of GMH-IVH (Shankaran et al. 1996). This may be due to a direct maturational effect on the brain, but other factors may also be involved, such as the reduction of the severity of lung disease and the decreased need for inotropes. Several studies have shown that male sex is associated with a higher incidence of IVH and an increased rate of severe IVH (Mohamed and Aly 2010; Kent et al. 2012).

Intrapartum Risk Factors

There is still no agreement about the effect of the mode of delivery on the occurrence of GMH-IVH. A reduced mortality but not a reduced risk of a GMH-IVH was reported in a Swedish population-based study of preterm infants with a gestation of 25–36 weeks', when avoiding vaginal breech delivery (Herbst and Källén 2007). In a cohort study, a protective effect of a Caesarean section was seen only for the most immature infants (<27 weeks' gestation) (Thorp et al. 2001). A vaginal breech delivery is in some studies associated with a higher risk of a large GMH-IVH, but this effect was lost in a multivariable analysis (Riskin et al. 2008; Shankaran et al. 1996). Neonatal transport for infants born outside a tertiary centre has also been shown to be a risk factor (Mohamed and Aly 2010). It was recently suggested that it might not be the transport itself but the association with underlying clinical variables (Watson et al. 2013). Being born during the night was also reported with an increased risk for development of a GMH-IVH. Off-peak hour delivery was associated with increased odds of severe IVH among survivors (OR 1.39, 95% CI 1.23-1.57) and the composite outcomes of death or severe IVH (OR 1.16, 95% CI 1.07-1.25) and death or major morbidity (OR 1.08, 95% CI 1.02-1.15). (Jensen and Lorch 2017.)

Neonatal Risk Factors

Respiratory problems, and respiratory distress syndrome (RDS) in particular, have been recognised as important risk factors in the development of GMH-IVH. This association is most probably not causal but related to the concomitant complications occurring during mechanical ventilation for RDS, such as hypercapnia, pneumothorax and acidosis (Kaiser et al. 2006; Vela-Huerta et al. 2009). As a result of improvement in ventilatory techniques, including an increased use of nasal continuous positive airway pressure, hypercapnia and severe acidosis have become less common. It has been noted that hypercapnia, a potent cerebral vasodilator, especially when combined with a severe acidosis, is associated with GMH-IVH (Vela-Huerta et al. 2009). Postnatal administration of surfactant has also led to less severe RDS, with fewer complications such as pneumothorax and a decrease in the duration of mechanical ventilation.

Haemodynamic factors play an important role. The immature brain is considered vulnerable to fluctuations in blood pressure caused by limitations in autoregulation of

Figure 2.5 Preterm infant, gestational age 33 weeks'. (a) Axial T2-weighted sequence at 1 week shows an intraventricular haemorrhage with associated parenchymal haemorrhage (venous infarction) in the temporal lobe. (b) The optic radiation on the left side cannot be visualized with diffusion tensor imaging at term-equivalent age.
cerebral blood flow (CBF) (Lou 1988). Impaired autoregulation renders the cerebral circulation ‘pressure passive’ and hence unprotected from any wide swings or changes in blood pressure. This applies especially to sick preterm infants. An increase in systemic pressure can probably produce rupture of capillaries (Perlman et al. 1983; Miall-Allen et al. 1989), which could probably occur if a period of hypotension and ischaemia, with injury of the germinal matrix vessels, precedes the peaks of hypertension. The fluctuating pattern may be exaggerated in hypovolaemia (Pyrdys 1991). Using near-infrared spectroscopy (NIRS), it was shown that routine caregiving procedures in critically ill, preterm infants are associated with major circulatory fluctuations and that these cerebral haemodynamic changes were associated with early parenchymal ultrasound abnormalities (Limperopoulos et al. 2008). Hypotension is common in infants with severe RDS and, in the presence of a pressure-passive cerebral circulation, may lead to hypoxia–ischaemia of the germinal matrix. It has been shown that arterial hypotension precedes the development of GMH-IVH, with the haemorrhage occurring during a period of reperfusion (Vela-Huerta et al. 2009). Osborn et al. (2003) showed a low flow in the superior vena cava, detected during the first few hours of life, preceding an IVH. In a study using continuous NIRS and mean arterial blood pressure (MABP) measurements, MABP–regional cerebral oxygen saturation (rScO₂) correlation suggested more blood pressure-passive brain perfusion in infants with an IVH (Alderliesten et al. 2013). A reduction in GMH-IVH has been seen during an era of closer attention to blood pressure, gentle handling, synchronous ventilation, less need for invasive respiratory support and less severe RDS, because of antenatal steroid and postnatal surfactant therapy, rather than any specific drug used as prophylaxis.

Thrombophilic disorders, including the factor V Leiden mutation, which renders factor V resistant to cleavage by activated protein C, and the prothrombin G20210A mutation, which was found to be associated with raised plasma concentrations of prothrombin, were suggested to play a role in the development of GMH-IVH (Ryckman et al. 2011). In preterm infants with an atypical time of onset, either antenatal or beyond 96 hours after birth, an association was noted with polymorphism in the factor V gene (Harteman et al. 2012a; Ment et al. 2014). Aden et al. (2013) analysed genotypes for seven genes from 224 unborn preterm neonates, treated with antenatal steroids, and with grade III–IV IVH and 389 matched controls. They found methylenetetrahydrofolate reductase (MTHFR) to be more prevalent only in infants with grades III and IV haemorrhage compared with 389 matched controls. In smaller studies, the IL-6 CC genotype had been noted to increase the risk of developing severe haemorrhagic lesions and an impairment of cognitive outcome, according to some but not others (Harding et al. 2005; Göpel et al. 2006). Antenatal porencephaly has been reported to be associated with a mutation in the collagen 4A1 and 4A2 gene (COL4A1, COL4A2) encoding procollagen type 4a1, a basement membrane protein, in two preterm siblings and preterm twins (de Vries et al. 2009; Bilguvar et al. 2009). The diagnosis of a COL4A1 mutation can be made before birth and should be considered in the presence of a parenchymal haemorrhage associated with a cerebellar haemorrhage (Lichtenbelt et al. 2012). A mutation in the collagen 4A2 gene may result in the same imaging abnormalities (Verbeek et al. 2012).

**Cerebellar Haemorrhage**

The cerebellum is rapidly developing (fivefold increase in volume between 24 and 40 weeks’ corrected age), and may therefore be especially vulnerable (Chang et al. 2000). Injury to the cerebellum is often related to cognitive and behavioural deficits later in life (Limmeropoulos et al. 2007; van Kooij et al. 2012 Ranger et al 2015). Primary cerebellar haemorrhage (CBH) in preterm infants may originate in the external granular layer, from the germinal matrix that is present in the subependymal region around the fourth ventricle. The vulnerable capillaries, present in these structures, can easily rupture, especially with the circulatory changes in the vulnerable preterm infant (Volpe 2009). The possible role of bands used for fixation of facemasks has in the past been suggested as a cause, but this appears unlikely because the incidence was found to be similar when masks were not applied (Paneth et al. 1994).

**Neuroimaging Findings**

This type of haemorrhage appears to occur more often in the very immature preterm infant with a gestational age <28 weeks (Limmeropoulos et al. 2005; Steggerda et al. 2009). Ultrasonography, especially when performed through the mastoid fontanelle as the acoustic window, can be diagnostic when the lesion is at least 4mm in diameter (Steggerda et al. 2009). The lesion may be unilateral or bilateral, large or punctate, and may also affect the vermis (Limmeropoulos et al. 2005; Ecury-Goossen et al. 2010) (Fig. 2.6). It is often associated with a supratentorial IVH. The incidence varies between 3% and 9%, when using cranial ultrasonography, including the mastoid fontanelle (Limmeropoulos et al. 2005), but was reported as 15% in a more recent cohort (Steggerda et al. 2009). When using MRI the incidence increases dramatically and can be as low as almost 20%, mainly as a result of recognition of punctate lesions, which are a much more common finding in the extremely preterm infant, but are less likely to be associated with severe adverse neurological sequelae (Tam et al. 2011a). Steggerda et al. (2013) diagnosed these small CBHs on routine term equivalent age (TEA) MRI in 16 of 108 very preterm infants (<32 weeks’ gestation). In this study low-frequency oscillation ventilation and severe IVH were recognised to be independent risk factors of small CBHs. There was no association between small CBHs and neurodevelopmental outcome at 2 years of age. Besides the actual lesion in the cerebellar tissue, there are additional deleterious effects such as the toxicity of blood breakdown products...
such as haeme and iron in the CSF as a result of (supratentorial) haemorrhage. This iron accumulation and free radical attack have been associated with cerebellar atrophy (Tam et al. 2011b) (Fig. 2.7). In several studies, where MRI was not used routinely, cerebellar atrophy, as well as atrophy of the pons, has been reported as a common sequela of severe immaturity. It is likely that the atrophy was preceded by a cerebellar haemorrhage in the neonatal period (Bodensteiner and Johnsen 2005; Johnsen et al. 2005; Messerschmidt et al. 2005; Srinivasan et al. 2006; Tam et al. 2011b; Fumagalli et al. 2015).

Diagnosis and Clinical Manifestations

The onset of GMH-IVH has been noted to occur earlier in preterm infants weighing <1000g than in larger ones. Perlman and Volpe (1986) found that the onset in such infants was 10±8 hours, as opposed to the second or third day in larger infants. Clinical symptoms are not too common and the diagnosis is most often made using routine cranial ultrasonography. With increased use of MRI, including the use of SWI we are aware that ultrasonography is less accurate in less severe GMH-IVH, and may miss a small IVH or a germinal matrix haemorrhage in areas distant from the caudate groove, e.g. in the temporal lobe. Electroencephalography (EEG) is not particularly helpful in making the diagnosis, although a change in the background pattern may precede the development of the haemorrhage (Connell et al. 1988). The presence of positive rolandic sharp waves correlates well with presence of GMH-IVH but even better with white matter lesions such as periventricular leukomalacia, and is thus non-specific (Marret et al. 1992). Using amplitude integrated EEG (aEEG), infants with an IVH showed a more discontinuous background pattern, lack of sleep–wake cycles and a higher likelihood of seizure activity when compared with age-matched controls (Olischar et al. 2007). In another study the number of bursts per hour counted on the continuous amplitude-integrated EEG was found to be helpful with regard to prognosis (Hellström-Westas et al. 2001). Using continuous NIRS, several studies have been able to show lower rSO2 and higher cerebral fractional oxygen extraction values before the development of an IVH (Alderliesten et al. 2013; Noori et al. 2014).

Three clinical syndromes can be recognised in preterm infants not paralysed or heavily sedated on the ventilator (Volpe 2008). The first is known as catastrophic deterioration, noted by a sudden deterioration in the infant’s clinical state, e.g. an increase in oxygen or ventilatory requirement, a fall in blood pressure and/or acidosis. The fontanelle may be tense or even bulging, and clinical seizures may be noted. More often, however, a drop in haematocrit is seen without a clear change in the infant’s condition. The saltatory syndrome is more common and gradual in onset, presenting with a change in spontaneous general movements. The third and most frequent presentation is asymptomatic: 25–50% of infants with GMH-IVH have no obvious clinical signs. On careful neurological assessment, impaired clinical signs, such as visual tracking and later development of roving eye movements, a tight popliteal angle, and a decrease in tone and poor motility have been shown to correlate with GMH-IVH (Dubowitz et al. 1981). Motor agitation was noted to precede the diagnosis of a cerebellar haemorrhage (Ecury-Goossen et al. 2010).

Course and Sequelae

With ultrasonography largely available in neonatal units, most low-risk, preterm infants have a routine ultrasound scan soon after admission, or within the first few days after birth, rather than a full neurological assessment. GMH-IVH may already be present on the first ultrasound examination, performed soon after admission, and 90% of infants with the condition...
can be detected by the fourth day after birth (Volpe 2008). The haemorrhage tends to reach its maximal extent within 3–5 days of diagnosis and it is rare to see the development of a GMH-IVH beyond the end of the first week.

The course is rarely fatal and death may follow redirection of care in view of a poor prognosis, especially when there is bilateral parenchymal involvement (Maitre et al. 2009). This decision is usually not based just on cranial ultrasonography, but takes other factors into account such as the aEEG background activity, the neurological assessment and the presence of seizures. The mortality rate among 214 preterm infants with a large intraventricular haemorrhage (grade III) or PVHI seen in Utrecht was 33% (Brouwer et al. 2008).

Once the diagnosis is made, sequential examinations are recommended to assess the evolution of the haemorrhage. When the haemorrhage is restricted to the germinal matrix (grade I) one can see subsequent development of a germinal matrix cyst. These cysts tend to resolve over the next 3–6 months and appear to be of little clinical consequence according to some (Payne et al. 2013), but not others (Bolisetty et al. 2014). This might be explained by destruction of neuron and glial cell precursors, which will have consequences on subsequent brain development (Del Bigio 2011).

Posthaemorrhagic ventricular dilatation (PHVD) and infantile hydrocephalus are an important sequel of a usually severe GMH-IVH. PHVD is considered to be caused by adhesive arachnoiditis. It is more common in infants who had a large haemorrhage, where blood has passed through the aqueduct and the foramina of Luschka and Magendie into the basal cisterns (Fig. 2.8). Acute outflow obstruction is less common but does occur, and is usually caused by a clot obstructing the aqueduct. PHVD may occur shortly after a large IVH, due to a large obstructing clot, but it is more common to see the development over the next 7–14 days. Having a large IVH is an indication for sequential ultrasound examinations, because it is well known that the larger the haemorrhage the higher the risk of developing PHVD (Brouwer et al. 2008).

Without sequential ultrasound examinations, severe ventricular dilatation can be missed, since it can develop without any clinical symptoms or a rapid increase in head circumference, because the extracerebral space is large in the very preterm infant (Ingram et al. 2014). Once it has been recognised that the ventricles are starting to enlarge, the baseline size should be measured by ultrasonography. The most widely adopted measurement system is that of Levene and Starte (1981). This ‘ventricular index’ is the distance between the midline and the lateral border of the ventricle, measured in a coronal view in the plane of the third ventricle. Another useful measurement is the depth of the frontal horn taken just in front of the thalamic notch, the anterior horn width (AHW), a height of >3mm being used to define ventriculomegaly and one of >6 mm to suggest a PHVD (Davies et al. 2000). Measuring the occipital horn, the thalamo-occipital distance (TOD), in a sagittal plane is also useful because there can be a discrepancy between the anterior and posterior horn widths. Any measurement >24mm also suggests severe PHVD. The ventricular index graph of Levene has an age range between 27 and 40 weeks. New reference values for the ventricular index and anterior and posterior horn widths were published with an age range between 24 and 42 weeks (Brouwer et al. 2012).

In a study by Murphy et al. (2002), a total of 248 very-low-birthweight infants had a GMH-IVH (all grades) and a quarter of these developed PHVD. Spontaneous arrest was seen in 38%. Of the remaining 62%, 48% required non-surgical therapy, whereas 34% required surgical intervention and 18% died. In a more recent study of 208 preterm infants with a severe IVH (grade III/PVHI) from our own centre, 195 (94%) developed PHVD after IVH grade III or IV (VI >p97). Temporary treatment with lumbar punctures and punctures from a ventricular reservoir was sufficient for most of the infants. A ventricular reservoir was inserted in 135 infants (65%) and 47 of 196 survivors (24%) eventually required a ventriculoperitoneal shunt (Brouwer et al. 2015).

Raised CSF pressure can cause symptoms, including visual disturbance, seizures, feeding intolerance and apnoea. Short-term adverse effects on the nervous system have been confirmed using somatosensory and visual evoked potentials, Doppler estimates of cerebral blood flow velocity and NIRS (Soul et al. 2004; van Alfen et al. 2007; Klebermass-Schre-hof et al. 2013). Soul et al. (2004) showed a pronounced effect of CSF removal on cerebral perfusion, irrespective of the opening pressure and the amount of fluid removed. The impact of removal of CSF on cerebral tissue was also assessed using advanced volumetric three-dimensional MRI, showing an increase in both cortical grey and myelinated white matter.
cognitive disabilities (defined as severe sensori
cerebral and cerebellar volume, measured at TEA, strongly
to both motor and cognitive outcome measured with the
Bayley Scales of Infant Development, second edition (BSID-II)
at 2 years of age. It was noted that CSF hypoxanthine levels,
transforming growth factor-beta 1, soluble Fas levels were
raise in infants with PHVDs, especially so in those with

In spite of all these data, there is no direct evidence that
early drainage of CSF alters the natural history or outcome
of PHVD. In several retrospective studies early intervention
PHVD appeared to be associated with a better outcome and
a reduced need for a ventriculoperitoneal shunt (de
Vries et al. 2002; Brouwer et al. 2008; Bassan et al. 2012). A
prospective randomised controlled trial allocating the infants
to early versus later insertion of a subcutaneous reservoir has
recently stopped enrolling patients (ISRCTN43171322)
but the results have not been published yet. The initial data
of the drainage intervention fibrinolytic therapy (DRIFT)
study showed a reduced need for shunt insertion, 22% ver-
sus around 60% in the ventriculomegaly and acetazolamide
multicentre studies (Whitelaw et al. 2003), but this reduction
was not confirmed in the subsequent randomised controlled
trial, with a large number of secondary IVHs in the group
allocated to DRIFT (Whitelaw et al. 2007). No significant
differences were seen across the 34 infants allocated to DRIFT
and the 36 treated by tapping of CSF by reservoir. Among
the survivors, 11 of 35 (31%) in the DRIFT group had severe
cognitive disabilities (defined as severe sensorimotor disability
and cognitive disability <55 on the BSID-II) versus 19 of 32
(59%) in the standard group (adjusted odds ratio [OR]: 0.17
[95% confidence interval or CI: 0.05–0.57]).

Neurodevelopmental Outcome

Development of neurological sequelae depends mainly on the
severity of the initial haemorrhage and on involvement of the
periventricular white matter. Several studies (van de Bor et al.
2004; Bolisetty et al. 2014) have shown that even infants with
a small GMH-IVH have a higher incidence of disability than
those without. In a recent study by Vohr et al. (2014), after
preterm birth and a grade II IVH, preterm adolescents were
found to be at increased risk of learning challenges, including
cognitive and executive function deficits, even after exclusion
of those adolescents with associated periventricular haemor-
 rhage. A large study from Australia reported outcome on a
cohort comprising more than 2000 preterm infants, with 515
(21.3%) infants with a grade I–II GMH-IVH, diagnosed with
cranial ultrasonography. They found increased rates of neuro-
sensory impairment, developmental delay, CP (10.4%) and
default at 2–3 years corrected age in those with a grade I–II
GMH-IVH. The CP rate was also quite low (6.8%) in those
without cranial ultrasonography abnormalities (Bolisetty et al. 2014). Another recent study (Payne et al. 2013) did
not confirm these observations, which were based on ultra-
sound findings and may have missed associated white matter
lesions and/or cerebellar haemorrhage. Vasileiadis et al. (2004)
showed a 16% reduction in cortical volume at near term age
in 23 preterm infants with an uncomplicated IVH. Kaban et al.
(1999) noted that ventriculomegaly after a small haem-
orrhage was associated with a worse outcome, but this is
more likely to be the result of associated white matter lesions,
which probably play a more important role in determining
outcome than a haemorrhage that is restricted to the lateral
ventricle. The outcome of infantile hydrocephalus (PHVD
with the need for a ventriculoperitoneal shunt) in preterm
infants with a gestational age <33 weeks’ was reported by
Persson et al. (2005, 2006), showing that although the prev-
ence came down to six per 1000 livebirths, 88% of these
infants went on to develop CP. The outcome of infants with
parenchymal haemorrhage depends very much on the size and
in particular the site of the lesion (de Vries et al. 2011; Jary
et al. 2012b). The mortality rate in a series reporting the out-
come of large parenchymal haemorrhages is low and varies
between 37% and 84% (Larroque et al. 2003; Futagi et al. 2006;
Brouwer et al. 2008). Development of a single pore-
cephalic cyst after a large globular parenchymal haemorrhage
is not so common any more. In our experience, multiple small
cysts after a more triangular-shaped haemorrhage, which is
not or only partly communicating with the lateral ventricle,
are more often seen nowadays, and the outcome appears to
be better. Of 76 infants found to have a unilateral intrapa-
renchymal lesion >1 cm in diameter, 39 (51%) did not have
any motor sequelae at all at follow-up (Brouwer et al. 2008).
Early prediction of hemiplegia is now possible, using MRI at
40–42 weeks’ postmenstrual age (Cowan and de Vries 2005;
de Vries et al. 2011). At term, myelination should be present
in the posterior limb of the internal capsule; infants who had
asymmetry or lack of myelination in the posterior limb of
the internal capsule at term went on to develop hemiplegia
(de Vries et al. 1999). Diffusion tensor MRI can be used
to visualise the tracts at an even earlier stage and motor out-
come can already be predicted on an early MRI performed
within the first 4 weeks’ after birth (Arichi et al. 2014; Roze
et al. 2015).

Prevention

The increasing frequency of GMH-IVH in most centres is
difficult to attribute to one single factor. Administration of
teroidal corticosteroids is, according to several studies, the
most important protective factor for development of GMH-
IVH (Shankaran et al. 1996; Brownfoot et al. 2013). The
effect may be due to a direct maturational effect on the brain,
but other factors may also be involved, such as the reduction of the severity of lung disease and the decreased need for inotropes after birth. Dexamethasone has been associated, in a recent meta-analysis, with a reduced risk of IVH compared with betamethasone (relative risk [RR] 0.44, 95% CI = 0.21–0.92) (Brownfoot et al. 2013). However, dexamethasone may increase the risk of periventricular leukomalacia (Baud et al. 1999) and it is, therefore, still unknown which steroid is better overall (Brownfoot et al. 2013). Many more infants are no longer ventilated for hyaline membrane disease but manage on the newer nasal continuous positive airway pressure or infant flow systems. Surfactant is sometimes given, following the so-called InSurE procedure, where the infant is intubated, given endotracheal surfactant and then extubated. Another, even less invasive method is minimally invasive surfactant therapy or less invasive surfactant administration where surfactant is administered using a Magill forceps and a thin orogastric tube without the use of premedication or intubation (Dargaville et al. 2013). Not having to be ventilated has led to less handling and the elimination of procedures during which fluctuations of cerebral blood flow will occur, such as endotracheal suctioning. When ventilation is required, more care is taken to avoid the infant fighting the ventilator and the use of muscle paralysis decreases the risk of IVH, but is not recommended (Cools and Offringa 2005). An increased risk of developing GMH-IVH using low-frequency oxygen ventilation (HFOV) has been suggested but, in a systematic review, this was found to be significant only in a subgroup of two trials not using a low-volume strategy with HFOV (Cools et al. 2009).

Delayed cord clamping has been shown to reduce the incidence of GMH-IVH. In a systematic review, there were no significant differences for infant deaths, but a significant difference in the incidence of GMH-IVH with less intraventricular haemorrhage (ultrasound diagnosis all grades) among 10 trials, enrolling 539 infants (RR = 0.59, 95% CI = 0.41–0.85) (Rabe et al. 2012). It was suggested that this could be the result of a higher flow in the superior vena cava after delayed cord clamping.

Pharmacological intervention may be promising, especially the prophylactic use of indomethacin, immediately after birth. The results of a meta-analysis, involving 19 trials and a total of 2872 infants, showed a significant reduction in the incidence of grade III and IV haemorrhages, with a pooled risk ratio (RR) of 0.66 and a 95% CI of 0.53–0.82 (Fowlie et al. 2010). The children of the original cohort studied by Ment et al. (1994a, 1994b) were reassessed at 8 years of age and no effect of indomethacin was seen on long-term outcome (Vohr et al. 2003). It was of interest, however, that male preterm infants randomly assigned to saline tended to have lower scores on the Peabody Picture Vocabulary Test – Revised than all of the other preterm groups. Using functional MRI to assess long-term influences of early indomethacin exposure on language processing, a significant treatment-by-sex effect was demonstrated in three brain regions: the left inferior parietal lobule, the left inferior frontal gyrus (Broca’s area) and the right dorsolateral prefrontal cortex (Ment et al. 2006). Another large trial (Schmidt et al. 2001) also could not show an improvement in survival without sensory impairment at 18 months, despite a reduction in the incidence of severe GMH-IVH. A meta-analysis of ibuprofen involving 27 studies did not show a reduction in the incidence of GMH-IVH in a subgroup of 571 infants, with a typical RR of 1.21 (95% CI = 0.74–1.98) (Ohlsson et al. 2013).

Phenobarbital was the first drug used postnatally in the prevention of GMH-IVH. The first studies were promising, but a meta-analysis of 12 trials could not show a reduction in the incidence or severity of GMH-IVH (RR = 0.91; 95% CI 0.77 to 1.08) (Smit et al. 2013).

Other drugs such as ethamsylate and vitamin E are considered to have a stabilising effect on the fragile vessels in the germinal matrix. Ethamsylate looked promising at first and some studies reported a decreased risk in the incidence of any grade of GMH-IVH, but a recent meta-analysis was unable to find a reduction in mortality or neurodevelopmental impairment in treated infants (Fish et al. 1990; Hunt and Hey 2010). The data for vitamin E are controversial.

The use of magnesium sulfate given prenatally has been studied extensively and the data obtained give different results (Weintraub et al. 2001; Mittendorf et al. 2002). A systematic review published in 2009, involving over 6000 infants, substantially reduced the risk of CP (RR = 0.68, 95% CI = 0.54–0.87). The number of women who needed to be treated to benefit one infant by avoiding CP is 63 (95% CI = 43–87) (Doyle et al. 2009). No reduction in the incidence of either a small or a large GMH-IVH was found in a large, randomised, multicentre study (Crowther et al. 2003). In a multicentre, randomised controlled trial, no significant reduction was found for the incidence of a large GMH-IVH (2.1% vs 3.2%; RR = 0.64; 95% CI = 0.38–1.06). Moderate or severe CP occurred significantly less frequently in the magnesium sulfate group compared with the control group (1.9% vs 3.5%; RR = 0.55; 95% CI = 0.32–0.95) (Rouse et al. 2008). Although the number of women who needed to be treated to avoid one case of CP is 63, the treatment appears to be cost-effective (Bickford et al. 2013).

**WHITE MATTER INJURY**

The most common hypoxic–ischaemic lesion in the preterm infant is white matter injury, previously most often referred to as c-PVL (Fig. 2.9). This condition has also been reported by Miller et al. (2000) in term infants, and the more focal punctate white matter lesions are also commonly seen in term infants with congenital heart disease (Andropoulos et al. 2010). The term ‘periventricular leukomalacia’ was coined by Banker and Larroche in 1962, describing softening (malacia) of the white (leukos) matter. Most of the infants in this study were born at more than 28 weeks’ gestation and were several weeks’ old at the time of death. Anoxic events were recorded...
in all. Pathological examination was able to show bilateral, although not necessarily symmetrical, coagulation necrosis adjacent to the external angle of the lateral ventricles. In more recent years the classic pattern is less often recognised and in a study by Paneth et al. (1990) only three of 15 infants with white matter necrosis showed the classic changes of PVL. A distinction is nowadays made (Volpe 2008) between the more focal type of white matter damage – with cystic lesions limited to the regions of the trigone and occipital horns, involving the optic radiations, sometimes extending more anteriorly in the frontoparietal white matter – and the more diffuse type, which is now more commonly referred to as white matter injury (WMI) rather than PVL (Leviton and Gilles 1984; Back 2006). Although evolution into cystic lesions, well visualised with cranial ultrasonography, is the hallmark of the focal type, more diffuse changes in signal intensity can be noted on MRI, a more appropriate technique to diagnose the more diffuse white matter disease (Counsell et al. 2003). Cystic PVL was diagnosed for the first time using cranial ultrasonography in 1982 (Hill et al. 1982). The lesions were haemorrhagic in older pathology studies, in about 25% of the infants (Levene et al. 1983). The incidence of c-PVL has decreased over the last decade (Hamrick et al. 2004; van Haastert et al. 2011) from 5% to 10% to <1% in some centres.

### Neuroimaging Correlates

The initial changes seen with ultrasonography are areas of increased periventricular echogenicity (PVE), which is a very subjective finding (Fig. 2.10). Some researchers suggest assessing PVE by comparing it with the echogenicity of the choroid plexus. The duration of the PVEs should be taken into account, and the longer they exist the more likely they are to represent white matter injury (WMI). It may also help to look at the homogeneity of the PVE. When there is inhomogeneity (‘patchy’ PVE), it is more likely that one is dealing with WMI, and the patchy areas often correlate with punctate white matter lesions (PWMLs) on MRI (Sie et al. 2000b; Ramenghi et al. 2007; Kersbergen et al. 2014) (Fig. 2.11). The ultrasound grading system, according to de Vries et al. (1992a) classified WMI into four categories based mainly on the presence and extension of cystic lesions. Grade I can be further divided into two subgroups: (1) homogeneous and (2) inhomogeneous (patchy) PVE (Table 2.2). This classification is still useful although cystic WMI is nowadays much less prevalent. Grade I can be divided into two subgroups: (1) homogeneous and (2) inhomogeneous (patchy) PVE.

The increasing use of MRI in the preterm population has shown other potential signs of WMI, such as punctate lesions and diffuse excessive low-signal intensity (DEHSI) (Rutherford et al. 2010b). DEHSI, noted on T2-weighted spin-echo sequences around TEA in up to 70% of preterm infants, could be a correlate of early PVEs, although there is poor correlation between PVEs and contemporary signal intensity changes in the white matter (Maalouf et al. 2001; Debillon et al. 2003; Miller et al. 2003; Inder et al. 2003a; van Wezel-Meijler et al. 2011). Measurements of diffusion parameters (apparent diffusion coefficient [ADC], fractional anisotropy [FA], axial

PVE, periventricular echogenicity; c-PVL, cystic PVL; SCL, subcortical leukomalacia.
diffusivity and radial diffusivity) suggest that these findings truly reflect alterations of the white matter (Counsell et al. 2003, 2006; Cheong et al. 2009; Liu et al. 2012; Bassi et al. 2011).

In a small number of infants, areas of PVE gradually evolve into localised or more extensive cysts (Fig. 2.12). The smaller and more localised the cysts, the longer it will take for the cysts to develop. Small cysts may easily remain undetected. More than 50% of the small cysts were first seen using weekly ultrasound examinations beyond day 28 (Pierrat et al. 2001; de Vries et al. 2004). In more than half the infants the small cysts had resolved by TEA, resulting in mild ventricular enlargement (ventriculomegaly, ex vacuo dilatation) in some, but not all, infants. With fewer ventilated infants and a very low turnover rate, most infants will be referred back to the local hospital before the development of the cysts and come back to the follow-up clinic at TEA or beyond. When ultrasound examinations are no longer performed in the local hospital, the cysts will remain undetected, which is probably the major reason for the poor reputation of cranial ultrasonography in predicting CP (de Vries et al. 2004). When cranial ultrasonography is routinely performed every week during admission, at discharge and again at TEA, the risk of missing periventricular cysts becomes negligible (van Haastert

Figure 2.10 Preterm infant, gestational age 30 weeks. Cranial ultrasonography performed on day 1: (a) coronal view through the anterior fontanelle and (b) parasagittal view through the posterior fontanelle. Severe ‘patchy’ echogenicity is seen in both views.

Figure 2.11 Preterm infant, gestational age 32 weeks', with antenatal atrial flutter and pulmonary atresia. Good outcome at 3 years of age. MRI at 2 weeks’ (a) axial T2 and (b) apparent diffusion coefficient (ADC) map and (c) at term equivalent age (TEA) (axial T1). Multiple punctate white matter lesions are seen; they are also present on the ADC map, indicating their ischaemic origin. Early gliosis is seen as low signal intensity lesions at TEA. The outcome is within the normal range (IQ of 109 on the Griffiths test) at 3 years.
et al. 2011). To improve the surveillance of the children who are most at risk of developing cysts, diffusion-weighted MRI (DWI) has been shown to play a potential role. Inder et al. (1999b) were the first to show extensive changes on DWI that preceded cystic evolution. Few data are available because only very limited numbers of infants with PVE have been studied at an early stage of this severe disorder (Bozzao et al. 2003; Kidokoro et al. 2008; Fu et al. 2009). A new MRI based classification system has recently been reported (Martinez-Biarge M et al. 2016). The score illustrates that MRI findings should be scored taking the presumed time of injury, the severity of the preceding lesions seen with cUS and MRI and the presence of other signs indicative of previous injury into account. (Table 2.3).

Cysts, even when extensive, will resolve over weeks’ to a few months, and MRI plays a major role for assessing the extent of the white matter damage later in infancy. A rather classic picture with irregular dilatation of the lateral ventricles, a variable degree of white matter loss, sulci abutting the ventricular wall, a delay in myelination and periventricular gliosis can be recognised later in infancy (Byrne et al. 1990; Truwit et al. 1992). De Vries et al. (1993) found a good correlation between the severity of neonatal ultrasound abnormalities and gliotic changes on MRI performed in infancy (Fig. 2.13). Newer techniques, using diffusion tensor imaging (DTI) can perform diffusion tensor tractography (DTT), and thus map and quantify the pyramidal white matter tracts of preterm newborn infants (Miller et al. 2002; Berman et al. 2005; Partridge et al. 2005). Counsell et al. (2006) showed significantly increased radial diffusivity in the posterior limb of the internal capsule and the splenium of the corpus callosum, as well as significantly increased radial and axial diffusivity in the white matter of the centrum semiovale, and frontal, periventricular and occipital white matter. Kersbergen et al. (2016) performed tractography of the corticospinal tracts and segmentation of the thalami, shortly after birth and again at TEA in infants with extensive c-PVL and the comparison group, and they could identify damage to the corticospinal tracts (CST) on the early MRI; this was still present on the term scan, whereas the changes in thalamic volume developed in the weeks’ between the early and TEA MRI. This suggests a difference between acute and remote effects of the extensive injury caused by c-PVL to the white matter.

Pathogenesis of PVL

The pathogenesis of PVL is multifactorial and less well understood than that for GMH-IVH. The condition was initially considered to be caused by hypoperfusion of boundary zones in the white matter, but studies using continuous blood pressure measurements have so far been unable to identify hypotension as an independent risk factor for white matter injury (Trounce et al. 1988; Dammann et al. 2002; Logan et al. 2011). Severe hypocapnia, which causes a decrease in cerebral blood flow, has been identified as an independent risk factor for c-PVL in several studies (Okumura et al. 2001; Shankaran et al. 2006; Resch et al. 2012). Both cerebral blood flow and cerebral oxygen delivery were found to be significantly reduced in infants who went on to develop c-PVL (Pryds 1994). Using NIRS, Tsuji et al. (2000) confirmed dysfunction of cerebral autoregulation in 17 of 32 preterm infants; nine of these children developed severe intracranial lesions compared with only two of the 15 with intact autoregulation.

Several interesting studies have found an association of ascending intrauterine infection, production of inflammatory cytokines and WMI (Minagawa et al. 2002; Nelson et al. 2003; Hansen-Pupp et al. 2005; Leviton et al. 2011). Moreover, elevated blood concentrations of proinflammatory...

This MRI-based White Matter Injury (WMI) Classification for preterm infants born at ≤35 weeks’ gestational taking into account when the MRI is performed in relation to the time of the insult:
- within 2 weeks; cysts are unlikely to be seen; focal or extensive DWI changes may be present.
- between 2–6 weeks, cysts will have developed in infants with moderate or severe WMI and VM may have started to become apparent.
- at TEA cysts may still be there or may already have been replaced by early gliosis, white matter loss and VM. Whether cysts will still be present or not at TEA will depend not only on the severity of the WMI, but on the number of weeks since the initial insult.
PWML, Periventricular white matter lesions; DWI, Diffusion weighted imaging; SI, Signal intensity; VM, Ventriculomegaly; PLIC, Posterior limb of the internal capsule; BGT, Basal-ganglia thalami.

Figure 2.13  Inversion recovery sequence and T2-weighted MRI in a preterm infant with extensive cystic periventricular leukomalacia grade III.
(a) Extensive cysts are seen in the centrum semiovale at term equivalent age whereas (b, c) late MRI performed at 2 years shows angular ventricular dilatation, extensive periventricular gliosis and severe white matter loss.
cytokines in the first postnatal weeks’ have been correlated with adverse neurodevelopmental outcomes in very preterm infants (O’Shea et al. 2012). Leviton et al. (2005) suggested that white matter damage results from the innate and adaptive immune systems reinforcing each other. The relationship between chorioamnionitis and CP has been evaluated in a meta-analysis; chorioamnionitis was found to be a risk factor for both CP (RR = 1.9; 95% CI = 1.5–2.5) and PVL (RR = 2.6; 95% CI = 1.7–3.9) (Wu and Colford 2000). Another more recent meta-analysis, including studies performed between 2000 and 2009, showed that both clinical chorioamnionitis (OR = 2.42; 95% CI = 1.52–3.84), and histological chorioamnionitis (OR = 1.83; 95% CI = 1.17–2.89) were risk factors for CP (Shatov et al. 2010). However, newer prospective studies, using magnetic resonance techniques, have not found a significant association between histological chorioamnionitis and WMI on MRI, or with abnormal metabolic or microstructural brain development (Chau et al. 2009). Whether this difference between previous and newer studies is the result of heterogeneity of the studies included in the meta-analyses, or of improved neonatal intensive care, is still unknown (Chau et al. 2014). Chau et al. (2009) did find an association between WMI seen on early MRI and postnatal hypotension requiring treatment, and with culture-positive postnatal infections.

Back and Rosenberg (2014) have defined the ‘developmental window of vulnerability’ as the period in human white matter development that precedes the onset of myelination (23–32 weeks’), when the risk of hypoxic–ischaemic or oxidative injury to the metabolically active pre-oligodendrocyte is highest. During the peak time when WMI occurs, the late oligodendrocyte progenitors are predominantly present. These pre-oligodendrocytes are very vulnerable not only to glutamate, but also to other chemical mediators such as cytokines, adenosine and several reactive oxygen species (Volpe et al. 2011; Back 2014). It is increasingly recognised that an additional contributing factor in preterm diffuse WMI is an aberrant response to this acute pre-oligodendrocyte death. The pre-oligodendrocytes are regenerated but the new ones do not mature properly into the myelinating cells required for normal growth of white matter. This abnormal process has been called ‘cerebral dysmaturation disorder’ (Back and Miller 2014).

Clinical Manifestations

Clinical signs are uncommon and may easily go unnoticed. Seizures may occur, but are often subtle or subclinical. Sequential abnormal findings on EEG during the neonatal period have been described in infants with WMI. Acute changes (decreased continuity, lower amplitude of background activity) are seen soon after birth, usually between days 1 and 4, whereas chronic changes (disorganised pattern with or without frontal and/or occipital sharp waves, positive Rolandic sharp waves and abnormal brushes) are observed mainly between days 5 and 14. In cases of extensive c-PVL these EEG abnormalities are more severe and persist longer (Kidokoro et al. 2009).

Positive Rolandic sharp waves are specifically associated with WMI in preterm infants (Marret et al. 1992); one study showed a better sensitivity in preterm infants with a gestational age >28 weeks’ (Baud et al. 1998). The frequency of these positive Rolandic sharp waves in infants with WMI has been related to later neurodevelopmental outcomes (Vermeulen et al. 2003). Infants with milder degrees of WMI may not show positive Rolandic sharp waves, and their frontal and occipital sharp waves may have higher sensitivity (Okumura et al. 2003). Lethargy or hypotonia may be present in the acute phase and some infants may be ventilator dependent, being acutely ill with septicaemia or necrotising enterocolitis. A characteristic picture is usually recognised after several weeks’, when the infant becomes increasingly irritable and shows hypertonia, with extension of the lower limbs and flexion of the upper limbs. Tremors and startles are common and the Moro reflex is often abnormal. General movement studies reported a pattern of movements, called ‘cramped—synchronised’ (Cioni and Prechtl 1990), which has been associated with the site and extension of the white matter injury (Bos et al. 1998; Spittle et al. 2008). This abnormal pattern of general movements during the first 6 weeks’ of post-term age predicts impaired motor development, especially when is followed by absent ‘fidgety’ movements at 3 months (Spittle et al. 2009). Cortical visual impairment is often recognised in infancy in these children (Lanzi et al. 1998; Fazzi et al. 2009). Although (subcortical) tracking can be elicited at TEA (Eken et al. 1994b; Cioni et al. 1997), more refined visual assessments in the neonatal period have shown abnormal visual function in a large proportion of infants with WMI (Ricci et al. 2011). Cortical visual impairment in children with WMI not only is the result of injury to the optic radiations and occipital cortex but is also related to thalamic atrophy which is so commonly seen in these infants (Ricci et al. 2006).

Neurodevelopmental Outcome

Neurodevelopmental outcome is invariably poor in infants with extensive cystic lesions in the parietal and occipital white matter, due to interruption of conduction in the fibres descending from the inner aspect and superior part of the hemisphere, which are involved in the motor function of the lower limbs and/or the optic radiation. This explains why they cause spastic diplegia and/or visual impairment. Advanced MRI techniques have shown that, in addition to the injury to the corticocospinal tract, children who develop spastic diplegia have reduced cortical volume and connectivity in the somatosensory and motor areas (Lee et al. 2011), as well as disruption of thalamocortical connections (Hoon et al. 2009). Cystic PVL is the most powerful predictor of later CP, usually spastic diplegia (van Haastert et al. 2011). Single cysts or cysts restricted to the frontoparietal, periventricular, white matter carry a better prognosis with a normal outcome or milder diplegia (Pierrat et al. 2001). Even PVE without cystic evolution carries a small risk of about 5–10% of developing CP, more often seen in the infants with longer
duration of the PVE (Chen et al. 2004; de Vries et al. 2004; Resch et al. 2006). Jongmans et al. (1993) showed that almost half the children with PVE who did not develop CP developed transient abnormalities in tone pattern, and were noted to have a higher total impairment score when assessed again at the age of 6 years with the Movement ABC test. The severity and extent of WMI predict not only the risk of CP, but also its severity and functional impact. The vast majority of infants with PVE without cystic evolution (PVL grade I) who develop CP have mild motor impairment and are able to walk independently before school age. PVL grade II is associated with a more significant motor impairment, but most of these children will still reach independent or assisted ambulation. In contrast, children with extensive PVL (grades III and IV) will show severe motor impairment (spastic diplegia or spastic quadriplegia) and will not walk or will require assistance to walk (Pierrot et al. 2001; Serdaroglu et al. 2004; van Haastert et al. 2008).

Cerebral visual impairment (CVI) caused by damage to the optic radiations, the occipital cortex and/or the visual association areas is highly prevalent in children with c-PVL. The range of visual problems is wide, from mild-to-moderate impairment (suboptimal visual acuity, restriction of the visual fields, visuospatial problems) to complete blindness (Dutton 2013). Abnormal signal intensity in the optic radiations, reduced volume in the periventricular white matter, atrophy of the calcarine cortex and reduced thalamic volume seen on MRI have been related to the presence and severity of visual impairment in these children (Ricci et al. 2006). Even in children with normal intelligence and normal visual acuity, impairment of higher visual abilities (visual object recognition, visuospatial skills, visual memory) is common (Fazzi et al. 2009). Strabismus and refractive errors are also frequent in children with c-PVL (Jacobson and Dutton 2000).

Cognitive impairment is the other main sequel of c-PVL. Performance scores are usually lower than verbal scores (which can be within the normal range), reflecting the impact of visuo-perceptual impairments on learning abilities (Pagliano et al. 2007).

The effect of punctate white matter lesions and DEHSI on later outcome is still controversial. Punctate lesions did not have a negative influence on early neurodevelopmental outcome according to some authors (Cornette et al. 2002; Kersbergen et al. 2014), but others have shown an association between the presence of more than six of these lesions with lower developmental scores and a higher risk of CP (de Bruïne et al. 2011). Volume and location of PWML was quantified on MRI in 216 neonates (median gestational age 27.9 weeks) who had motor, cognitive, and language assessments at 18 months corrected age. PWML were present in about one third of the infants who were scanned at a median postmenstrual age of 32 weeks and were seen at 18 months corrected age. Infants with greater PWML volumes in frontal, parietal, and temporal lobes had adverse motor outcomes (all, p < 0.05), but only frontal WMI volumes predicted adverse cognitive outcomes (p = 0.002) (Guo et al 2017). Some groups have found an adverse effect of DEHSI on learning abilities (Dyet et al. 2006; Parikh et al. 2013; Pogribna et al. 2014), whereas others have not found this association (Kidokoro et al. 2011; de Bruïne et al. 2011; Hart et al. 2011). An important observation by Inder et al. (1999a) was the loss of grey matter volume at TEA using three-dimensional volumetric MRI, following (non-cystic) white matter disease. A later study by the same group confirmed these findings in a larger cohort of preterm infants (Inder et al. 2005). Since then, several studies have described this secondary loss of grey matter volume in preterm infants, not only during the neonatal period, but also throughout childhood and adolescence. These findings have been correlated with lower developmental scores and suboptimal cognitive function (Boardman et al. 2010; de Kieviet et al. 2012).

**Prevention**

Very few data are available with regard to the prevention of WMI, but over the years a decrease in the prevalence has been noted in several units, and the extensive cystic form has become a rare disease (Hamrick et al. 2004; van Haastert et al. 2011). Improved obstetric and neonatal care appears to play an important role. In utero transfer, increased use of antibiotics in the management of prolonged rupture of membranes and the use of antenatal corticosteroids all appear to be protective (Kenyon et al. 2001; Roberts and Dalziel 2006). Although the first retrospective studies observed a more neuroprotective effect of betamethasone compared with dexamethasone (Baud et al. 1999; Canterino et al. 2001), later prospective clinical trials have not found the same association and it is still unclear whether one steroid has advantages over the other (Brownfoot et al. 2013). The use of less aggressive ventilation strategies has proven to reduce the risk of hyperventilation and hypocarbia and has been associated with a decreased risk of preterm WMI (Peng et al. 2014). Elevated hypoxanthine in plasma and protein carbonyl levels, in the CSF of children who went on to develop c-PVL, suggested involvement of free radical damage (Russell et al. 1992; Inder et al. 2002). So far only one randomised study has been performed using allopurinol, showing no protective effect (Russell and Cooke 1995). Another potentially neuroprotective drug is human recombinant erythropoietin (EPO). EPO is routinely used in preterm infants to prevent and treat anaemia, but is also known to protect against glutamate toxicity, inhibit injury-induced apoptosis and attenuate nitric oxide release in the nervous system (Brown et al. 2009). A recent meta-analysis of seven clinical trials has shown that EPO is associated with a small but significant reduction in the rate of global neurodevelopmental disability (RR = 0.77; 95% CI = 0.60–0.99), but not with a reduced rate of CP, or a lower rate of motor, cognitive or visual impairment (Zhang et al. 2014). It is not clear whether this improvement is the result of a reduction in the occurrence of WMI, because this outcome has not been specifically reported. A randomized, double-blind, placebo-controlled study was recently conducted in Switzerland between 2005 and 2012, enrolling 495 infants. In a nonrandomized...
subset of 165 infants (n=77 erythropoietin; n=88 placebo), brain abnormalities were evaluated on MRI acquired at term-equivalent age. Infants treated with recombinant human erythropoietin (rhEPO) had less often abnormal scores for white matter injury (22% [17/77] vs 36% [32/88]; adjusted risk ratio [RR], 0.58; 95% CI, 0.35-0.96), and grey matter injury (7% [5/77] vs 19% [17/88]; adjusted RR, 0.34; 95% CI, 0.13-0.89) (Leuchter et al 2014). Neurodevelopmental outcome data was available for 365 (81%) of the 448 infants in a prospective MRI study, that most of the 351 infants with neonatal WM injury had sustained brain injury at or near the time of birth. As a result of the causal relationship between perinatal asphyxia and HIE not always being apparent, the non-committal term ‘neonatal encephalopathy’ has been proposed instead (Dammann et al. 2011; Leviton 2013). Although the diagnosis of HIE should not be made without a strict clinical evaluation, and alternative diagnoses such as infection, trauma, inborn errors of metabolism and other congenital disorders should be carefully considered, especially because they may have a significant impact on treatment, prognosis and genetic counselling, the term ‘neonatal hypoxic–ischaemic encephalopathy’ should be used in those infants who present with neonatal encephalopathy of early onset, preceded by signs of perinatal hypoxia–ischaemia (low Apgar scores, metabolic acidosis, need for resuscitation), and show neuroimaging features consistent with an acute hypoxic–ischaemic insult (Volpe 2012).

Pathogenesis

The deficit in oxygen supply that produces HIE can result from two mechanisms: hypoxaemia, i.e. a reduced supply of oxygen in blood, and ischaemia, i.e. a reduced perfusion of the brain (Fig. 2.14a) (Douglas-Escobar and Weiss 2015). In most patients both are caused by asphyxia, i.e. hypoxia associated with hypercapnia. Acidosis, which is usually present with hypoxia, is largely related to increased production of lactate via anaerobic glycolysis, a much less efficient process, than oxidation through the tricarboxylate cycle (Krebs cycle) and mitochondrial electron transport system. Oxidation of each molecule of glucose metabolised under anaerobic conditions generates only two molecules of ATP compared with 38 under aerobic conditions. Despite a considerable increase in the rate of glycolysis and an increase in cerebral blood flow caused by acidosis and hypercapnia, the energy needs of the brain may not be satisfied. The increased rate of glycolysis results in a decline in brain glucose levels. Ultimately, there is reduction in brain cell phosphocreatine and ATP as a consequence of the lack of oxygen, the final electron acceptor. Ischaemia has similar effects to asphyxia. Glycolysis is increased but the uptake of glucose is prevented by impairment of the blood supply, and hence the low-energy phosphates are depleted and lactate production rises.
Figure 2.14a Excito-oxidative cascade of events that mediate hypoxic–ischaemic brain injury. Severe hypoxia impairs oxidative metabolism, leading to neuronal depolarization and ischaemia. Ischaemia reduces delivery of the glucose necessary for anaerobic metabolism, which powers neurotransmitter reuptake pumps on perisynaptic astrocytes. This leads to flooding of the synaptic cleft with glutamate and neuronal depolarisation, which in turn triggers opening of N-methyl-d-aspartate (NMDA) receptor channels and other calcium channels, including acid-sensing ion channels, leading to excess calcium influx into neurons. Calcium flooding through NMDA channels activates the enzyme nitric oxide synthase (NOS), leading to low levels of the toxic free radical neurotransmitter nitric oxide (NO). This toxic free radical, along with additional oxygen free radicals generated by reoxygenation of mitochondria after a period of hypoxia, attacks enzymes associated with oxidative phosphorylation and electron transport. Calcium toxicity is also mediated by activation of other enzymes, including caspases, calpains, other proteases and lipases, that attack mitochondria and other cellular machinery. Signals released from damaged mitochondria lead to apoptosis or programmed cell death, as long as energy supplies persist, but exhaustion of energy supplies leads to necrosis, in which cellular membranes are destroyed. Lactic acid accumulates when oxidative phosphorylation within mitochondria is impaired, but its toxicity seems to be less important in the neonatal brain than in adult brains. Similarly, cerebral oedema occurs when pumps required for water homeostasis are impaired by reduced energy supplies, as a result of damaged mitochondria. Oedema seems to be a sign of energy failure rather than a cause of damage on its own. This excito-oxidative cascade occurs over a period of days to weeks. EAAT, excitatory amino acid transporter; Gln, glutamine; Glu, glutamate; nNOS, neuronal NOS; VDCC, voltage-dependent calcium channels.

Apoptosis could play a more prominent role in the evolution of hypoxic–ischaemic injury in the neonatal brain compared with adults; it could be even more important than necrosis after injury (Blomgren et al. 2007; Johnston et al. 2011). During neonatal brain injury several pathways, including excitotoxicity, oxidative stress and inflammation, occur simultaneously and interact with each other; all contribute to accelerated cell death by means of apoptosis or necrosis, depending on the region of the brain affected and the severity of the insult (McLean and Ferriero 2004; Blomgren et al. 2007). Acute HIE consists of two successive stages, the second one, in which definitive/permanent brain damage occurs, is delayed for several hours and is referred to as secondary energy failure. The mechanisms of cell damage and death with hypoxia or ischaemia are not simply the result of energy failure. When a critical level of energy deficit has been reached this energy failure secondarily triggers a cascade of deleterious events. Such events take place over several hours. Excessive membrane depolarisation and the release of excitatory amino acid neurotransmitters, especially glutamate, lead to calcium influx through N-methyl-d-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA*) membrane
Figure 2.14b Downstream signaling pathways that mediate the apoptosis–necrosis continuum. Delayed cell death signaling pathways mediate the effects of hypoxia–ischaemia in the brain. The extrinsic pathway mirrors the cells’ external environment and begins when inflammatory cytokines (to the right of the figure at the cell surface) bind to and activate Fas-cell death receptors, whereas the intrinsic pathway is activated when signals released from within stressed mitochondria activate caspase- and non-caspase-mediated, cell-death pathways within the nucleus. These two pathways activate common signaling networks within the mitochondria and the nucleus. Mitochondria exposed to caspase-induced stress can release either cytochrome c through channels formed by the Bax and Bak proteins in the outer mitochondrial membrane (caspase-mediated cell death) or apoptosis-inducing factor (AIF), which directly activates DNA fragmentation (non-caspase pathway). Cytochrome c can combine with Apaf1 and caspase 9 to form the apoptosome, which triggers activation of caspase 3. DNA breaks mediated by free radicals such as NO• and peroxynitrite activate poly-ADP-ribose polymerase 1 (PARP1), which consumes NAD+ and worsens energy shortage for mitochondria (shown within the nucleus). Convergence of signalling for the extrinsic (Fas) and intrinsic cell-death pathways is responsible for the interaction between infection (endotoxin) and hypoxia–ischaemia that increases cell death. AIF, apoptosis-inducing factor; Apaf1, apoptotic protein-activating factor 1; Bax and Bak, proapoptotic proteins that form channels in outer mitochondrial membrane releasing cytochrome c to trigger apoptosis; BclXL, antiapoptotic proteins in the Bcl2 family of proteins; Bid, BH3 interacting domain proapoptotic protein; CAD, caspase-activating DNAse; Cyt c, cytochrome c; FADD, Fas adaptor death domain protein; Fas, death receptor in tumour necrosis factor family; FASL, Fas death receptor ligand; GSH, glutathione, an antioxidant; IAP, inhibitor of apoptosis; NAD, nicotinamide adenine dinucleotide; ROS, reactive oxygen species; SMAC, antagonist of inhibitor of apoptosis; tBid, truncated BH3-only proapoptotic protein; PAR, poly-ADP ribose formed by ribosylation of DNA and proteins; Vm, membrane potential; VSSC, voltage-sensitive calcium channel. Reproduced from The Lancet Neurology Vol. 10 No. 4, Johnston et al., Treatment advances in neonatal neuroprotection and neurointensive care, pp. 372–382, © 2011, with permission from Elsevier.'
receptors, and to the accumulation of cytosolic calcium (Robertson and Groenendaal 2012). Calcium, in turn, activates various lipases, proteases and nucleases with the resultant injury to essential cellular proteins. Activation of caspases, a family of proteases that are the primary mediators of apoptosis, results in proteolysis of cytoskeletal proteins and kinases, which eventually leads to nuclear fragmentation (Fatemi et al. 2009) (Fig. 2.14b). (Fig 2.16 and 2.17)

Another apoptotic pathway is mediated by free radicals, which are also generated as a direct or indirect result of increased cytosolic calcium. They play a role in peroxidation of fatty acids, membrane injury and cell necrosis. The developing brain is more vulnerable to oxidative stress because of two reasons: first because of its higher content in pro-oxidant substances such as polyunsaturated fatty acids and iron; and secondly because of the immaturity of its antioxidant defence system (Robertson and Groenendaal 2012).

The third main factor implicated in brain cell death is inflammation. Hypoxia–ischaemia induces an inflammatory response within minutes after the insult, which in turn exacerbates brain injury (Liu and McCullough 2013). Pre-existing fetal infection/inflammation may worsen hypoxic–ischaemic brain injury (Fatemi et al. 2009). The potential mechanisms include production and release of cytokines and microglia activation (Fatemi et al. 2009; Robertson and Groenendaal 2012; Liu and McCullough 2013).

**Neuropathology**

Early MRI studies revealed two main patterns of injury in neonates with HIE. Infants who had sustained acute, near-total, intrapartum asphyxia showed a consistent pattern of injury to the basal ganglia, thalami and brain stem, with relative sparing of the cortex and white matter (Barkovich 1992; Pasternak and Gorey 1998; Sie et al. 2000a) (Fig. 2.15). These lesions are bilateral and symmetrical, and found particularly in the ventrolateral thalami, posterolateral lentiform nuclei, posterior mesencephalon, hippocampi and sometimes the peri-rolandic cortex (Barkovich 1992). In contrast, in infants with partial, prolonged asphyxia, brain lesions are more diffuse, associated with oedema, and affect mainly the cortex and subcortical white matter in the vascular watershed zones (anterior–middle and posterior–middle cerebral arteries); they are often referred to as a boundary zone or watershed injury (Barkovich 1992; Miller et al. 2005). An overlap between the two main types of injury is, however, commonly seen (Figs. 2.16 and 2.17).

These patterns of injury seen on neonatal neuroimaging have been correlated with different perinatal antecedents and neonatal clinical courses. The basal ganglia–thalamus (BGT) pattern is typically seen in infants who have been exposed to a sentinel event during labour (uterine rupture, placental abruption, cord prolapse, tight nuchal cord) or to a prolonged terminal bradycardia. These infants are usually born in a poor condition, with a moderate-to-severe encephalopathy, a multisystem dysfunction that may be mild or absent and a motor outcome that is consistently impaired (Pasternak and Gorey 1998; Miller et al. 2005; Okerefor et al. 2008). Infants with the white matter/watershed pattern of injury are generally born in a better condition and experienced milder clinical courses, although they can experience hypoglycaemia and infection more frequently (Miller et al. 2005; Li et al. 2009; Harteman et al. 2013a; Wong et al. 2013). A recent study has found an association between this white matter/watershed pattern of injury and the presence of the MTHFR 677 CT or TT genotypes, and with higher levels of homocysteine (Harteman et al. 2013a). Motor outcome is normal in most of these children, but cognitive and behavioural problems are common (Steinman et al. 2009; van Kooij et al. 2010; Martinez-Biarge et al. 2012; Harteman et al. 2013b).

An association between these two different patterns of injury and placental pathology has recently been shown. The white matter/watershed pattern of injury, with or without concomitant BGT lesions was associated with fetal placental thrombosis and with decreased maturation of the terminal villi, whereas none of the placentas from infants with predominant BGT injury pattern showed evidence of decreased maturation.
This suggests a role for antenatal, chronic hypoxia in the white matter/watershed pattern of injury (Harteman et al. 2013c). (Fig 2.16 and 2.17)

**Clinical Manifestations**

The characteristic clinical signs of neonatal encephalopathy are an altered level of consciousness, abnormal muscle tone and motor responses, abnormal reflexes and abnormal cranial nerve function (especially feeding difficulties). Seizures are frequent (Volpe 2012). When the neonatal encephalopathy is due to an episode of perinatal asphyxia, this clinical syndrome is present from the time of birth, although its severity may change over the first few hours or days. The severity of the neonatal encephalopathy is commonly classified as stage 1, 2 or 3 according to the criteria by Sarnat, or alternately mild, moderate or severe, depending mainly on the degree of depression of consciousness. Although neonates with mild neonatal encephalopathy may be irritable or slightly lethargic, infants with moderate neonatal encephalopathy show different degrees of stupor and severely affected infants are usually comatose (Volpe 2008). The severity of encephalopathy correlates with the risk of mortality and overall adverse developmental outcome. Hypothermia treatment may alter the prognostic value of the clinical assessment in the first 6 hours after birth. Clinical trials on hypothermia have found that cooled infants might experience a faster clinical recovery and that persistence of severe encephalopathy at 72 hours increased the risk of death or disability, irrespective of the treatment (Shankaran et al. 2012a). Cooled infants...
with moderate encephalopathy at 72 hours may have a better outcome than expected without hypothermia treatment (Gunn et al. 2008).

Seizures are common in the acute phase of HIE and affect 50–65% of infants with moderate-to-severe HIE (Gluckman et al. 2005; Azzopardi et al. 2009). A significant proportion of seizures is subclinical, especially after the administration of antiepileptic drugs, and whether to treat them remains controversial. Electographic seizures have been associated with the severity of brain injury on MRI (Nash et al. 2011; Glass et al. 2011a; Shah et al. 2014), but there are insufficient data showing an association between these episodes and neurodevelopmental outcome. In a small randomised controlled trial treating only clinical seizures or clinical and subclinical seizures, there was a trend for a reduction in seizure duration when clinical and subclinical seizures were treated, and the severity of brain injury seen on MRI was associated with a longer duration of seizure patterns (van Rooij et al. 2010a). Recent observational studies suggest that hypothermia might reduce the number of electrographic seizures in infants with moderate and severe HIE (Low et al. 2012; Srinivasakumar et al. 2013).

Diagnosis of HIE
Diagnosis should be made based on a combination of the antecedents, clinical examination and clinical course, neuroimaging findings and electrophysiological data, and not just on the results of a single test. Clinical assessment of neurological status within the first 6 hours after birth is necessary to identify infants suitable for hypothermia treatment. Several scoring systems may help in the identification of infants with moderate or severe encephalopathy (Thompson et al. 1997). Subsequent neurological examinations during the first 3–4 days and at discharge provide useful prognostic information (Gunn et al. 2008; Murray et al. 2010; Shankaran et al. 2012a).

Amplitude-integrated EEG (aEEG) is one of the most useful tools in the clinical management of the infant with HIE and is also a good predictor of neurodevelopmental outcome. Interpretation of aEEG is based on the pattern recognition of background activity and voltage criteria. The combination of these two criteria produces five categories of aEEG traces in term infants: continuous normal voltage pattern, discontinuous normal voltage pattern, discontinuous background pattern burst suppression pattern, continuous background pattern of very low voltage and mainly inactive tracing (flat trace). There is a good correlation between these aEEG patterns and the EEG background pattern in term infants with moderate-to-severe neonatal encephalopathy (Toet and Lemmers 2009). The presence of an abnormal pattern (burst suppression, continuous low voltage or flat trace) within the first 6 hours after birth supports the diagnosis of significant (moderate or severe) HIE, and helps in the selection of infants for hypothermia treatment. The presence of abnormal aEEG patterns within the first 6 hours after birth, and the absence of recovery before 24 hours, both predicted death or significant disability before the introduction of therapeutic hypothermia (Toet et al. 1999; van Rooij et al. 2005). Onset of sleep-waking cycling before or after 36 hours of age also strongly correlated with outcome (Osrédkar et al. 2005). Recent studies have shown that the predictive value of aEEG differs in cooled infants compared with non-cooled infants (Azzopardi 2014a). In cooled infants the predictive value of an abnormal aEEG trace within the first 6 hours is reduced. Infants treated with hypothermia may still have a favourable outcome even when an abnormal aEEG tracing persists beyond 24 hours, as long as the recovery occurs before 48 hours (Thoresen et al. 2010). The onset of sleep-wake cycling is also delayed in neonates treated with hypothermia (36 vs 24 hours), but most cooled infants will eventually show sleep-wake cycling within the first 4–5 days after birth (Thoresen et al. 2010; Takenouchi et al. 2011). The presence of an early normal or mildly abnormal EEG or aEEG pattern is highly predictive of a normal outcome, in both cooled and non-cooled neonates (Murray et al. 2009; Thoresen et al. 2010). The predictive value of the aEEG might be higher when it is combined with NIRS-monitored rScO₂ (Lemmers et al. 2013; Goerl et al. 2017).

Despite the widespread use of MRI techniques in the assessment of neonatal encephalopathy, cranial ultrasonography still plays an important role in the evaluation of brain injury (Daneman et al. 2006). Ultrasonography can detect abnormalities that suggest metabolic, congenital or infectious processes, such as established ventricular dilatation, germinal matrix cysts, lenticulostriate vasculopathy, increased subarachnoid and interhemispheric space, cerebellar abnormalities, absent or abnormal corpus callosum and abnormal cortical folding (Leijser et al. 2007). When performed soon after birth, ultrasound examination can help to determine the timing of the injury. Established abnormal parenchymal echogenicity in the first 24–48 hours suggests a recent antenatal insult, whereas calcification or atrophy is a sign of a more longstanding injury (Leijser et al. 2006). Acute changes on an ultrasound scan typical of HIE have been well described and correlate well with contemporaneous MRI findings (Epelman et al. 2010). An early abnormal resistance index (≤0.55), measured by Doppler ultrasonography, predicts poor outcome in non-cooled infants (Eken et al. 1994a), but not in infants treated with hypothermia (Elstad et al. 2011), although it regains its predictive value after rewarming (Skranes et al. 2014). On conventional MRI, brain lesions are best seen during the second and third weeks after the hypoxic–ischaemic insult. BGT lesions (typically seen in the ventrolateral thalamus and the lentiform nuclei) are the most prevalent site of injury after acute perinatal hypoxia–ischaemia (Miller et al. 2005; Okerekeaf et al. 2008), and are usually accompanied by abnormal signal intensity in the posterior limb of the internal capsule, which is a strong predictor for hypothermia treatment.

On conventional MRI, brain lesions are best seen during the second and third weeks after the hypoxic–ischaemic insult. BGT lesions (typically seen in the ventrolateral thalamus and the lentiform nuclei) are the most prevalent site of injury after acute perinatal hypoxia–ischaemia (Miller et al. 2005; Okerekeaf et al. 2008), and are usually accompanied by abnormal signal intensity in the posterior limb of the internal capsule, which is a strong predictor for hypothermia treatment.
of adverse motor outcome (Rutherford et al. 1998). The severity of the BGT injury, together with the signal intensity in the posterior limb of the internal capsule, is the best predictor of the presence and severity of motor impairment (Miller et al. 2005; Rutherford et al. 2010a; Martinez-Biarge et al. 2011). It is relatively common to see abnormal signal intensity in specific cortical regions, such as the central sulcus, the interhemispheric fissure and the insula. The adjacent white matter is also frequently affected. In severe cases, BGT injury may extend to the brain stem, a sign that has been associated with neonatal and later death (Martinez-Biarge et al. 2011). (Fig. 2.18) Isolated white matter and cortical injury can be seen in neonates after a less severe perinatal course (Miller et al. 2005; Martinez-Biarge et al. 2012; Harteman et al. 2013b). White matter injury may also occur accompanying moderate or severe BGT injury either as part of the original insult or secondary to the BGT lesions, and is usually seen to evolve over the later neonatal period. In these patients repeat studies tend to show atrophy in the areas involved and gliotic changes can be seen later in infancy or childhood (Groenendaal and de Vries 2005). The predictive value of conventional MRI is not affected by the use of therapeutic hypothermia. Hypothermia treatment seems to reduce lesions in the basal ganglia and thalami, and in the white matter (Rutherford et al. 2010a; Cheong et al. 2012; Shankaran et al. 2012b).

Diffusion-weighted MRI within the first few days of birth can detect changes in the thalami, basal ganglia, hippocampus, brain stem and peri-rolandic cortex before conventional imaging, usually within the first 48–72 hours after birth (Rutherford et al. 2004), but visual assessment of diffusion changes may underestimate the severity of injury to these structures (Rutherford et al. 2010c). The apparent diffusion coefficient (ADC) can be calculated and may be of further use in making a distinction between those with milder or those with more severe injury to the basal ganglia (Rutherford et al. 2004; Barkovich et al. 2006); it may be of prognostic value (Hunt et al. 2004; Liauw et al. 2009 Charon et al. 2016). Timing of the MRI during the first week after birth is crucial as areas of restricted diffusion may initially only involve the ventrolateral thalami, but will also show involvement of the basal ganglia a few days later (Barkovich et al. 2006). ADC values change over time and will pseudo-normalise by the end of the first week (McKinstry et al. 2002; Barkovich et al. 2006). They are low from days 1–2 to days 3–5, subsequently increasing thereafter (Barkovich et al. 2006). This pseudo-normalisation of diffusion imaging values could be delayed by 2–3 days in infants treated with therapeutic hypothermia (Bednarek et al. 2012). Diffusion changes can also be seen in the anterior and posterior watershed areas, usually in a bilateral and symmetrical distribution. The association between these white matter changes and later outcome is less obvious, and the outcome depends mainly on whether concomitant BGT injury is involved (Harteman et al. 2013b).

Magnetic resonance spectroscopy (MRS) studies have shown that metabolic ratios are abnormal on the first 2 days after birth and continue to worsen until days 4–5, before changes on conventional MRI can be seen (Cheong et al. 2006; Barkovich et al. 2006). Lactate: N-acetylaspartate (Lac:NAA) peak area ratio in the basal ganglia and thalami, assessed between days 1 and 30 after birth, is highly accurate in the prediction of adverse neurodevelopmental outcome (Thayyil et al. 2010). MRS can also be helpful when a metabolic cause for the encephalopathy is suspected. A combination of conventional, diffusion and MRS findings provides more prognostic information than each technique alone (Alderliesten et al. 2011; Goergen et al. 2014). The predictive value of MRS appears to be similar when used in infants who received therapeutic hypothermia (Ancora et al. 2013, Alderliesten 2017).

Prognosis and Outcome of HIE

Prognosis after HIE has traditionally been established based on the clinical severity of the encephalopathy, but this approach has some limitations, especially in children with moderate HIE, in whom prognosis has always been difficult to determine. Infants with mild encephalopathy have been
considered to have a good outcome, whereas those with severe HIE almost always die or develop significant neurodevelopmental sequelae. However, recent long-term follow-up studies have revealed that children with mild encephalopathy might be at increased risk of neurodevelopmental problems, including fine motor problems, specific neuropsychological deficits and behavioural difficulties (van Kooij et al. 2010; van Handel et al. 2010, 2012; Perez et al. 2013; Murray et al. 2016). The pattern and severity of the brain lesions have consistently correlated with the incidence and severity of the neurological sequelae. The recognition of these neuroimaging patterns may help to improve prediction of outcome.

Recent clinical trials on hypothermia have shown that the mortality rate in the neonatal period is around 20%–35% in infants with moderate-to-severe HIE; these figures are lower in cooled than in non-cooled neonates (Tagin et al. 2012). An additional 5–15% of these children will die over the next 18–24 months. Most neonatal deaths occur after redirection of care (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009; Jacobs et al. 2011; Glass et al. 2017).

Infants with severe basal ganglia and brainstem injury seem to be at higher risk of post-neonatal death; (Martinez-Biarge et al. 2011).

CP is the most severe sequela after neonatal HIE and affects 25–35% of survivors of moderate-to-severe HIE (Azzopardi et al. 2009; Jacobs et al. 2011). Although the clinical trials on hypothermia reported a slightly reduced risk of CP in cooled infants, most children with CP still had significant motor impairment (Gross Motor Function Classification System GMFCS levels III–V) and were non-ambulant (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009; Simbruner et al. 2010; Jacobs et al. 2011; Natarajan et al. 2014). However, a recent observational study on cooled infants has reported significant less severe motor impairment in the subgroup of children with CP than the figures reported in the clinical trials (Jary et al. 2015) CP is more common and severe among children with basal ganglia-thalamic injury; whereas in children with lesions restricted to the white matter the incidence is much lower (Miller et al. 2005; Martinez-Biarge et al. 2011, 2012). Children with BGT injury who do not develop CP are still at risk of having mild motor problems at school age (van Kooij et al. 2010).

Clinical trials on hypothermia have reported a 25–35% prevalence of developmental delays (Bayley II or Griffiths Developmental Scales scores <70) in children with moderate-to-severe HIE at 18–24 months (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009; Simbruner et al. 2010; Jacobs et al. 2011). Two clinical trials have reported childhood outcomes after therapeutic hypothermia. In one, the prevalence of an IQ less than 70 in survivors was 27% in cooled and 33% in non-cooled infants; this difference did not reach statistical significance. The percentage of children who died or had severe disability, CP or an IQ <55 was significantly lower in the cooled group (Shankaran et al. 2012c). In the TOBY trial, cooled participants assessed at age 6–7 years were significantly more likely to have a normal IQ (≥85; 52% vs 39%). Again, the rates of severe disability and CP were lower in the cooled group (Azzopardi et al. 2014b). Assessing the cognitive abilities of children with significant motor impairment may be challenging and many long-term studies have focused on children who do not have CP. In these children, the extent of the damage to the white matter has been correlated with cognitive function at age 2–4 years (Steinman et al. 2009; Martinez-Biarge et al. 2012). Van Kooij et al. (2010) found that at age 9–10 years, 25% of children with mild and moderate HIE, who had not developed CP, had an IQ <1 standard deviation (SD) and 7% were <2 SD. Although the mean IQ of the subgroup of children with mild HIE was within the normal range, it was significantly lower than in the normal comparison group. More than 80% of children with CP had an IQ <85 at this age. As well as global low or suboptimal IQ, specific neuropsychological deficits have been described in these children, including attention problems, executive dysfunction and memory impairment (Marlow et al. 2005; van Handel et al. 2012). There is also increasing concern about the impact of HIE on behavioural functioning in childhood and adolescence. Van Handel et al. (2010) found that children with mild and moderate HIE had a higher rate of social problems at age 9–10 years compared with controls; anxious/depressed behaviours and attention problems were also significantly more prevalent in children with moderate HIE.

Visual deficits affect 10–20% of infants with moderate-to-severe HIE (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009); they are more frequent in children with severe BGT lesions or very extensive white matter injury (Mercuri et al. 2004a; Martinez-Biarge et al. 2012). Hearing impairment after HIE is less common; the reported prevalence is around 5% of survivors (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009). Low gentamicin levels in the neonatal period may be a risk factor for permanent hearing loss in infants treated with therapeutic hypothermia (Smit et al. 2013). The risk of epilepsy in infancy is not well known, but it is estimated at around 10–15% in the group of children with moderate-to-severe HIE (Gluckman et al. 2005; Azzopardi et al. 2009; Liu et al. 2017). Risk factors for the development of later epilepsy are the severity of neonatal encephalopathy, the presence and severity of neonatal seizures and the extent of brain injury on neonatal MRI (van Kooij et al. 2010; Glass et al. 2011b; McDonough et al. 2017).

Treatment and Prevention of HIE

After many years without proven treatments, whole body or selective head cooling is now the standard of care for term infants with HIE in low-income countries, and it is increasingly used in middle- and low-income countries, although in these settings its efficacy remains unclear (Pauliah et al. 2013). Recent meta-analyses have shown that, when combined

Hypothermia reduces the metabolic rate, resulting in a slower depletion of energy stores and reduced cerebral oxygen consumption; it preserves tissue pH during impaired cerebral blood flow. As brain injury after hypoxia–ischaemia develops with a delayed pattern (‘secondary brain injury’), which may open a therapeutic window after the insult has taken place, hypothermia should be initiated within the first 6 hours of the hypoxic–ischaemic insult.

Hypothermia is considered to be a safe therapy. Adverse effects are usually mild and reversible; the most common are sinus bradycardia and thrombocytopenia (Jacobs et al. 2013). Most neonatal units treat cooled infants with opioids in order to reduce discomfort and stress; sedation might also improve the effectiveness of hypothermia (Thoresen and Whitelaw 2005). The results of a multicentre clinical trial on hypothermia suggest that opioids could improve neurological outcome in cooled infants (Simbruner et al. 2010).

In addition to hypothermia treatment, supportive intensive care is still a critical element in the management of the infant with HIE. This includes correction of acidosis, cardiorespiratory and metabolic management, and monitoring for multiorgan failure (Azzopardi 2010). Some aspects deserve special attention because they may worsen brain injury. Early hypoglycaemia in the context of HIE correlates with the severity of encephalopathy (Salhab et al. 2004; Basu et al. 2009; Nadeem et al. 2011), and with an increased risk of injury to the corticospinal tract and subsequently worse motor outcome (Tam et al. 2012). Hyperglycaemia has also been associated with worse outcomes in infants with HIE, although the pathological mechanisms are not clear (Spies et al. 2014). Both hyperoxaemia and hypocapnia within the first hours of birth may have deleterious effects in infants with HIE and have been associated with adverse outcomes (Klinger et al. 2005; Pappas et al. 2011; Sabir et al. 2012).

**New Treatments for Hypoxic-Ischaemic Encephalopathy**

Hypothermia does not completely prevent brain injury, especially in neonates with severe encephalopathy. Some drugs used in combination with hypothermia might improve neuroprotection, by prolonging the therapeutic window or by their synergistic neuroprotective effect. Potential therapies that have been investigated in neonates include allopurinol, recombinant human EPO (rhEPO), topiramate, xenon and melatonin.

**Allopurinol** inhibits xanthine oxidase, thereby reducing production of oxygen free radicals during the reperfusion occurring after hypoxia–ischaemia. Despite the first promising results showing a protective effect in neonates and an absence of significant side effects, one meta-analysis of three clinical trials concluded that current data are insufficient to determine whether allopurinol is beneficial in HIE (Chaudhari and McGuire 2012). Allopurinol might be more effective in the subgroup of infants with moderate encephalopathy (Kaandorp et al. 2012). It is thought that administration of allopurinol before or during the hypoxic–ischaemic insult could be more effective than when given after the insult. A dose of 500mg allopurinol, administered to the mother when the first signs of intrapartum fetal distress are seen, is quickly transferred to the fetus and seems to be safe for both mother and infant (Kaandorp et al. 2014). One multicentre clinical trial on antenatal administration of allopurinol did not significantly lower neuronal damage markers in cord blood. Post-hoc analysis revealed a potential beneficial treatment effect in girls (Kaandorp et al. 2015). A large RCT has started (ALBINO trial) administering allopurinol within 30 minutes after delivery.

**Recombinant human EPO** has neuroprotective and neuroregenerative effects. High-dose EPO is well tolerated in term neonates (Wu et al. 2012). Three clinical trials have suggested a beneficial effect of rhEPO administered within the first 48 hours of birth. One of these studies found fewer neonatal seizures among infants treated with rhEPO (Elmahdy et al. 2010). Zhu et al. (2009) found a reduction in the number of children with moderate-to-severe disability and/or death at 18 months, but this was seen only in the subgroup of infants with moderate encephalopathy. A phase II double-blinded, placebo-controlled trial studied 50 newborn infants randomized to receive EPO (1000 U/kg intravenously; n = 24) or placebo (n = 26) at 1, 2, 3, 5, and 7 days of age. All infants had moderate or severe encephalopathy and underwent hypothermia. Neonatal deaths did not significantly differ between EPO and placebo groups (8% vs 19%, P = 0.42). Brain MRI at a mean age of 5.1 days showed a lower global brain injury score in EPO-treated infants; treated infants also obtained better scores on the Alberta Infant Motor Scale at 12 months. (Wu et al 2016).

**Topiramate** is an anticonvulsant drug with multiple mechanisms of action, including anti-glutamatergic properties. Topiramate has been shown to be safe in neonates with HIE treated with hypothermia (Filippi et al. 2010) and one clinical trial using topiramate showed the drug to be safe but did not show a reduction in mortality and severe neurological disability (Filippi et al. 2017).

**Xenon** is a non-toxic anaesthetic gas with very few side effects; it is known to reduce neurotransmitter release to antagonise NMDA receptors. One recent clinical trial (Azzopardi et al. 2016) did not find a significant difference in lactate to N-acetyl aspartate ratio in the thalamus, measured with MRS, or in fractional anisotropy in the posterior limb of the internal capsule, measured with MRI, between 46 infants who received hypothermia in combination with 30% inhaled xenon for 24 hours and 46 infants who received only hypothermia. At the time of writing another clinical trial is testing the effect of 50% inhaled xenon for 18 hours in combination with hypothermia (Dingley et al 2014 [ClinicalTrials.gov identifier: NCT01545271]).

Another potential neuroprotective agent is melatonin, which is well tolerated in the neonatal period and has antioxidantive
Neonatal stroke includes arterial ischaemic stroke (70%) and cerebral sinovenous thrombosis (30%). Arterial ischaemic stroke can be defined as a documented partial or complete occlusion of a vessel in relation to a focal brain lesion, or pattern of lesions that can be explained only by occlusion of a specific brain vessel; however, neonatal cerebral sinovenous thrombosis (SVT) is the presence of a thrombus in a cranial venous sinus, a large deep brain vein or a smaller cortical or deep vein, with partial or complete occlusion (Govaert et al. 2009).

**ARTERIAL ISCHAEMIC STROKE**

The prevalence of perinatal arterial ischaemic stroke (PAIS) is estimated to be between 1 in 2300 and 1 in 5000 live births (Lee et al. 2005a; Schulzke et al. 2005; Darmency-Stamboul et al. 2012). Neonatal stroke is the second most common cause of neonatal seizures (Tekgul et al. 2006; Garfinkle and Shevell 2011; Weeke et al. 2015).

Recent attempts to identify risk factors with the use of population-based studies have implicated both antepartum factors, such as primiparity, pre-eclampsia, infertility and intrauterine growth restriction (Lee et al. 2005a; Kirton et al. 2011; Harteman et al. 2012b Martínez-Biarge et al 2016), and intrapartum factors, such as prolonged rupture of membranes, maternal fever, presence of meconium, prolonged second stage of labour and abnormal fetal heart rate (Kirton et al. 2011; Harteman et al. 2012b). One recent study has identified maternal smoking during pregnancy as an independent risk factor for neonatal stroke (Darmency-Stamboul et al. 2012). Others have emphasised the association with coagulation abnormalities (decreased levels of protein C, protein S and antithrombin III, and elevated levels of homocysteine and Lp(a) lipoprotein, protein Z), as well as certain genetic mutations and polymorphisms (factor V Leiden G1691A, antiphospholipid antibodies, factor II G20210A and MTHFR C677T) (Günther et al. 2000; Kurnik et al. 2003; Curry et al. 2007; Simchen et al. 2009; Kenet et al. 2010). However, as a result of the very low recurrence rate of neonatal stroke (Golomb et al. 2001; Kurnik et al. 2003; Fullerton et al. 2007), thrombophilic factors are unlikely to play a substantial role in the pathogenesis of perinatal stroke (Curtis et al 2017). Male infants are overrepresented in almost all epidemiological studies (Golomb et al. 2009; Govaert et al. 2009; Darmency-Stamboul et al. 2012).

PAIS may also present in association with some neonatal conditions such as meningitis and hypoglycaemia (Fitzgerald and Golomb 2007; Harteman et al. 2012b; van der Aa et al. 2013a). Infants with congenital heart disease are at low risk of perinatal and postnatal brain injury. Perioperative stroke, sometimes after balloon atrial septostomy, is the most common brain lesion seen in this group of neonates (McQuillen et al. 2007).

The left hemisphere is more frequently involved than the right (Govaert et al. 2009; Kirton et al. 2011; Harteman et al. 2012b). Middle cerebral artery infarction accounts for 80% of all instances of PAIS, whereas the posterior cerebral artery is involved in 8–15% of cases (Govaert et al. 2009; van der Aa et al. 2013a). The anterior cerebral artery is rarely affected, but this may reflect the silent nature of symptoms related to the involvement of this vessel. In addition to the better-known cortical infarcts, perforator strokes are also possible in the neonatal period. Risk factors appear to be very similar to those for main artery strokes (Ecury-Goosen et al. 2013).

**Clinical Manifestations of Perinatal Arterial Ischaemic Stroke**

Acute onset of seizures within the first 48 hours of birth is the most common presenting feature of perinatal arterial ischaemic stroke (PAIS) (Kurnik et al. 2003; Golomb et al. 2007b; Kirton et al. 2011). The convulsions are usually of the focal clonic variety, but multifocal tonic or subtle seizures may also be seen. Although many infants with these seizures have undergone a complicated labour and suboptimal Apgar scores, most infants appear healthy in the immediate newborn period and are sent to the postnatal ward with their mother (Martínez-Biarge et al 2016). Many infants show no major clinical neurological abnormality between seizures, although neonatal stroke in infants with mild or moderate HIE has been reported (Ramaswamy et al. 2004; Harteman...
basal ganglia and posterior limb of the internal capsule). The latter method was reported to be strongly associated with early and school age motor outcome (Mercuri et al. 1999, 2004b; Cowan and de Vries 2005). DWI plays an important role in early detection and, along with T1- and T2-weighted changes, can help to define the timing of the infarction (Dudink et al. 2009). Restricted diffusion within the infarcted parenchyma results in increased signal intensity and decreased ADC values on DWI during the first week after birth (Dudink et al. 2009; van der Aa et al. 2013b). Lower ADC values have been seen in larger middle cerebral artery strokes compared with smaller infarcts (van der Aa et al. 2013b). Abnormal signal intensity on DWI in the descending corticospinal tracts, including the cerebral peduncles, has been reported to be a reliable predictor for the development of hemiplegia (de Vries et al. 2005; Kirton et al. 2007; Husson et al. 2010) (Figs. 2.19 and 2.20). This abnormal signal intensity has been shown to precede Wallerian degeneration (de Vries et al. 2005) and is therefore referred to as ‘pre-Wallerian degeneration’. Established Wallerian degeneration of the ipsilateral corticospinal tract and secondary reduction in thalamic size/volume can also be seen on conventional imaging after the first month (Dudink et al. 2009). Additional MRI techniques, such as diffusion tensor imaging, have recently shown to be useful in predicting outcome (van der Aa et al. 2011, 2013c).

Diagnosis of PAIS

Although the diagnosis of PAIS can be made using cranial ultrasonography in most cases (Cowan et al. 2005; Abels et al. 2006), the area of infarction may remain undetected, especially when ultrasonography is restricted to the first days after birth, or when the infarction is small or located superficially in the parietal or occipital region (Golomb et al. 2003a). The increased use of MRI has facilitated early recognition of this type of injury (Cowan et al. 1994; de Vries et al. 2005; Dudink et al. 2009). On T2-weighted images the infarct can be seen from day 2 as increased signal intensity in the cortex and white matter, associated with loss of grey–white matter differentiation and poor delineation of the borders during the first few days. On T1-weighted images, the affected cortex is initially of low signal intensity, changing to a low-signal intensity (cortical highlighting) after day 6, whereas the adjacent white matter is of moderately low-signal intensity for the first 8–10 days. Signs of tissue loss, including focal atrophy and cystic evolution, can be seen from the start of the third week, and especially after the first month (Dudink et al. 2009). The area of infarction can be described by looking at either the branches that are affected (main branch, cortical branch, or one or more lenticulostriate branches of the middle cerebral artery) or the number of sites that are involved (hemisphere, basal ganglia and posterior limb of the internal capsule). The latter method was reported to be strongly associated with early and school age motor outcome (Mercuri et al. 1999, 2004b; Cowan and de Vries 2005). DWI plays an important role in early detection and, along with T1- and T2-weighted changes, can help to define the timing of the infarction (Dudink et al. 2009). Restricted diffusion within the infarcted parenchyma results in increased signal intensity and decreased ADC values on DWI during the first week after birth (Dudink et al. 2009; van der Aa et al. 2013b). Lower ADC values have been seen in larger middle cerebral artery strokes compared with smaller infarcts (van der Aa et al. 2013b). Abnormal signal intensity on DWI in the descending corticospinal tracts, including the cerebral peduncles, has been reported to be a reliable predictor for the development of hemiplegia (de Vries et al. 2005; Kirton et al. 2007; Husson et al. 2010) (Figs. 2.19 and 2.20). This abnormal signal intensity has been shown to precede Wallerian degeneration (de Vries et al. 2005) and is therefore referred to as ‘pre-Wallerian degeneration’. Established Wallerian degeneration of the ipsilateral corticospinal tract and secondary reduction in thalamic size/volume can also be seen on conventional imaging after the first month (Dudink et al. 2009). Additional MRI techniques, such as diffusion tensor imaging, have recently shown to be useful in predicting outcome (van der Aa et al. 2011, 2013c).

EEG reveals characteristic focal abnormalities in most patients (Mercuri et al. 1999; Selton et al. 2003; Low et al. 2014). These include ipsilateral suppression of the background activity, unilateral theta bursts with intermixed sharp or spike waves and disturbed sleep cycling over the infarcted side (although usually still present), and a characteristic pattern of seizures (focal sharp waves and spike–polyspike seizures at a frequency of 1–2Hz over the area of infarction) (Low et al. 2014). These abnormalities can be detected soon.
after birth, even before the onset of the clinical seizures (Walsh et al. 2011). Neonatal seizures can be difficult to recognize on the basis of clinical observation alone (Malone et al. 2009). Continuous EEG monitoring should therefore be started in all infants with a suspected neonatal stroke and should continue until the infant is seizure free for at least 24 hours (Shellhaas et al. 2011). EEG is useful for detection of ongoing seizure activity and to monitor response to therapy; and also aids in the prediction of outcome. Mercuri et al. (1999) found that an abnormal background pattern, even when recorded on only two channels, was the best predictor of adverse motor outcome. Although the criterion standard for neonatal brain monitoring is continuous multichannel EEG, aEEG can be used to document the overall patterns of background activity and to identify seizures of longer duration. Shorter and some focal seizures can be missed with the use of aEEG alone (Boylan et al. 2013). In infants with unilateral injury, two-channel recording can detect more seizure patterns on the affected side, and sometimes also a difference in background activity, compared with one-channel recording (van Rooij et al. 2010b; Boylan et al. 2013); it is therefore the aEEG modality of choice in these neonates (Boylan et al. 2013).

Other investigations can be helpful in order to exclude a specific cause for the stroke: thrombophilia screen, echocardiogram, assessment of vascular neck anatomy and Doppler ultrasonography of the umbilical or femoral vessels if or when catheters have been used.

**Prognosis and Outcome of PAIS**

Unilateral spastic CP (USCP) is the most important sequela and affects 25–40% of infants with unilateral arterial infarction (Boardman et al. 2005; Lee et al. 2005b; Husson et al. 2010, Chabrier et al. 2016). The upper limb is more affected than the lower limb and almost all children can walk (Golomb et al. 2003b). An additional 30% of children with unilateral ischaemic infarction may show minor signs of motor impairment at school age, such as asymmetry or poor motor competence (Mercuri et al. 2004b). Motor signs usually appear towards the end of the first year, but neurological assessment at the age of 3 months (including assessment of general movements) can be helpful in identifying infants who will develop USCP (Guzetta et al. 2003, 2010; van der Aa et al. 2011). Global and cognitive development are usually normal during the first 2–3 years, and most children have good cognitive results at early school age (Ricci et al. 2008), but long-term longitudinal follow-up of these children has revealed that a significant proportion of them may show emerging deficits in several cognitive domains as academic demands increase (Westmacott et al. 2009; van Buuren et al. 2013, Chabrier et al. 2016). Usually these deficits are in the mild range and most children are still able to attend mainstream school. Cognitive impairment is more common in children who develop USCP and epilepsy (Golomb et al. 2007a; Ballantyne et al. 2008; van Buuren et al. 2013 Chabrier et al. 2016). Specific neuropsychological deficits, such as poor visuomotor integration, impaired working memory and poor complex language skills have also been described (Westmacott et al. 2009; van Buuren et al. 2013; Reilly et al. 2013). Boys seem to be at higher risk of poor performance than girls (Westmacott et al. 2009).

Abnormalities in visual function are not common, but can be seen in some children with large infarcts who subsequently develop USCP, and in children with infarcts in the territory of the posterior cerebral artery (Mercuri et al. 2003; van der Aa et al. 2013a).

Children who had PAIS are at higher risk of developing seizures or even epilepsy in infancy and childhood. The incidence of this problem is unknown (Chabrier et al. 2016) and the reported rates are very variable (Golomb et al. 2007a; Ricci et al. 2008; Wanigasinghe et al. 2010, Fox et al 2016). In a prospective study 73% of children who had a neonatal stroke were seizure free at the age of 3 years; only half of those who had seizures eventually developed epilepsy (Wusthoff et al. 2011). Epilepsy is more common in children who also have USCP (Golomb et al. 2007a).

**Treatment and Prevention of PAIS**

Management of infants with PAIS includes general supportive care, correction of hypoglycaemia, antibiotics in cases of...
documented or suspected infection, and anticonvulsants. Anticoagulation therapy is not recommended, unless there is a documented ongoing cardioembolic source or in neonates with recurrent infarcts (Monagle et al. 2008). One study has suggested that hypothermia could be protective in neonates with arterial ischaemic infarction, by reducing the occurrence of acute seizures. In this study all the treated infants had presented with encephalopathy and had been cooled within the first 6 hours of birth (Harbert et al. 2011). The lack of obvious symptoms during the first hours after birth, when hypothermia is thought to be neuroprotective, is a potential limitation in the treatment of neonatal stroke. Some pharmacological agents are currently being tested and could be beneficial in the near future. One of these, rhEPO, has anti-inflammatory and anti-apoptotic properties and has been found to be safe in a study in neonates with stroke (Benders et al. 2014). Another focus of research is stem cell-based therapies. Stem cells have an intrinsic potential for self-renewal and are currently being tested in several clinical trials in neonates with neurological disorders, including stroke (Wågenaar et al. 2017).

CEREBRAL SINOVENOUS THROMBOSIS

The reported incidence of cerebral sinovenous thrombosis (CSVT) varies from < 1 to 12 per 100 000 live births (Berfelo et al. 2010; Yang et al. 2010). Although infrequent, CSVT in the neonatal period is associated with a mortality rate of 10–20% (usually due to the associated morbidities), and with a low incidence of long-term neurological sequelae. As in arterial ischaemic infarction, male infants seem to be at higher risk of CSVT (Golomb et al. 2009; Tan et al. 2011).

Antecedent risk factors and clinical history are usually different from infants with HIE or arterial ischaemic stroke. A significant number of neonates with CSVT have other medical conditions at the time of diagnosis, such as congenital heart disease, meconium aspiration syndrome or sepsis/meningitis, or had been on extracorporeal membrane oxygenation (ECMO) (Wu et al. 2002). Maternal and intrapartum complications (pre-eclampsia, chorioamnionitis, complicated delivery, low Apgar scores) have also been described (Wu et al. 2002; Fitzgerald et al. 2006; Berfelo et al. 2010). The presence of multiple risk factors is not uncommon (Wu et al. 2002). Dehydration has been traditionally associated with CSVT (deVeber et al. 2001), although, in recent studies, its frequency has decreased (Berfelo et al. 2010).

Prothrombotic disorders have been reported in 20% of infants with CSVT (deVeber et al. 2001), but, as in arterial infarction, their role in the pathogenesis of CSVT remains unclear. It has also been proposed that occipital bone compression of the superior sagittal sinus, which is associated with supine head positioning, might play a role in the pathogenesis of CSVT in neonates (Tan et al. 2011).

The sagittal and the transverse sinuses are the most commonly involved (Fitzgerald et al. 2006; Teksam et al. 2008; Tan et al. 2011). More than half the neonates with CSVT show involvement of multiple sinuses. (Fitzgerald et al. 2006; Tan et al. 2011; Kersbergen et al. 2011). The vast majority of infants with symptomatic CSVT have concomitant brain lesions, generally correlated with the corresponding venous drainage territory (Teksam et al. 2008). The most common lesion is intraventricular hemorrhage, usually associated with thalamic hemorrhage (Kersbergen et al. 2011) (see Fig. 2.3). Other patterns of injury that have been described are occipital or parietal-occipital infarction, periventricular infarction and haemorrhagic lesions in the caudate nuclei (Wu et al. 2002; Kersbergen et al. 2011).

Clinical Manifestations of CSVT

As in arterial stroke, seizures are the most common presenting symptom, occurring in 50–70% of cases (Wu et al. 2002; Fitzgerald et al. 2006; Berfelo et al. 2010), but more subtle signs are also frequent, including lethargy, apnoea, irritability, abnormal muscle tone and a full fontanelle (deVeber et al. 2001; Wu et al. 2002; Fitzgerald et al. 2006; Berfelo et al. 2010). Infants on ECMO may not show clinical symptoms because they are paralysed, and a low index of suspicion is needed to establish the diagnosis in these neonates (Wu et al. 2002).

Diagnosis of CSVT

Cranial ultrasonography should be performed in all neonates with seizures, apnoeas or other neurological symptoms, and can detect intraventricular and thalamic haemorrhages, which are highly suggestive of CSVT in term infants (Wu et al. 2003; Kersbergen et al. 2011). Colour Doppler ultrasonography is very useful in the evaluation of normal cerebral venous sinuses (Miller et al. 2012), and can suggest CSVT by showing complete or partial absence of flow from an occlusive thrombus (Berfelo et al. 2010). When IVH or unilateral thalamic haemorrhage is seen on ultrasonography, early confirmation of diagnosis with MRI within the next 24–48 hours is indicated. MRI including MR venography (MRV) can show lack of flow in a sinus, and can also define the site of the venous occlusion; it is, therefore, required to confirm the diagnosis (Roach et al. 2008; Kersbergen et al. 2011). Follow-up MRI, 6–12 weeks’ later, is useful to document recanalisation of the affected sinus, which occurs in almost all cases within the first 3 months (Moharir et al. 2011), and to delineate the extent and severity of the parenchymal lesions.

Prognosis and Outcome of CSVT

Abnormal neurodevelopmental outcomes range between 40% and 80% (Fitzgerald et al. 2006; Kersbergen et al. 2009; Berfelo et al. 2010) and include motor problems, cognitive impairment, epilepsy, visual deficits and development of posthaemorrhagic hydrocephalus. The presence of associated
BILIRUBIN ENCEPHALOPATHY

The term ‘kernicterus’ was initially applied to the yellow staining of the basal nuclei found post mortem in deeply jaundiced infants who died with severe erythroblastosis fetalis. Later, it was also used to designate the clinical picture of choreoathetosis and hearing loss that followed severe haemolytic disease. More recently the term has been applied to similarly stained brains of infants who died without blood group incompatibility and had only modest rises of blood bilirubin. Some authors have suggested that such modest rises could be associated with impairment of cognitive or other neurological functions, although others did not find such a relationship.

The term ‘bilirubin encephalopathy’ is now more often used than kernicterus for the neuropathological findings of bilirubin staining of brainstem and basal nuclei, and for the classic neurological picture, even though neuronal damage can be present without staining; conversely, bilirubin staining may be an agonal phenomenon unrelated to bilirubin toxicity (Ahdab-Barmada and Moossy 1984). Some investigators have proposed a stricter definition requiring both staining and neuronal damage (see Volpe 2017), whereas simple staining of nuclei without neuronal lesions in preterm infants, often associated with only moderate hyperbilirubinaemia, is considered to be a different phenomenon. Similarly, the term ‘chronic bilirubin encephalopathy’ will be used for all demonstrated or possible sequelae of bilirubin toxicity. An incidence of one in 44,000 live births was recently reported from a Canadian-based population, with a bilirubin serum level exceeding 425µmol/L or 24.8mg/dL (Sgro et al. 2012). In another population-based study an incidence of approximately one in 95,000 live births was found for acute bilirubin encephalopathy in Ireland and the UK, based on surveillance from May 2003 to May 2005. The lower incidence can be explained by the higher cut-off value of 515µmol/L (Manning et al. 2007).

NEONATAL STROKE IN THE PRETERM INFANT

There are very few reports on the prevalence and clinical characteristics of neonatal ischaemic infarction in preterm infants. In a tertiary referral centre in the Netherlands perinatal stroke was diagnosed in seven per 1000 preterm infants admitted to the neonatal unit (Benders et al. 2007). This incidence is much higher than in term infants. Only 23% of these infants presented with seizures or apnoeas; an additional 13% had HIE. In the vast majority, the diagnosis was made by routine cranial ultrasound examination. As in term infants, the left middle cerebral artery was the most affected territory, but lenticulostriate infarcts were relatively more common than in term infants, especially among the more immature group (Benders et al. 2007). Reported risk factors for neonatal stroke in this population are twin-to-twin transfusion syndrome, intrapartum abnormal fetal heart rate pattern and neonatal hypoglycaemia (Benders et al. 2007; Golomb et al. 2008; Ecury-Goossen et al. 2013).

The scarce follow-up data available suggest that preterm infants who have an arterial ischaemic stroke experience more neurodevelopmental problems and a higher rate of CP than term infants (Golomb et al. 2008; Benders et al. 2009).

CSVT has been considered rare in the preterm infant (Wu et al. 2002), but its incidence in this group may be underestimated because most infants are asymptomatic. Systematic serial cranial ultrasound examinations in a preterm population have shown an incidence of SVT of 4.4% (Raets et al. 2013). Extensive white matter injury is the predominant pattern of lesions in preterm infants with CSVT. Intraventricular haemorrhage (usually of late onset) and unilateral thalamic haemorrhage can also occur, although less common than in term infants (Kersbergen et al. 2011).
Pathology and Pathogenesis

In addition to the macroscopic staining of the globus pallidus, dentate nuclei, cerebellar vermis, hippocampus and medullary nuclei, yellow pigment may be present in the meninges and choroid plexus. Microscopically, spongy degeneration and gliosis are present in the stained areas and in zones that are not macroscopically involved, such as the cochlear nuclei and pathways. Pigment deposition is visible in neurons and glial cells. Neuronal necrosis generally involves the same structures as bilirubin staining, although some structures, (e.g. Purkinje cells), may be severely affected without significant staining.

The mechanism of kernicterus is unclear. The interrelationship of albumin, free and bound bilirubin, and kernicterus or bilirubin encephalopathy is shown schematically in Figure 2.21. Free bilirubin, i.e. the fraction of bilirubin not bound to albumin, crosses the blood–brain barrier and exhibits neurotoxicity. Bilirubin is undoubtedly toxic when it reaches neural tissue, perhaps by inhibiting phosphorylation and respiration in mitochondria (Perlman and Frank 1988). Normally, bilirubin is maintained within the vascular compartment where it is bound to albumin in an approximately equimolar concentration. The small unbound fraction may increase as a consequence of displacement from bilirubin-binding sites on albumin by exogenous agents, such as certain drugs, or endogenous substances such as fatty acids. Bound bilirubin may not be harmless and it can cross the blood–brain barrier, especially when the latter is damaged by factors such as hypercapnia or hyperosmolarity, although unbound bilirubin is the major offender (Volpe 2017). In haemolytic disease, the low amount of free bilirubin accounts for the occurrence of kernicterus, at levels beyond 340µmol/L (20mg/dL), although much higher levels are not necessarily noxious (Newman et al. 2006). Petersen et al. (2014) studied the role of uridine diphosphate glucuronosyltransferase 1A1 (UGT1A1), in particular the UGT1A1*28 genotypes, in extreme hyperbilirubinaemia (>24.5mg/dL). They did not find an association between the UGT1A1*28 allele and the risk for developing extreme hyperbilirubinaemia. Determination of the binding capacity of albumin has not proved helpful in practice, the more so because many factors that increase the risk of bilirubin encephalopathy do not produce detectable increases in free levels. Even though preterm infants with low albumin levels, acidosis, sepsis or peri-intraventricular haemorrhage (Govaert et al. 2005) are much more likely to develop kernicterus than those without such factors, it remains impossible to predict which infant will exhibit bilirubin toxicity. In the study by Govaert et al. (2003), five preterm infants of 25–29 weeks’ gestational age presented with total serum bilirubin (TSB) levels below commonly advised exchange transfusion thresholds. Mixed acidosis was present in three infants around the TSB peak. The bilirubin: albumin (B:A) molar ratio was >0.5 in all, in the absence of displacing drugs. All failed to pass bedside hearing screen tests and had severe hearing loss on auditory brain response testing. Four of the five infants presented with severe developmental delay as a result of dyskinetic CP and hearing loss. In a prospective, randomised controlled trial, 615 preterm infants of 32 weeks’ gestation or less were randomly assigned to treatment based either on the B:A ratio and TSB thresholds or on just the TSB thresholds, and outcome was assessed at age 2 years. The additional use of the B:A ratio in the management of hyperbilirubinaemia in preterm infants did not improve their neurodevelopmental outcome (Hulzebos et al. 2014).

Some evidence (Perlman and Frank 1988) suggests that bilirubin could enter the brain in a reversible manner and be responsible for a ‘subclinical neurotoxicity’ that could either be transient or evolve into definitive neuronal damage. This hypothesis is based mainly on alterations of auditory and visual evoked potentials with hyperbilirubinaemia. Evoked potentials may return to normal after an exchange transfusion (Delic et al. 1990). If this hypothesis were to be confirmed, it would be possible to contemplate exchange transfusion on the basis of clinical and electrophysiological signs rather than solely on bilirubin levels (Perlman and Frank 1988), but the evidence is far from complete and the method difficult to use in practice. A similar attempt using MRI (Palmer and Smith 1990) remained inconclusive.

Clinical and Neuroimaging Manifestations

BILIRUBIN ENCEPHALOPATHY IN THE TERM INFANT

The classic picture of the term infant with typical kernicterus is not common in developed countries, although there appeared to be a slight increase after the changes to the guidelines in the 1990s which allowed higher bilirubin levels before initiating treatment (Ebbesen 2000). The increase in the number of cases of kernicterus was considered by Ebbesen to have been caused by, among other things, (1) a decreased awareness of the pathological signs, (2) a change in the assessment of the risk of bilirubin encephalopathy and (3) difficulty in estimating the degree of jaundice in certain groups of immigrants. Furthermore, immigration and intermarriage allowed the spread of glucose-6-phosphate dehydrogenase (G6PD) deficiency mutants to geographical areas distant from its place of origin and thus transformed severe neonatal jaundice associated with G6PD deficiency into a global problem.

The first neurological signs develop between age 48 hours and 4 days. The early phase presents with lethargy, hypotonia and poor suck. These changes are usually reversible with appropriate treatment. In the intermediate phase, moderate stupor, irritability and hypertonia are seen. Fever, low-pitched cry, drowsiness and hypotonia may be present. Hypertonia is manifested by the backward arching of the neck (retrocollis) and trunk (opisthotonos). Many believe that acute bilirubin encephalopathy that has advanced to this stage is irreversible, but recent evidence suggests that reversibility may be possible (Hansen et al. 2009). In the advanced phase, pronounced retrocollis/opisthotonos, shrilr cry, anorexia, apnoea, fever, deep stupor to coma and seizures may be seen, and the infants may die. Although rare, an apparently normal outcome has been described (Hansen et al. 2009). A scoring system (bilirubin-induced neurological dysfunction – BIND) has
Figure 2.21  Schematic representation of the relationship between albumin, free and bound bilirubin, and kernicterus or bilirubin encephalopathy.

[Modified from Hansen and Bratild (1986).]

(*) May be due to drugs (e.g. sulfonamides), low albumin levels, and perhaps other factors such as acidosis: also observed in Crigler–Najjar syndrome (glucuronid transferase deficiency). Except in the latter case it is almost exclusively observed in preterm infants.

(**) Generally due to Rh haemolytic disease or ABO incompatibility.

(***) Intervention might be possible at this point to prevent neurological involvement.
been developed to follow the onset, severity and progression of acute bilirubin encephalopathy (Hansen 2011). In this scoring system, characteristics of mental state, muscle tone and cry are grouped into three levels of increasing abnormality: stage IA, minimal signs; stage IB, progressive but reversible with treatment; and stage II, advanced and largely irreversible, but may be significantly decreased by treatment. Characteristics for each category are given a weight of 1, 2 or 3 according to their severity and then summed up for an overall score. Greater risk is associated with higher numbers (0–9). A recent study performed in 220 (near) term infants with severe hyperbilirubinaemia showed that the BIND score can be used to evaluate the severity of acute bilirubin encephalopathy and predict residual neurologic and hearing dysfunction. The BIND score was obtained serially at 6- to 8-hour intervals and were correlated with TSB, neurological and auditory outcomes. All infants with a BIND scores of 7-9 either died or suffered residual neurological and auditory impairment. Fifteen (62.5%) of 24 cases with moderate encephalopathy (BIND 4-6), were normal at follow-up following intervention. Three of 73 infants with mild encephalopathy (BIND scores 1–3) but severe jaundice (TSB ranging 33.5–38 mg/dL; 573–650 µmol/L) had residual neurological and/or auditory impairment. A BIND score ≥4 had a specificity of 87.3% and a sensitivity of 97.4% for predicting poor neurological outcomes (El Houchi et al 2017). Deafness and choreoathetosis may appear later, even in the absence of neurological signs in the neonatal period.

Neuroimaging is not straightforward. Cranial ultrasonography may show increased echogenicity in the pallidum, but MRI is the imaging method of choice, even though abnormalities are not seen in all affected infants (Fig. 2.22) (Cece et al. 2013). In a study by Gkoltsiou et al. (2008), 11 infants were reported with total serum bilirubin levels of 235–583µmol/L in the preterm and 423–720µmol/L in the term infants. On the early MRI, the T1-weighted sequence tended to show increased signal intensity in the globus pallidus. On later MRI, the predominant abnormality was increased signal intensity on T2-weighted images with low signal intensity on T1-weighted images. Early scans did not reliably predict motor deficits although all children with CP had abnormal central grey matter on later scans. In the absence of MRI abnormalities at term equivalent age it was suggested that MRI be repeated at age 5 months. Low signal intensity in the globus pallidus on T1-weighted images may be normal in late preterm infants and can be difficult to distinguish from pathology that may also be caused by liver disease, prolonged parental nutrition and manganese exposure (Mirowitz et al. 1991). Abnormalities in the subthalamic nuclei were seen only at term but were associated with hearing loss even when the neonatal auditory brainstem response (ABR) was reported as normal, suggesting that careful observation of this region is important at this age. In a large study by Cece et al. (2013), MRI, including DWI, was performed in 30 infants with acute bilirubin encephalopathy. Neonatal imaging abnormalities were seen in 22 of 30 infants. Rather than a decrease in ADC values in the globus pallidum, a significant increase was noted. In another large study (Wang et al. 2008), including 24 term infants with bilirubin encephalopathy, ADC values were also noted to be increased but this did not reach statistical significance. Similar to the study by Cece et al. (2013), not all infants (19 of 24) had abnormalities on their MRI. They were also able to...
perform proton MRS (1H-MRS) and found that the peak area ratios of NAA: choline and NAA: creatinine were significantly decreased (P<0.05) in the patients compared with the comparison group in the basal ganglia.

**Bilirubin Encephalopathy in the Preterm Infant**

Making the diagnosis of bilirubin encephalopathy is especially difficult in the preterm infant. Several studies have shown that bilirubin encephalopathy in the preterm infant may not be recognised during the neonatal period (Govaert et al. 2003; Okumura et al. 2009). In a report on eight preterm infants with a gestational age <34 weeks’, no infant showed neurological symptoms characteristic of classic acute bilirubin encephalopathy (Okumura et al. 2009). Gestational age was <26 weeks’ in six of the eight infants. Peak serum bilirubin levels were >15mg/dL in only three infants. All patients developed extrapyramidal motor impairment, without apparent spasticity after discharge. Dystonic posture and abnormal muscle tone were first recognised within 6 months (of corrected age) in all patients. MRI showed typical signal intensity changes in the globus pallidus on T2-weighted imaging at age 6–8 months, but no abnormalities were found on neonatal MRI.

### Clinical Outcome of Bilirubin Encephalopathy

There is no single criterion to determine whether neurological or neurodevelopmental problems are due to hyperbilirubinaemia in children and adults. In his review, Shapiro (2010) uses combined information from history, physical (neurological) examination and laboratory studies. On examination, atetosis (slow writhing movements), dystonia (abnormal tone, fixed postures, co-contraction of agonist and antagonist muscles), variable hypo-/hypertonia, spasticity, ataxia, incoordination, impaireupgaze, staining or flaking of deciduous teeth (enamel hypoplasia), dysarthria, hearing impairment or difficulty localising sound may be found. Although their cognitive function is extremely difficult to assess due to their severe movement disorders and deafness, Shapiro considers it to be well within the normal range in most children. As localisation can be characterised as either auditory or motor predominant, a new classification was proposed (Table 2.4).

Vandborg et al. (2012) studied outcome in term and late preterm infants with severe and extreme neonatal hyperbilirubinaemia (total serum bilirubin level >25mg/dL) with no symptoms of intermediate or advanced bilirubin encephalopathy in the neonatal period, and compared these infants with a matched control group. They used the parent-completed Ages and Stages Questionnaire (ASQ) and found no evidence of developmental delay in children aged between 1 and 5 years compared with a matched control group.

Several authors have entertained the possibility that bilirubin toxicity in preterm infants may remain unapparent

### Therapy of Bilirubin Encephalopathy

The treatment of kernicterus in term infants with haemolysis rests on the prevention of excessive hyperbilirubinaemia.
Exchange transfusion is indicated for infants with erythroblastosis at a level of 340 µmol/L (20 mg/dL) (Hansen 2011). Prevention and prenatal treatment of blood group incompatibility have resulted in almost complete disappearance of this problem. In a study by Watchko and Claassen (1994) only three of 81 infants had demonstrated kernicterus at relatively low bilirubin levels. Half the remaining 78 infants had bilirubin levels in excess of those recommended by the US National Institute of Child Health and Human Development, so the indications for exchange remain uncertain (American Academy of Pediatrics Subcommittee on Hyperbilirubinemia 2004; Wennberg et al. 2006). In preterm infants, exchange transfusion is of uncertain value and there is no agreement as to the levels at which it should be performed (Watchko and Maisels 2003). Although relatively safe, the procedure carries certain risks.

Phototherapy effectively increases the removal process of bilirubin in preterm infants. The technique is safe, and breakdown products do not seem to produce bilirubin encephalopathy while lowering peak levels of bilirubin by an average of 70 µmol/L (4 mg/dL). The value of mesoporphyrin mesoporphyrin compounds inhibiting heme-oxygenase of bilirubin production is being tested and encouraging results have been reported, for instance in infants with G6PD deficiency (Kappas et al. 2001).

Low levels of bilirubin may induce some behavioural changes in the absence of encephalopathy but these are probably of limited significance.

### METABOLIC INSULTS: NEONATAL ASPECTS

Metabolic disorders are considered in Chapter 9. Only the specific aspects of metabolic problems in the newborn infant are discussed here.

#### NEONATAL HYPOGLYCAEMIA

The level of blood glucose concentration that leads to cerebral injury in newborn infants and adverse neurodevelopmental outcome is unknown: low blood glucose levels are observed during postnatal adaptation of healthy term infants without apparent adverse consequences, and the capacity to mobilise and use alternative cerebral fuels when blood glucose levels are low varies between patient groups. There is a lot of discussion about the definition of hypoglycaemia and the cut-off value of safe glucose levels in the newborn infant (Cornblath et al. 2000). The conventional definition of significant hypoglycaemia in the neonate is a blood sugar level of <1.1 mmol/L (20 mg/dL). Related to a paper by Koh et al. (1988), values <2.6 mmol/L (45 mg/dL) are now also considered to be potentially deleterious to the developing brain. Both figures are rather arbitrary because some infants may be symptomatic with levels of 1.6–2.2 mmol/L (30–40 mg/dL), whereas many others do not have symptoms even at levels well below 1.1 mmol/dL. Other factors such as the rate of fall of glucose and the duration of low glucose levels and associated hypoxia–ischaemia are thus important. Asymptomatic, transient hypoglycaemia can be detected in 11% of all newborn infants during the first hours postpartum before oral feeding is initiated (Fenichel 1997), especially in those with fetal growth restriction or birth asphyxia, or in those born to mothers with diabetes or toxemia (Cornblath and Schwartz 1991). The incidence of symptomatic hypoglycaemia is certainly much lower. It is important to sample whole blood because the glucose concentration of plasma is higher than that of whole blood, and it is essential that accurate methods of measurement be used to make the diagnosis of neonatal hypoglycaemia, and to be aware that measurements from glucose reagent strips are not reliable in this low range (Beardsall 2010, Martinelli et al 2017).

#### Mechanisms and Pathology

The mechanisms of neonatal hypoglycaemia are diverse. Rarely infants suffer from grave conditions such as nesidioblastosis. In most, especially in small-for-gestational age neonates, an imbalance between a relatively large brain, which consumes glucose as its primary fuel, and a small liver depleted of glycogen reserves seems to compromise supply of glucose to the CNS. The absence of symptoms in many infants with hypoglycaemia may be related to the fact that the newborn brain can oxidise fuels other than glucose, such as ketone bodies, lactic acid and fatty acids.

The pathology of hypoglycaemia is reminiscent of that of hypoxia, with which it is often associated. Neuronal cell loss involves not only the brain but also the anterior horn cells of the spinal cord, but it usually predominates in the posterior part of the cerebrum.

In infants with neonatal encephalopathy after perinatal hypoxia–ischaemia, involvement of the white matter and the WS pattern of injury was associated with hypoglycaemia, and hypoglycaemia was also identified as an independent risk factor in the preterm (Benders et al. 2007) and term newborn infants with PAIS (Harteman et al. 2012b, 2013).

#### Neuroimaging Findings

As the posterior part of the cerebrum is not well visualised using the anterior fontanelle, in recent years information about brain injury has become available with the increased use of MRI. MRI data have shown predominant involvement of the parieto-occipital white matter, as well as abnormal signals in the deep grey matter structures of the thalamus and basal ganglia, after symptomatic neonatal hypoglycaemia in term neonates (Barkovich et al. 1998; Filan et al. 2006; Tam...
et al. 2008; Burns et al. 2008). In the study of Tam et al. (2008) MRI was performed early, concentrating on DWI findings, whereas, in the study of Burns et al. (2008), neuroimaging was performed within the first 6 weeks after birth. In the study by Tam et al. (2008) there was a significantly higher incidence of occipital lobe findings. In a large study of more than 100 infants with hypoglycaemia, including also preterm infants and infants older than 28 days, abnormal MRI findings were found in 4% of preterm infants, 32.5% of term infants and 43.5% of older infants (Caksen et al. 2011). Abnormal MRI findings were significantly more common in symptomatic infants than in asymptomatic infants (Fig. 2.23).

Clinical Features of Neonatal Hypoglycaemia

Neurological manifestations of neonatal hypoglycaemia include apnoea, jitteriness, low-pitched cry, cyanosis, vomiting, seizures and coma, isolated or in any combination. The occurrence of symptoms seems to depend more on the duration of hypoglycaemia than on its degree. Several types can be observed. In the first few hours after birth, an ‘adaptive’ hypoglycaemia frequently occurs in infants of diabetic mothers, those with erythroblastosis fetalis and many preterm asphyxiated infants. Most infants with onset in the first 12 hours after birth remain asymptomatic. Secondary hypoglycaemia usually occurs in the latter part of the first day after birth and is seen in severely asphyxiated infants born at or before term. The part played by hypoglycaemia in such cases is difficult to disentangle from that of the primary disorder. The classic type is seen primarily in small-for-gestational age infants. Symptoms are present in about 20% of such patients. They appear in the latter part of the first day or in the second day.

The outlook depends on the severity and duration of the hypoglycaemia and on therapy. Recurrent hypoglycaemia, however, is usually associated with hyperinsulinism, glucagonoses, fructose intolerance, or other disorders of carbohydrate metabolism or regulation. Congenital hypopituitarism, although infrequent, is an important cause because recognition is essential to avoid recurrences and intellectual disabilities. Symptomatic hypoglycaemia in otherwise healthy, breastfed, term newborn infants has also been reported and is seen in children where the breast milk intake is insufficient and additional intake not given (Moore and Perlman 1999). Breastfed children are known to have lower blood glucose concentrations and higher ketone body concentrations on days 2 and 3 after birth than formula-fed infants (Hawdon et al. 1994).

There is increasing evidence of neurodevelopmental sequelae after symptomatic neonatal hypoglycaemia, usually not in the form of severe CP but with some milder motor problems, visual, learning and behavioural difficulties, poor head growth and later seizures (Yalnizoglu et al. 2007; Caksen et al. 2011; Karimzadeh et al. 2011; Tam et al. 2012). Lasting effects may follow relatively mild hypoglycaemia. Koh et al. (1988) reported delayed nerve conduction velocities in children with marginal hypoglycaemia that persisted after correction of the metabolic defect. Lucas et al. (1988) found that children who had prolonged biochemical hypoglycaemia had a 3–14-point disadvantage on the Bayley scale compared with normoglycaemic children, although this was a retrospective study with consequent limitations. In a large study of almost 1000 moderately preterm infants (gestational age 32–36 weeks’), hypoglycaemia, defined as at least 1 plasma glucose value <1.7 mmol/L (30 mg/dL) within the first 72 hours after birth, was noted in 8.1% of the infants. In the multivariable
analysis only hypoglycaemia remained significantly associated with a developmental delay (OR = 2.19; 95% CI = 1.08–4.46) (Kerstjens et al. 2012).

Treatment of Neonatal Hypoglycaemia
An algorithm for the management of severe hypoglycaemia was suggested by Boardman et al. (2013). Treatment of neonatal hypoglycaemia consists of the intravenous administration of 0.5–1.0g/kg of glucose as a 25% solution at a rate of 1mL/min, followed by continuous infusion of 8–10mg/kg per min. The bolus injection should be used only in case of emergency and should always be associated with an increase in the glucose intake after the bolus (AAP guidelines 2011). The underlying cause must be determined. Asymptomatic infants should probably have their glycaemia corrected by continuous infusion when blood glucose is <2.2mmol/L (40mg/L) (Deshpande and Ward Platt 2005).

HYPOGLYCORRHACHIA WITHOUT HYPOGLYCAEMIA
Hypoglycorrhachia without hypoglycaemia (De Vivo et al. 1991; Leen et al. 2010) is a rare condition, the importance of which lies in the possibility of active treatment and its diagnostic difficulties. The disorder is caused by deficiency of the carrier protein glucose transporter-1 (GLUT-1) that transports glucose from blood to the CSF. GLUT-1 deficiency syndrome is caused by mutations in the SLC2A1 gene in most patients, and results in impaired glucose transport into the brain (Leen et al. 2010). It is transmitted as an autosomal recessive trait and usually manifests clinically from the end of the first month onwards. GLUT-1 deficiency syndrome is caused by haploinsufficiency of the blood–brain barrier hexose carrier. Truly neonatal cases are known (Brockmann et al. 2001). The major clinical features are seizures, although ataxia, paroxysmal disturbances of consciousness and even periodic weakness have been observed. A low CSF lactate level may be a clue and the diagnosis is further supported with paired blood and CSF glucose samples. Treatment by ketogenic diet prevents neurological deficit and has been successfully maintained for several years.

HYPERGLYCAEMIA
Marked hyperglycaemia occurs occasionally in neonates with CNS disturbances (Cornblath and Schwartz 1991) and has a grave prognostic significance. Hyperglycaemia may be due to transient neonatal diabetes mellitus. This is a rare form of diabetes that presents within the first 6 months of life. In almost 70% of the cases the condition is due to genetic or epigenetic aberrations at an imprinted locus on chromosome 6q24, and can be sporadic or inherited. Most infants recover by 3 months of age but are predisposed to developing type 2 diabetes in later life (Temple and Shield 2010).

With increased survival of extremely preterm infants, hyperglycaemia is now also more commonly seen in the neonatal intensive care unit. In these very immature infants, hyperglycaemia is likely to be caused by altered metabolism, as well as the need for continuous parenteral nutrition. Hyperglycaemia in extremely preterm infants has been associated with increased rates of death, IVH, sepsis and retinopathy of prematurity, and with increased lengths of hospital stay. Alexandrou et al. (2010) have shown that hyperglycaemia, defined as a plasma glucose level >8.3mmol/l, occurring on the first day after birth, was associated with an increased risk of death and white matter reduction on the MRI performed at TEA. In term infants with perinatal asphyxia, hyperglycaemia occurring on day 1 was associated with death or worse gross motor outcome (Spies et al. 2014).

DISTURBANCES OF ELECTROLYTE METABOLISM
Hypocalcaemia, Hypophosphatasia, and Hypomagnesaemia
Hypocalcaemia is defined as a blood calcium level <1.75mmol/L (7mg/dL) and is often associated with hypomagnesaemia, a magnesium level <0.6mmol/L (1.5mg/dL). Two distinct forms of neonatal hypocalcaemia form the bulk of the patients seen in the neonatal period, but both have become very rare with improved neonatal care, total parenteral nutrition in the preterm infant and improved cows’ milk formulae.

Early hypocalcaemia occurs before 48 hours of age mainly in preterm infants, infants of mothers who are diabetic, and those who are small for gestational age or have suffered asphyxia. Between 21% and 60% of such infants have calcium levels <1.75mmol/L (7mg/dL) or ionised calcium levels <0.75–0.85mmol/L (3–3.5mg/dL). This form has no symptoms of its own, and any clinical manifestation observed is likely to be caused by the primary condition of the infant.

Late hypocalcaemia presents at between 5 and 10 days of life, typically in infants fed cows’ milk formulae with a low phosphorus content. The excess phosphate load cannot be completely excreted by the immature kidney and the resulting hyperphosphataemia induces hypocalcaemia. Infants born in winter or early spring to mothers of low social class with subclinical vitamin D intake are at particular risk. Late hypocalcaemia has become rare since modified formulae have been in common use.

The clinical features are those of classic ‘neonatal tetany’. The Chvostek and Trousseau signs can be elicited in infants with severe hypocalcaemia. Focal or multifocal clonic seizures appear in apparently normally alert and hungry infants. Jitteriness is almost universally present between seizures that occur repeatedly, and may last intermittently for several days if untreated. The prognosis for late hypocalcaemia is good. Remarkably, the seizures, even when lasting for hours and days, do not leave residua (Lombroso 1996).
Late hypocalcaemia may also occur in infants born to mothers with hyperparathyroidism. As maternal hyperparathyroidism is often clinically silent, routine determination of calcium and phosphorus in maternal blood is in order if no obvious cause for the hypocalcaemia is present. Hypocalcaemia is also a manifestation of Di George syndrome, in which the seizures may precede the signs of immunodeficiency that occur in association with cardiac and other malformations.

Another cause for hypocalcaemia may be the HDR syndrome, an autosomal dominant disorder characterised by hypoparathyroidism, sensorineural deafness and renal anomaly, caused by mutation of the GATA3 gene located at chromosome 10p15 (Ohta et al. 2011).

Hypophosphatasia (HPP) is a rare metabolic bone disease caused by loss-of-function mutations in the gene ALPL encoding the tissue nonspecific alkaline phosphatase (TNSALP). Infants may present with neonatal seizures and develop multicystic encephalomalacia. Enzyme replacement therapy has been reported (Whyte et al. 2012, Okazaki et al 2016).

Familial hypomagnesaemia with secondary hypocalcaemia (OMIM 602014) is an autosomal recessive disease that results in electrolyte abnormalities shortly after birth. Affected individuals show severe hypomagnesaemia (<0.08 mmol/L, 0.2 mg/dL) and moderate hypocalcaemia, which lead to seizures and tetany. The disorder was thought to be caused by a defect in the intestinal absorption of magnesium, rather than by abnormal renal loss of magnesium. Restoring the concentrations of serum magnesium to normal values by low-dose magnesium supplementation can overcome the apparent defect in magnesium absorption and in serum concentrations of calcium. Life-long magnesium supplementation is required to overcome the defect in magnesium handling by these individuals. This condition is due to a mutation of TRPM6 (Walder et al. 2002).

Hypercalcaemia and Hypermagnesaemia

Hypercalcaemia in newborn infants may occur with fat necrosis in some infants receiving intravenous infusion of calcium gluconate, and in rare patients with a defect of intestinal transport of tryptophan, the so-called ‘blue diaper syndrome’. It is also a feature of Williams (‘elfin face’) syndrome, although it often goes unrecognised during the neonatal period (see Chapter 5). Prolonged moderate hypothermia is also an actual risk factor for subcutaneous fat necrosis and was seen several days after rewarming in 12 of 1239 infants registered with a national registry of newborn infants who were treated with moderate whole-body hypothermia (Strohm et al. 2011). Neonatal hyperparathyroidism is a rare, severe condition that features hypotonia, failure to thrive, respiratory distress associated with multiple rib fractures and early death when untreated (Waller et al. 2004). Familial hypocalciuric hypercalcaemia (FHH) is an autosomal dominant condition caused by heterozygous loss of function of calcium-sensing receptor (CaSR) mutations (Hendy et al. 2000). However, individuals who are homozgyous for CaSR mutations have neonatal severe hyperparathyroidism (NSHPT), which, unlike the relatively benign and asymptomatic FHH, can be fatal without parathyroidectomy (Waller et al. 2004). Hypercalcaemia may also be a feature of the more benign, asymptomatic, neonatal familial hypercalcaemia, in which remission occurs spontaneously.

Hypermagnesaemia may be observed after administration of large doses of magnesium sulfate to the mothers for treatment of pre-eclampsia. Clinical features include weakness, depressed or absent tendon reflexes, hypotonia and stupor, and it may lead to respiratory failure (Greenberg et al. 2011). As magnesium sulfate is now more widely used as neuroprotection, this will be seen more often, with apnoeas as a side effect of low blood levels of magnesium (Doyle et al. 2009).

Other Disturbances of Electrolyte Metabolism

These are uncommon. Hyponatraemia may be observed with neonatal dehydration or in infants receiving breast milk with a low sodium concentration, but is more common in extremely preterm infants. An increased sodium intake with subsequent hyponatraemia was associated with development of grade II–IV haemorrhage in a large cohort of 722 preterm infants with a birthweight <1500 g (Barnette et al. 2010). Hyponatraemia (<120 mmol/L) with convulsions has been observed in neonates and can be due to a variety of disorders, such as Bartter syndrome, pseudohypoaldosteronism, syndrome of inappropriate antidiuretic hormone secretion (SIADH) and adrenal insufficiency (Marcialis et al. 2011). Non-oliguric hyperkalaemia used to be a common problem in preterm infants with severe neonatal distress of various origins, but is no longer a common problem with improved neonatal care. It may be responsible for disturbances of cardiac rhythm (Vemgal and Ohlson 2012).

OTHER METABOLIC DISTURBANCES IN THE NEONATAL PERIOD

It is beyond the scope of this chapter to discuss metabolic disorders, which may present with neonatal encephalopathy and are sometimes referred to as “HIE mimicks” (vitamin B6 deficiency, pyridoxal phosphate deficiency, biotinidase deficiencies; and some important conditions such as glycine encephalopathy (non ketotic hyperglycinemia), molybdenum cofactor and sulphite oxidase deficiency) (Campistol and Plecko 2015). These are dealt with in Chapter 9 and are not discussed here. Many metabolic disorders may present with encephalopathy and/or neonatal seizures and should not be confused with perinatal asphyxia. An extensive family history (consanguinity, miscarriage, stillbirths or early neonatal demise) is of importance. A neurological deterioration usually
manifests itself after a symptom-free period of a few hours to a few days, often following the first feeds. Investigations for a metabolic disorder should always be performed in any infant where the history is not compatible with perinatal asphyxia. If the infant dies before all investigations have been performed and no permission for a full post-mortem investigation has been obtained, postmortem MRI can provide important additional information (Griffiths et al. 2005).

NEUROMUSCULAR DISEASES

These are described in Part 10 of this book. The presence of hypotonia is one of the most frequent neurological signs in newborn infants. Most hypotonic neonates have disorders of the CNS, as many as 82% in the study of Laugel et al. (2008). In such neonates, hypotonia is not accompanied by paralysis and there are usually other signs of CNS involvement such as lethargy, swallowing difficulties and abnormal primary reflexes. Such a picture is seen in HIE and acute neonatal distress of metabolic or infectious origin. Peripheral causes of neonatal hypotonia generally produce some degree of paralysis and often respiratory and swallowing difficulties. Once again a good clinical history is important in making the distinction (Vasta et al. 2005; Laugel et al. 2008). The family history is important, as is the presence of decreased fetal movements and polyhydramnios during pregnancy.

EXTRACRANIAL HAEMORRHAGE

Extracranial haemorrhage can be located between the bone and periosteum (cephalhaematoma), between the periosteum and the aponeurosis covering the scalp (subgaleal haemorrhage), or above the aponeurosis (caput succedaneum). Cephalhaematoma occurs in 1–2% of spontaneous births and is more frequent with mid-forceps and vacuum extraction deliveries (Govaert 1993; Volpe 2008). The haematoma is limited by the attachment of the periosteum to the periphery of the bone, usually the parietal, rarely the occipital squama. The lesion is firm and tense. The elevated periosteum is palpable at the margin of the bone, and may give the impression that there is a bony defect or a depressed fracture. In the rare occipital location, the haematoma can superficially resemble an encephalocele. Skull X-rays show an underlying linear fracture in up to 25% of cases (Volpe 2008).

The lesion spontaneously disappears in a few weeks’ or months. On late X-rays it may produce pseudolacunar images. Cephalhaematomas should not be tapped or evacuated because they disappear spontaneously and these manoeuvres imply a risk of infection. An infection of the cephalhaematoma has been reported but is rare (Zimmermann and Duppenthaler 2016). Subgaleal haemorrhage is not limited to a single bone. The blood may spread beneath the entire scalp and even dissect into tissues of the neck, forehead and eyelids. It often occurs as a consequence of vacuum extraction (Govaert et al. 1992b; Amar et al. 2003) (Fig. 2.24). Coagulation defects, especially vitamin K deficiency and haemophilia, are a frequent complicating factor. When present, the lesion tends to increase in size during the first two to three days and may reach massive proportions with consequent acute anaemia and hyperbilirubinaemia (Govaert et al. 1992b; Govaert 1993).

Subgaleal haemorrhage (also wrongly termed ‘giant cephalhaematoma’) may constitute a life-threatening emergency requiring urgent transfusion. A mortality rate of 12% was noted by Kilani and Wetmore (2006). Caput succedaneum is of no pathological significance.

SKULL FRACTURES

Linear fractures of the skull are not rare in newborn infants. They are seldom associated with intracranial pathology and are therefore of limited significance, requiring no treatment. A depressed skull fracture (the so-called ‘ping-pong lesion’) usually involves the parietal bones (Zalatimo et al. 2012). Palpation shows a localised depression, but neurological complications
rarely, if ever, occur. Surgical elevation is the classic treatment. Growing syndesmosal rupture is caused by tear of the connective tissue bridges between individual skull bones and bone erosion by pulsatile arachnoid tissue (Govaert 1993). Occipital osteodiasis, with consequent contusion of the cerebellum, is now rarely observed (Pape and Wigglesworth 1979).

### SPINAL CORD INJURY

Injury to the spinal cord is still observed in the newborn infant (Vialle et al. 2008). The frequency is difficult to evaluate. Towbin (1969) found cord lesions in over 10% of all newborn necropsies. This figure is certainly much too low and may be the result of inclusion of extreme congestion or haemorrhagic appearance of the epidural adipose tissue, which is a common finding (Friede 1989). Menticoglou et al. (1995) estimate, based on extrapolation of Towbin’s (1969) data, a prevalence of one per 90,000 live births. Most lesions involve either the lower cervical and upper thoracic cord with breech delivery, or the upper cervical region with cephalic presentation. Vertebral lesions are uncommon. There may be laceration of the meninges and severe destruction of the cord, leaving it severely attenuated with gliosis, cavitation, and destruction of tracts or cells that may affect the whole or part of the cord. Secondary necrosis due to circulatory disturbances has been observed (Adams et al. 1988a).

In a child who presents with hypotonia, a flaccid quadriplegia or low thoracic paraplegia after a difficult delivery, a spinal cord injury must be included in the differential diagnosis (Journeau et al. 2001). Cord injury occurs mostly in breech deliveries and mid-forceps extractions. Excessive longitudinal traction or rotation is the major mechanism. Hyperextension of the fetal head is an important factor. When detected prenatally, Caesarean section is indicated and usually avoids cord damage (Vialle et al. 2008).

The clinical manifestations are variable. Rapid death from respiratory failure may occur. The most common picture consists of paraplegia with massive hypotonia which may mimic a neuromuscular disorder and be accompanied by paradoxical respiratory movements and respiratory insufficiency. The abdomen is soft and bulging, and the bladder is distended and empty with gentle suprapubic pressure. However, pyramidal tract signs are present (sometimes only secondarily) and a sensory level is detectable. The upper limbs may be affected, especially the lower roots of the brachial plexus. Hypotonia may persist or evolve into spasticity. The diagnosis is not always easy, because extrinsic compression and congenital tumours, neuromuscular diseases and spinal cord necrosis secondary to intra-arterial umbilical catheters (Muñoz et al. 1993) may present with similar symptoms. Somatosensory evoked potentials may help determine an equivocal sensory deficit. Imaging of the cord confirms the diagnosis and allows a precise evaluation.

Plain X-rays and low-frequency ultrasonography are the initial modality for evaluation, which can be done at the bedside (MacKinnon et al. 1993). It might show haematomyelia, spinal disruption, extraspinal haematoma and malalignment.

MRI provides the best resolution (Mills et al. 2001) and is clearly superior to CT myelography with metrizamide. MRI needs to be performed to facilitate differential diagnosis of oedema, ischaemia and haemorrhage.

The prognosis is poor with persistence of the deficits and occurrence of respiratory or urinary complications (de León et al. 1995). The presence of breathing movements on day 1 was associated with mild disability, whereas the absence of breathing movements on day 1 and little or no recovery of motor function in the first 3 months were associated with permanent total dependency on mechanical ventilation and quadriplegia (MacKinnon et al. 1993). In occasional patients, more limited lesions may be responsible for suspended neurological signs with only mild spasticity of the lower limbs. In such patients the lesion may evolve into true syringomyelia (Yamano et al. 1992). As no treatment is effective, emphasis must be placed on prevention. Patients with paraplegia should be meticulously taken care of and rehabilitated. No evidence was found for the use of methylprednisolone in adults with spinal injury (Hurlbert 2001).

A few patients are on record with probable early prenatal damage to the spinal cord, possibly of vascular origin. The extent of damage was variable, from agenesis of the whole cord to segmental lesions, usually in the cervical region. Ramesh et al. (1989) have described segmental narrowing of the dorsal cord in association with vertebral abnormalities and congenital paraplegia, which they attributed to an early insult to the developing spinal cord and vertebrae. Bode et al. (1994) reported congenital hypoplasia of the medulla oblongata.

### SPINAL CORD INFARCTION

Spinal cord infarction after catheterisation of the umbilical artery (very seldom the umbilical vein), with or without injection of drugs or fluids, is a rare but dramatic event (Muñoz et al. 1993), probably related to progressive thrombosis or spasm involving the main branch of the anterior spinal artery. A similar adverse event has been reported after an inadvertent intra-arterial injection of viscid material during intramuscular injection. Non-traumatic intramedullary haemorrhage has been recorded (de León et al. 1995).

### INJURY TO NERVES, PLEXUS AND ROOTS

Brachial plexus injury, the most common peripheral nerve injury in the neonatal period, is discussed in Chapter 25.
Other injuries to nerves, also described in Chapter 25, are rare in the neonatal period. A typical example is injury to the median nerve as a result of attempts to catheterise the radial or brachial artery at the wrist or elbow for blood gas monitoring. Other examples include the following: injury to the radial nerve as a result of subcutaneous fat necrosis of the upper arm; and laryngeal nerve palsy, probably related to abnormal intrauterine posture with rotation and lateral flexion of the head, causing the thyroid cartilage to compress the superior branch of the nerve against the thyroid bone, and the recurrent nerve against the cricoid cartilage. Vocal cord paresis due to injury to the right laryngeal nerve has been reported after ECMO in neonates with severe respiratory distress (Schumacher et al. 1989).

Diaphragmatic paralysis is associated with brachial plexus injury in 80–90% of cases. When isolated, its diagnosis as a cause of neonatal respiratory distress is made by chest X-rays showing elevation of one or both hemidiaphragms. Stramrood et al. (2009) reported that plication of the diaphragm was required in 10 of 19 infants because of failure to wean from ventilatory support or serious persistent respiratory distress. Infants who failed to wean from ventilatory support and undergo early plication had a quick recovery and could be extubated successfully within a few days.

Left vocal fold paralysis is seen in about 20%–40% of extremely preterm infants after surgical closure of a patent ductus arteriosus. This may result in poor respiratory, feeding and/or developmental outcomes (Benjamin et al. 2010, Rukholm et al. 2012).

Prenatal Diagnosis, Treatment and Prevention of Brain Malformations 191
The development of the human cerebral cortex is a complex dynamic process that occurs during several gestational weeks (Gleeson and Walsh 2000). During the first stage, stem cells proliferate and differentiate into young neurons or glial cells deep in the forebrain, in the ventricular and subventricular zones lining the cerebral cavity. During the second stage, cortical neurons migrate away from their place of origin: most cells migrate along the radial glial fibres from the periventricular region toward the pial surface, where each successive generation passes the other and settles in an inside-out pattern within the cortical plate. When neurons reach their destination they stop migrating and order themselves into specific ‘architectonic’ patterns guiding cells to the correct location in the cerebral cortex. This third phase involves the final organisation within the typical six layers of the cortex, associated with synaptogenesis and apoptosis (Barkovich et al. 2012).

Abnormal cortical development is increasingly recognised as a cause of developmental disabilities and epilepsy. This recognition is largely due to improved magnetic resonance imaging (MRI) resolution, which makes it possible to assess the distribution and depth of cortical sulci, cortical thickness, the boundaries between grey and white matter and variations in signal intensity. Abnormalities of any or all of these features may be observed in different malformations of cortical development (MCD), which may be restricted to discrete cortical areas or may, alternatively, be diffuse (Guerrini and Dobyns 2014).

A classification scheme has been developed categorising MCD into three major groups that summarise the main developmental steps as malformations of cell proliferation, neuronal migration, or postmigrational cortical organisation and connectivity. Although the classification of MCD has advanced substantially during the past decade, in practice only a few categories are used, including lissencephaly, polymicrogyria, schizencephaly, focal cortical dysplasia and periventricular nodular heterotopia. However, emerging evidence suggests that MCD are far more heterogeneous than this classification suggests (Guerrini and Dobyns 2014; Parrini et al. 2016).

So far, more than 100 genes have been associated with one or more types of MCD. The biological pathways include cell cycle regulation at many steps (especially mitosis and cell division), apoptosis, cell-fate specification, cytoskeletal structure and function, neuronal migration and basement-membrane function, and many inborn errors of metabolism. A subset of MCD genes – especially those associated with megalencephaly – are associated with postzygotic (i.e. mosaic) mutations (Lee et al. 2012). However, it is important to keep in mind that a significant proportion of acquired causes, mostly viral infections and vascular events may cause morphological brain abnormalities, but have a quite different recurrence risk (Hennekam et al. 2013).

Genetic testing needs accurate assessment of neuroimaging features and familial distribution, if any, and can be straightforward in some disorders but requires a complex diagnostic algorithm in others. Because of substantial genotypic and phenotypic heterogeneity for most of these genes, a comprehensive analysis of clinical, neuroimaging and genetic data is needed to properly define them. Exome sequencing and ultra-high field MRI are rapidly modifying the classification of these disorders (Guerrini and Dobyns 2014).

**DISORDERS OF VENTRAL INDUCTION**

This term designates those malformations that result from induction failure involving the cephalic mesoderm, the adjacent neuroectoderm and associated neural crest derivatives, and the entodermal anlagen for facial structures. Induction failure is probably time-specific as ventral induction is completed prior to the 33rd post fertilisation day. The major defect is failure of the primary cerebral vesicle (telencephalon) to cleave and expand laterally. Midline facial defects that are frequently associated are a simultaneous consequence of the same defect involving the facial structures. A more detailed description can be found in Chapter 1.

**HOLOPROSENCEPHALY**

Holoprosencephaly, the most common malformation of the forebrain in humans, is a structural anomaly of the brain
resulting from failed or incomplete forebrain division in the third to fourth weeks of gestation. The forebrain (prosencephalon) incompletely cleaves into right and left hemispheres, deep brain structures, and the olfactory and optic bulbs and tracts (Solomon et al. 1993; Muenke and Cohen 2000; Lacbawan and Muenke 2002; Ming and Muenke 2002; Dubourg 2007). Previously named ‘arhinencephaly’, this term is improper as abnormal development of the rhinecephalic structures and, in particular, absence of the olfactory bulbs and stems can exist in brains with complete separation of the hemispheres (Kobori et al. 1987), although they are virtually always lacking with incomplete forebrain division.

Holoprosencephaly is the most common developmental defect of the forebrain with an incidence of 1 in 250 conceptions and about 1 in every 10 000 at term (Orioli and Castilla 2010). The aetiology includes both genetic and environmental causes (e.g. maternal diabetes, prenatal exposure to ethyl alcohol, retinoic acid [Muenke and Beachy 2000; Cohen and Shiota 2002]).

A generally accepted classification of cerebral defects in humans with holoprosencephaly includes five main subtypes from the most severe to the least severe based on the degree of separation of the cerebral hemispheres (reviewed in Hahn and Barnes 2010):

- **Alobar holoprosencephaly**, the most severe, in which there is a single ‘monoventricle’ and no separation of the cerebral hemispheres.
- **Semilobar holoprosencephaly**, in which the left and right frontal and parietal lobes are fused and the interhemispheric fissure is only present posteriorly.
- **Lobar holoprosencephaly**, in which most of the right and left cerebral hemispheres and lateral ventricles are separated but the frontal lobes, most rostral aspect of the telencephalon, are fused, especially ventrally.
- **Middle interhemispheric fusion variant** (syntelencephaly), in which the posterior frontal and parietal lobes fail to separate, with varying lack of cleavage of the basal ganglia and thalami and absence of the body of the corpus callosum but presence of the genu and splenium of the corpus callosum (Barkovich and Quint 1993).
- **A septo-preoptic type**, in which non-separation is restricted to the septal and/or preoptic regions; described in small case series (Hahn et al. 2010).

Other structural central nervous system (CNS) findings may occur with but are not specific to holoprosencephaly. The most common include anomalies of midline structures (undivided thalami, absent corpus callosum, callosal dysgenesis absent septum pellucidum, and absent or hypoplastic olfactory bulbs and tracts [arhinencephaly] and optic bulbs and tracts) and macrocephaly secondary to hydrocephalus (Rubinstein et al. 1996).

A spectrum of craniofacial anomalies accompanies holoprosencephaly in approximately 80% of affected individuals. The spectrum of facial anomalies ranges from cyclopia, the most severe presentation, to the normal face as seen in individuals. Common clinical features in individuals without obvious findings such as cyclopia, include microcephaly, closely spaced eyes, depressed nasal bridge, single maxillary central incisor and cleft lip and/or palate. Malformations of the nose include complete absence, agenesis of the nasal cartridge and proboscis (flat nose with a single central nostril without nasal bones). Palatal anomalies include various midline and lateral clefts, midline palatal ridge, bifid uvula, high-arched palate and absence of the superior labial frenulum (Solomon et al. 1993, 2010).

An important feature of holoprosencephaly is incomplete penetrance and variable expressivity. Patients carrying defined mutations may not manifest the disease at all, or have a spectrum of defects ranging from mild defects referred to as microforms (hypotelorism, midfacial hypoplasia, a single maxillary central incisor) that are generally non-lethal, to severe (cyclopia, proboscis), which are usually lethal (Shiota and Yamada 2010). It is currently unknown what drives manifestation of holoprosencephaly in genetically at risk individuals, but it has been speculated that other gene mutations and environmental factors may combine as cumulative insults (Ming and Muenke 2002). Currently, there are no effective preventive methods for holoprosencephaly, and children who survive require long-term multidisciplinary care at a significant financial and emotional cost.

### CLINICAL SUBTYPES OF HOLOPROSENCEPHALY

**Alobar holoprosencephaly** refers to a completely undivided, very small forebrain that assumes the shape of a horseshoe in the concavity of which lies a dorsal sac. This structure contains little neocortex, the concavity of the horseshoe being made of entorhinal cortex. The thalami are fused on the midline (Simon et al. 2000). The brainstem and cerebellum are well developed. Hydrocephalus is often associated.

Such brain anomalies may be associated with extremely severe facial defects and ocular abnormalities. In cyclopia, a rapidly lethal condition, there is a single eye or partially divided eye in single orbit with or without a proboscis above the eye. In cases of ethmocephaly, the nose is absent, replaced by a proboscis that is located above the level of the closely placed orbits. **Cebocephaly** patients present with closely spaced eyes with an abnormal nose with single nostril. The most frequent type is holoprosencephaly with median cleft lip in which the premaxillary bone anlage is missing. There is marked osseous hypotelorism. Such patients may live for several months or years, in contrast to those affected by the previously mentioned types.

In **semilobar holoprosencephaly**, there is no dorsal sac and the brain is divided into two hemispheres in its posterior part, while anteriorly abnormal transverse convolutions bridge the median fissure. The thalami are fused in the midline. In the most evolved forms, sometimes termed type A semilobar prosencephaly, the two hemispheres seem to be fully separated, even anteriorly. However, interhemispheric bridging is present in the anterior frontal region and there is no corpus callosum.
anteriortly, while the splenium may be present. Anteriorly, the cerebral mantle invaginates deeply with both grey and white matter layers crossing the midline after having lined a more or less sinuous ‘interhemispheric’ fissure (Oba and Barkovich 1995). The sinuous fissure may be a cue for the diagnosis by computed tomography (CT) of semilobar holoprosencephaly. MRI permits differentiation of the interhemispheric bridging from a true corpus callosum on sagittal cuts.

Facial appearance can be normal but facial abnormalities commonly found in semilobar holoprosencephaly, comprise closely spaced eyes, anophthalmia or microphthalmia, depressed nasal bridge, absent nasal septum, flat nasal tip, bilateral cleft lip with median process representing the philtrum-premaxilla anlage and midline cleft (lip and/or palate).

**Lobar prosencephaly**, in its fully developed forms, is characterised by almost complete separation of the hemispheres. Probst (1979) prefers not to classify it as holoprosencephaly, but it is included in the latter group by most investigators (Oba and Barkovich 1995). In this form, the hemispheres are fairly well separated; only the most anterior and ventral part is undivided. The genu of the corpus callosum is thin and the frontal horns are often rudimentary. The central grey nuclei are also partially or completely fused. The cases of telencephalic pseudo-monoventricle with a large cavum septum pellucidum in association with atresia of the frontal horns and various other abnormalities (Poll-The and Aicardi 1985) probably belong to this type.

In addition to these classic types, a less common type is now recognised (Lewis et al. 2002; Simon et al. 2002; Takahashi et al. 2003) in which there is failure of separation of the posterior frontal and parietal lobes whereas the frontal and occipital poles are well separated. The term syntelencephaly is used to designate such cases.

The diagnosis of holoprosencephaly is easy when facial abnormalities are present (Burck et al. 1981). In addition to those described above, there may be bilateral cleft lip and palate with hypoplasia of the median tubercle or trigonocephaly with orbital hypotelorism. However, the face may be normal in the less severe forms. Microcephaly is a feature common to most forms unless aqueductal stenosis, with resulting hydrocephalus, is present (Nyberg et al. 1987). Endocrine dysfunction, especially diabetes insipidus (Hasegawa et al. 1990), and adrenal and growth hormone deficiency, can contribute to the mortality and morbidity of holoprosencephaly.

Neuroimaging studies, especially MRI, confirm the diagnosis and permit detailed analysis of the abnormalities including those of the basal ganglia (Simon et al. 2000). Diagnosis can also be made by ultrasonography when the fontanelle is open. Infants with the most severe types rarely survive the neonatal period. Most surviving infants have severe intellectual disability, and develop seizures that are often infantile spasms with hypsarrhythmia. Neurological manifestations are highly variable, and some patients may survive into adulthood. Developmental delay is present in all individuals with the holoprosencephaly spectrum of CNS anomalies. The degree of delay is variable, correlating with the severity of the brain malformation, but tends to be severe. Seizures are common, and may be difficult to control. Hydrocephalus can occur, and may result in macrocephaly, rather than the more commonly observed microcephaly. Neural tube defects occur in a small proportion of individuals (Solomon et al. 1993, 2010; Levey et al. 2010).

The occurrence of endocrinological abnormalities is possible. Hypothalamic and brainstem dysfunction may lead to swallowing difficulties and instability of temperature, heart rate and respiration. Pituitary dysfunction is manifest by partial or complete panhypopituitarism with abnormal function of any or all of the anterior and/or posterior pituitary hormones, though central diabetes insipidus is by far the most common finding in persons with non-chromosomal, nonsyndromic holoprosencephaly. Short stature and failure to thrive are common, especially in more severely affected children. Growth hormone deficiency and/or chromosome anomalies may in part be responsible for poor growth in some individuals.

Feeding difficulties may be a major problem in children with holoprosencephaly. At least part of the difficulty may derive from axial hypotonia, poor suck as a result of neurological complications, lethargy, seizures and their effects, side effects of medications and lack of interest. Often gastroesophageal reflux, choking and gagging occur with feeds. More common problems include slowness in eating, frequent pauses and frank vomiting with risk of aspiration. Oral-sensory dysfunction may affect feeding especially when associated with textural aversion and labial and lingual weakness. Children with cleft lip and/or palate often have additional difficulties with oral feeding.

The most common teratogen in humans known to cause holoprosencephaly is maternal diabetes mellitus. Infants of mothers with diabetes have a 1% risk (a 200-fold increase) for holoprosencephaly. Other teratogens, including alcohol and retinoic acid, have been associated with holoprosencephaly in animal models, although their significance in humans is not established (Johnson and Rasmussen 2010). More recently, cholesterol-lowering agents (i.e. statins) have been associated with holoprosencephaly, although a causal relationship between prenatal statin use and holoprosencephaly in the infant has not yet been proven (Solomon et al. 1993; Edison and Muenke 2004). Approximately 25–50% of individuals with holoprosencephaly have a chromosome abnormality. Chromosomal abnormalities are nonspecific and either numeric or structural. Numeric chromosome abnormalities include trisomy 13, trisomy 18 and triploidy: holoprosencephaly is maternal diabetes mellitus. Infants of mothers with diabetes have a 1% risk (a 200-fold increase) for holoprosencephaly. Other teratogens, including alcohol and retinoic acid, have been associated with holoprosencephaly in animal models, although their significance in humans is not established (Johnson and Rasmussen 2010). More recently, cholesterol-lowering agents (i.e. statins) have been associated with holoprosencephaly, although a causal relationship between prenatal statin use and holoprosencephaly in the infant has not yet been proven (Solomon et al. 1993; Edison and Muenke 2004). Approximately 25–50% of individuals with holoprosencephaly have a chromosome abnormality. Chromosomal abnormalities are nonspecific and either numeric or structural. Numeric chromosome abnormalities include trisomy 13, trisomy 18 and triploidy: holoprosencephaly is maternal diabetes mellitus. Infants of mothers with diabetes have a 1% risk (a 200-fold increase) for holoprosencephaly. Other teratogens, including alcohol and retinoic acid, have been associated with holoprosencephaly in animal models, although their significance in humans is not established (Johnson and Rasmussen 2010). More recently, cholesterol-lowering agents (i.e. statins) have been associated with holoprosencephaly, although a causal relationship between prenatal statin use and holoprosencephaly in the infant has not yet been proven (Solomon et al. 1993; Edison and Muenke 2004). Approximately 25–50% of individuals with holoprosencephaly have a chromosome abnormality. Chromosomal abnormalities are nonspecific and either numeric or structural. Numeric chromosome abnormalities include trisomy 13, trisomy 18 and triploidy: holoprosencephaly is seen in approximately 70% of individuals with trisomy 13, which has a birth prevalence of 1:5000. Defects of the corpus callosum have been reported with trisomy 18 (Solomon et al. 2010). Chromosomal microarray (CMA) has identified copy number variants (CNVs) in 10–20% of all individuals with holoprosencephaly. These CNVs can include loci already known to be associated with holoprosencephaly, as well other loci whose relationship to holoprosencephaly is less well understood (Bendavid et al. 2009).
SYNDROMIC HOLOPROSENCEPHALY

Approximately 18–25% of individuals with holoprosencephaly have a pathogenic variant in a single gene causing syndromic holoprosencephaly. At least 25 different conditions in which holoprosencephaly is an occasional finding have been described; the majority of these disorders are rare. These include Pallister–Hall, Rubinstein–Taybi syndrome, Smith–Lemli–Opitz, Meckel syndrome, Hydrothalus syndrome (with hydrocephalus, polydactyly and other anomalies), facial clefts and brachial amelia and cardiowefacial syndromes.

NONSYNDROMIC HOLOPROSENCEPHALY

The nonsyndromic forms of holoprosencephaly that are best understood at a molecular genetic level are inherited in an autosomal dominant manner, but mostly sporadic (de novo mutations). The main genes involved in holoprosencephaly are typically SHH, ZIC2, SIX3 and TGIF1. Recently, some genotype–phenotype correlations have emerged both among persons with pathogenic variants in different genes and among persons with pathogenic variants in the same gene. Pathogenic variants in other genes, including CDON, DISP1, DLL1, FGF8, GAS1, FOXH1, NODAL and TDGF1, have been found in persons with holoprosencephaly spectrum anomalies.

The poor prognosis in the most severe forms justifies the importance of genetic counselling in affected families (Mercier et al. 2010). The genetic counselling requires a thorough clinical approach given the extreme variability of phenotype and aetiology. The karyotype is an essential diagnostic tool. Since mutations in the four major genes (SHH, ZIC2, SIX3 and TGIF) have been identified in patients with holoprosencephaly, molecular study is performed routinely in nonsyndromic holoprosencephaly. New molecular tools, such as array-CGH analysis, are now part of the diagnostic process. Prenatal diagnosis is based primarily on fetal MRI. For families with autosomal dominant nonsyndromic holoprosencephaly and no identifiable pathogenic variant, alobar holoprosencephaly can be diagnosed by prenatal ultrasound examination by 16 weeks gestation (Fig. 3.1) (Blaas et al. 2000). Orbital hypertelorism is the most reliable diagnostic feature for antenatal diagnosis, although it is not constant. Milder degrees of holoprosencephaly including semilobar or lobar holoprosencephaly cannot reliably be detected by prenatal ultrasound examination. Lobar holoprosencephaly can be recognised in utero with sonography. However, prenatal MRI may demonstrate an abnormal appearance of the fornices, which are rudimentary and fused into a single fascicle running within the third ventricle (Sonigo et al. 1998). Minor features such as single central incisor or anosmia seen in members of a proband’s family suggests the probability of a genetic form. In addition, molecular prenatal diagnosis can be performed if a mutation has been previously identified in a proband. Interpretations of molecular diagnosis must be given with caution, given the lack of strict genotype–phenotype correlation and should be offered in addition to fetal brain imaging, using ultrasound followed by fetal MRI.

Treatment should be provided by a multidisciplinary team when possible. This includes hormone replacement therapy for pituitary dysfunction, careful monitoring of fluid and electrolyte intake in case of diabetes insipidus, antiepileptic drugs for seizures, gastrostomy tube and/or Nissen fundoplication for feeding difficulties and gastroesophageal reflux, special feeding devices and surgical repair of cleft lip and/or palate, ventriculoperitoneal shunt placement for hydrocephalus together with appropriate education and family support (Levey et al. 2010).

CONDITIONS RELATED TO HOLOPROSENCEPHALY

Arhinencephaly without holoprosencephaly is occasionally encountered at autopsy in the brains of individuals with intellectual disability. Other malformations, especially microgyrias or heterotopias, are associated (Kobori et al. 1987). Holoprosencephaly may be unilateral.

FRONTONASAL DYSPLASIA

The median cleft face syndromes or frontonasal dysplasia are a group of conditions whose visible common denominator is hypertelorism. Several cases are associated with other ventral induction abnormalities, the commonest of which is anterior cranium bifidum. Hypertelorism is a frequent feature in cases of
corpus callosum agenesis, sometimes with cleft lip, bifid nose or similar anomalies. Anterior cephaloceles of various locations may be found, and these are frequently accompanied by extensive cortical and other malformations (Leech and Shuman 1986). A similar picture can obtain with lipomas of the corpus callosum.

RHOMBENCEPHALOSYNAPSIS

Rhombencephalosynapsis consists of partial or complete absence of the cerebellar vermis with continuity of the hemispheres across the midline, thought to be due to aberrant dorsal–ventral patterning. The aetiology of rhombencephalosynapsis is unknown. One hypothesis is that rhombencephalosynapsis is caused by dorsal–ventral patterning defects that result in loss of midline and fusion of lateral structures (Sarnat 2000). Alternatively, rhombencephalosynapsis could represent loss of anterior cerebellar anlage cells destined to become the vermis, or from transformation of these anterior cells to a more posterior and/or ventral hemispheric fate. The cerebellar fusion is in some ways comparable with holoprosencephaly in the forebrain, and indeed, these two malformations have been reported in multiple patients, suggesting a shared, but unknown, developmental mechanism (Pasquier et al. 2009, Ishak et al. 2012).

Malformations of cortical development (MCDs) are an important cause of epilepsy, intellectual disability and cerebral palsy. In addition, they represent an extremely interesting group of disorders from the perspective of brain development and its perturbations. Many novel MCDs have been described in recent years as a result of improvements in neuroimaging, genetic testing and understanding of the effects of mutations on the ability of their protein products to correctly function within the molecular pathways by which the brain functions. In this review, most of the major MCDs are reviewed from a clinical, embryological and genetic perspective (Table 3.1).

Several systems of classification of cortical malformations have been developed during the last 20 years (Barkovich et al. 1996, 2001). The most commonly used and recently updated is that of Barkovich et al. (2012) that divides these malformations into three groups according to the supposed timing of determination and mechanisms of formation of the various types. Group I are malformations secondary to abnormal neuronal and glial proliferation or apoptosis; Group II, malformations secondary to abnormal neuronal migration; Group III, malformations secondary to abnormal postmigrational development, as the process of cortical organisation begins before the termination of neuronal migration.

Table 3.1 shows a simplified form of this classification making it useful in everyday practice, while providing a theoretical basis for posing of academic questions. Other systems based on pathology, clinical presentation or genetic and molecular processes (Sarnat and Flores-Sarnat 2001, 2002, 2004) have been proposed.

From a clinical point of view, separating diffuse and localised or focal cortical malformations may be useful, although they usually share the same neurobiological mechanisms. Diffuse or generalised abnormalities (e.g. lissencephaly) are responsible for generalised seizures, especially infantile spasms, severe neurological signs and intellectual disability. By contrast, localised abnormalities (e.g. focal cortical dysplasias) are mostly responsible for focal epilepsy usually of early onset (Fauser et al. 2006), which may not be accompanied by cognitive or neurological deficits, and have a much better outcome. Only symptomatic therapy is possible for

Modified from Barkovich et al. (2001a).

Several mechanisms may be operative in a single case.

May be a postmigrational abnormality in some cases.
diffuse cortical abnormalities, whereas effective surgical treat-
m ent may be available for most cases of focal dysplasia. Some
diffuse abnormalities may result from metabolic defects (e.g.
Zellweger syndrome) or chromosomal abnormalities but also
from infectious, vascular or toxic insults for polymicrogyria.

The classification of Barkovich et al. (2001) schematically
indicates the most likely mechanisms for each type of cortical
malformation. The different stages of corticogenesis described
above are, in fact, interdependent and overlapping. The fate of
precursor cells is determined before they migrate (McConnell
and Kaznowski 1991), and this determination has a bearing
on the subsequent processes of migration and organisation.
Thus, abnormal cells, e.g. in tuberous sclerosis or in some types
of ‘cortical dysplasia’, often do not migrate to their normal
position and/or fail to establish normal connectivity. Likewise,
disorders of cell proliferation are frequently associated with
abnormal migration, e.g. in lissencephaly. As a result, it may
be difficult to determine which step of cortical development is
mainly interfered with in individual cases, and classifications
may be to some extent arbitrary. Some disorders do not fit
easily in the proposed scheme; e.g. a high proportion of cases
of microcephaly may not be disorders of cortical development
and may be due to clastic or other mechanisms rather than
developmental diseases. Moreover, even in some cortical
malformations the mechanisms presumed to be responsible
are mostly speculative and it is likely that many cortical devel-
opmental abnormalities are due to associations or interactions
of several known or unknown mechanisms.

**MALFORMATIONS SECONDARY TO
ABNORMAL NEURONAL AND GLIAL
PROLIFERATION OR APOPTOSIS**

This group of malformations is separated into three catego-
ries: reduced proliferation or accelerated apoptosis (congenital
microcephalies); increased proliferation or decreased apoptosis
(megalecephalies); and abnormal proliferation (focal and
diffuse dysgenesis and dysplasia) (Table 3.1). Tuberous sclerosis,
which belongs to the category of cortical dysgenesis with
abnormal cell proliferation but without neoplasia, is described
in Chapter 4, because of the prominence of the cutaneous
manifestations.

**MICROCEPHALY**

Congenital microcephaly, an occipital-frontal circumference of
equal to or fewer than 2–3 standard deviations (SD) below the age-
related population mean, denotes a fundamental impairment in
normal brain development (Woods and Parker 2013). All authors
admit that children with moderately small heads (between 2
and 3 SD below the mean) are frequently normal, but there is
statistically an increased prevalence of mild microcephaly among
children with learning disabilities. Intellectual disability may be
more common when a small head is associated with growth
retardation. However, even patients with head circumfer-
ence between 3 and 4 SD below the mean may have normal
intelligence.

The underlying aetiologies of genetic congenital micro-
cephaly are complex and multifactorial. Depending on the
underlying cause, congenital microcephaly can be associated
with structural brain malformations (e.g. gyriﬁcation issues,
agenesis of corpus callosum, pituitary abnormalities) or sec-
ondary consequences such as craniostenosis (Verloes et al.
1993). Congenital microcephaly can have an environmental
or genetic aetiology (Gilmore and Walsh 2013). Cerebral
cortical neurons must have developed by mid-gestation
although glial cell division and consequent brain volume
enlargement does continue after birth. Impaired neurogenesis
is, therefore, most obviously reﬂected clinically as congenital
microcephaly (Alcantara and O’Driscol 2014).

**Causes of Microcephaly**

The aetiology of microcephaly is diverse (Opitz and Holt
1990). Many cases, termed secondary microcephaly, are the
result of acquired clastic lesions or other pathological processes
incurred during pregnancy or even later, during the period of
rapid head and brain growth that takes place in the first years
of life. A signiﬁcant proportion of cases are apparently pri-
mary and are mostly of genetic origin (Table 3.2).

**Autosomal recessive primary microcephaly** (MCPH),
historically referred to as Microcephalia vera (also called
‘true’ microcephaly or ‘primary microcephaly’), is a genetic-
ally and clinically heterogeneous disease. Patients with
MCPH typically exhibit congenital microcephaly as well
as intellectual disability, but usually no further neurolog-
ical ﬁndings or malformations. The degree of microceph-
aly is usually marked (at 3 SD and often 5–6 SD below
the mean), with a narrow, receding forehead and a pointed
vertex, giving a peculiar clinical and neuroimaging appear-
ance. Paradoxically, individuals with MCPH do not exhibit
gross neurological signs, but hyperkinetic behaviour and
turbances of ﬁne motor coordination are frequently pres-
ent (Accardo and Whitman 1988). Seizures do not occur in
typical cases. Some degree of intellectual disability is present
but it is usually mild and most children can acquire at least a
simpliﬁed language. Their microcephaly with grossly preserved
macroscopic organisation of the brain is a consequence of a
reduced brain volume, which is evident particularly within the
cerebral cortex and thus results to a large part from a reduction
of grey matter (Verloes et al. 1993; Kaindl et al. 2010).

Primary autosomal recessive microcephalies (MCPH)
belong to the same spectrum of disorders to Seckel syn-
drome (SCKS) spectrum disorders (Verloes et al. 1993, 2013
updated). Both are characterised by microcephaly and the
absence of visceral malformations. Although MCPH and
SCKS were previously distinguished by height (maximum
height in SCKS was equivalent to the minimum height in
MCPH), stature is no longer a discriminating feature, leading
Table 3.2 Congenital microcephaly

Microcephaly with severe intrauterine growth retardation (MIC-IUGR) and short stature
- Seckel syndrome
- MOPD syndromes type 1 and 2
- Other MIC-IUGR syndromes

Microcephaly with variable short stature (severe to mildly short), moderate to severe DD/ID, normal to thin cortex, gyral simplification, +/- callosal hypogenesis
- Seckel syndrome or autosomal recessive primary microcephaly (MCPH)

Microcephaly with mildly short stature or normal growth, mild-moderate DD/ID, normal to thin cortex, +/- gyral simplification, +/- callosal hypogenesis and +/- focal PNH
- MCPH

Microcephaly with mildly short stature or normal growth, severe DD/ID, variable cortical development with gyral simplification or cortical dysgenesis and +/- ACC

- MIC with asymmetrical PMG
- MIC with atypical cortical dysgenesis
- MCPH, MIC with diffuse PMG or asymmetrical PMG
- MIC with diffuse PMG or asymmetrical PMG and ACC

Microcephaly with variable anomalies and less well characterised syndromes, +/- gyral simplification, +/- periventricular nodular heterotopia, +/- cerebellar hypoplasia
- MIC with diffuse periventricular nodular heterotopia
- MIC with disproportionate cerebellar hypoplasia
- MIC (extreme) with jejunal atresia

MIC with severe DD/ID and evidence of degeneration, with/without mildly short stature, +/- enlarged extra-axial spaces, +/- ACC, +/- atypical cortical dysgenesis
- MIC with enlarged extra-axial space
- MIC with enlarged extra-axial spaces and disproportionate cerebellar hypoplasia
- MIC due to fetal brain disruption with unknown
- Amish lethal microcephaly
- MIC-capillary malformation syndrome

MIC with lissencephaly (MLIS) – cortex thick, smooth white–grey border
- Barth MLIS syndrome
- Norman–Roberts MLIS syndrome
- MOPD1 variant with three-layer lissencephaly
- MIC with lissencephaly, cerebellar hypoplasia and Hirschsprung disease

MIC with tissue loss and enlarged ventricles (hydrocephalus ex vacuo or hydranencephaly), with/without cortical dysplasia and with/without ACC
- Fetal brain disruption sequence
- Familial fetal brain disruption-like syndrome with unknown cause
- Familial ‘microhydranencephaly’

MOPD, microcephalic osteodysplastic primordial dwarfism; MIC, microcephaly; IUGR, intrauterine growth retardation; DD, developmental disorder; ID, intellectual disability; MCPH, microcephaly primary, autosomal recessive; PNH, periventricular nodular heterotopia; MLIS, microlissencephaly; PMG, polymicrogyria; ACC, agenesis of the corpus callosum.

To the conclusion that these phenotypes constitute a spectrum rather than distinct entities.

Diagnosis of microcephaly is characterised by (1) onset during the second trimester of gestation; (2) occipito-frontal head circumference at birth equal to or less than 2 SD below the mean for sex, age and ethnicity; (3) slower than average increase in head circumference after birth. Variable findings in the MCPH-SCKS spectrum disorders include (1) normal brain structure, in the majority; (2) usually mild to moderate cognitive impairment without significant motor
delay in the majority of persons with MCPH and more severe in those with SCKS and MCPH with brain malformations; (3) degree of short stature; (4) craniosynostosis which may be secondary to poor brain growth (Verloes et al. 1993).

The diagnosis of MCPH-SCKS spectrum disorders is based on clinical findings, brain MRI that shows reduced brain volume with grossly normal architecture, family history consistent with autosomal recessive inheritance and molecular genetic testing when available. Primary microcephaly is genetically heterogeneous. Recessive inheritance is the rule. The genes in which biallelic mutation is known to cause MCPH-SCKS spectrum disorders are separated into those that are currently known to be associated with:

**MCPH phenotype only:** MCPH1 (locus name MCPH1), WDR62 (MCPH2), CDK5RAP2 (MCPH3), KNL1 (MCPH4), ASPM (MCPH5), STIL (MCPH7), CEP135 (MCPH8) and CDK6 (MCPH12); **SCKS phenotype only:** ATR (locus name SCKL1), NIN (SCKL7) and ATRIP; and **MCPH, SCKS and/or intermediate phenotypes:** RBBP8 (locus name SCKL2), CEP152 (MCPH9/SCKL5), CENPJ (MCPH11). These pathways affect processes – alterations of cell cycle length, spindle positioning or DNA repair – that affect neurogenesis and, in particular, the cell cycle phases of mitosis. WDR62, ASPM and STIL are spindle pole proteins, suggesting that focused spindle poles are of great significance in neural progenitor cell division.

Microcephaly secondary to mutations of WDR62 has associated cortical malformations (Yu et al. 2010) (Fig. 3.2). Mutations of ARFGF2 have associated periventricular nodular heterotopia and some individuals with microcephalic osteodysplastic primordial dwarfism have cortical dysgenesis; in addition, dyskinetic movement disorders are one of the clinical features in ARFGF2 related disorders (de Wit et al. 2009; Ferland et al. 2009). Mutations of other primary microcephaly genes described so far do not have obvious brain anomalies other than simplification of the gyral pattern and hypoplasia of the corpus callosum (Passemard et al. 2009), although few have had pathological analyses. No definable clinico-imaging characteristics have been identified that separate microcephalies caused by mutations affecting different parts of the mitotic cycle.

**MICROLISSENCEPHALY/MICRENCEPHALY**

In other cases of microcephaly, the cortex is abnormally thick and shows only a small number of abnormal convolutions. These cases have been termed microlissencephaly (Barkovich et al. 1998) or oligogryic microcephaly. Microlissencephaly is an extremely rare entity characterised by the combination of extreme primary microcephaly with poor development of the frontal lobes and disordered cortical lamination with absent sulci and gyri. Several subtypes probably exist (Ross et al. 2001) (Table 3.2). Most cases of microlissencephaly are described in consanguineous families suggesting an autosomal recessive inheritance. However, only few affected genes have been identified so far, including biallelic mutations in NDE1, which encodes a multidomain protein that localises to the centrosome and mitotic spindle poles (Alkuraya et al. 2011; Bakircioglu et al. 2011), DNA repair (MCPH1) (Thornton and Woods 2009), progenitor proliferative capacity (ASPM and STIL) (Kumar et al. 2009; Passemand et al. 2009); interference with mitotic spindle formation (WDR62) (Bilguvar et al. 2010; Yu et al. 2010); NDE1 (Feng and Walsh 2004), DNA repair deficit (PNKP) (Shen et al. 2010) and PCNT (Griffith et al. 2008). These pathways affect processes – alterations of cell cycle length, spindle positioning or DNA repair efficiency – that affect neurogenesis and, in particular, the cell cycle phases of mitosis. WDR62, ASPM and STIL are spindle pole proteins, suggesting that focused spindle poles are of great significance in neural progenitor cell division.

**Figure 3.2** Microcephaly secondary to mutations of WDR62 in a 2-year-old boy, showing extreme microcephaly, bilateral polymicrogyria with schizencephaly and dysmorphic corpus callosum.
mutations in tubulin genes, TUBA1A, TUBB2B and TUBB3 (Fallet-Bianco et al. 2014) have been identified, further highlighting the critical implication of the microtubule cytoskeleton in microcephaly.

Remarkably, most of the genes involved in microlissencephaly are also responsible for microcephaly, suggesting that both conditions belong to the same disease spectrum. Despite significant progress in understanding the underlying genetic bases of these conditions, the causative genes and pathophysiological mechanisms of most microcephaly/microlissencephaly cases remain unknown, which challenges diagnosis, prenatal testing and genetic counselling.

The differential diagnosis with total craniosynostosis does not raise real problems, and the shape of skull, exophthalmia, normal development, signs of increased intracranial pressure and plain X-rays of the skull make the diagnosis obvious. The most important issue in diagnosis is to differentiate acquired (clastic) micrencephaly from genetic types. Marked neurological involvement, severe intellectual disability and a history of abnormal prenatal or perinatal events in the face of moderate microcephaly support a clastic origin, while the reverse features favour a genetic microcephaly. However, clinical features leave considerable room for uncertainty. The demonstration of destructive changes by neuroimaging is of great value. A normal CT, on the contrary, does not exclude an acquired origin.

Antenatal diagnosis may be difficult, especially in the absence of associated malformations, and errors by excess or by default have been frequent (Deter 2016; Leibovitz et al. 2016). Simple measurement of the biparietal diameter is not sufficient as it may be low in fetuses with sagittal craniosynostosis or marked intrauterine moulding. Repeated examinations with full attention to skull shape are essential.

**MACROCEPHALIES**

Macrocephaly, like microcephaly, is defined by reference to head circumference, the arbitrary limit of 2 SD above the age norm being often accepted. With this statistical criterion, the definition includes typical individuals as well as a collection of diverse and totally unrelated entities. A majority of the cases of macrocephaly are not due to abnormal brain development but will be considered here as the large head is a common and striking feature. Lorber and Priestley (1981) studied 510 children with head circumference above the 98th centile. Seventy-five per cent of these had hydrocephalus and increased intracranial pressure, 3% had specific syndromes and 20% had primary megalencephaly with normal pressure. Only 13% of this last group had intellectual disability or neurological abnormalities. The major diagnostic consideration is hydrocephalus or pericerebral collections because these may necessitate immediate treatment. Boys outnumbered girls by 4 to 1, and 50% of the patients had a family history of macrocephaly.

The macrocephalies consist of two main groups: megalencephaly, and hydrocephalus and pericerebral collections. The latter group is studied in Chapter 7.

**Megalencephaly with periventricular nodular heterotopia**

**Megalencephaly with polymicrogyria and other cortical dysgenesis**

- Hemimegalencephaly
- Dysplastic megalencephaly
- Megalencephaly-capillary malformation syndrome, includes megalencephaly-polymicrogyria-polydactyly-hydrocephalus
- Thanatophoric dysplasia or Apert syndrome with mutation of FGFR3 (six-layered PMG-like cortex)

DD, developmental disorder; ID, intellectual disability.

**Megalencephaly**

Megalencephaly (MEG) is a developmental disorder characterised by brain overgrowth that occurs due to either increased number or size of neurons and glial cells. The former may be due to either increased neuronal proliferation or decreased apoptosis. The degree of brain overgrowth may be extensive, ranging from generalised MEG affecting the entire cortex – as with mutations in PTEN phosphatase and tensin homolog on chromosome 10 (PTEN) – to unilateral hemispheric malformations as in classic hemimegalencephaly (HME) (Mirzaa and Poduri 2014). Megalencephaly is classically defined as an oversized and overweight brain that exceeds the age-related mean by 2 SDs or more. Clinically, the distinction between megalencephaly (enlarged brain) and macrocephaly (enlarged head overall) relies on neuroimaging examination of the brain and recognition of enlarged cerebral structures. Whereas megalencephaly is associated with specific syndromes, macrocephaly can be caused by a myriad of causes such as hydrocephalus or ventriculolomalgy, enlarged extra-axial spaces, and thickened skull bones (Table 3.3). Therefore, the distinction between megalencephaly and macrocephaly is clinically helpful toward accurate diagnosis.

Megalencephaly has long been classified based on pathogenesis into metabolic and non-metabolic (or anatomic) subtypes.
Weaver syndrome, Simpson Golabi Behmel syndrome and nevoid basal cell carcinoma syndrome. Clinical manifestations of megalencephaly are extremely variable and frequently they are absent altogether; most patients have intellectual disability and many have seizures and diffuse neurological abnormalities.

### Hemimegalencephaly

Hemimegalencephaly is a severe brain malformation characterised by overgrowth of all or part of a cerebral hemisphere, often with ipsilateral severe cortical dysplasia or dysgenesis, white matter hypertrophy and a dilated and dysmorphic lateral ventricle. The gyral pattern of the affected hemisphere is abnormal, resembling pachygyric or polymicrogyric cortex (Fig. 3.3). In cases that have been studied microscopically (Robain and Dulac 1992; Sarnat and Flores-Sarnat 2001, 2002, 2004; Flores-Sarnat 2002; Salamon et al. 2006), the cellular hypertrophy due to cellular edema or accumulation of metabolic substrates can cause megalencephaly in a wide range of neuro-metabolic syndromes, such as Canavan disease, glutaric aciduria type I and lysosomal storage disorders, among others. A growing number of developmental (or non-metabolic) genetic syndromes are known to be associated with generalised or focal megalencephaly, including HME. Table 3.4 represents a broad overview of genetic disorders where megalencephaly is a defining/diagnostic or common feature. Brain overgrowth in these syndromes varies widely in severity, distribution and co-occurrence of other malformations of cortical development from a mild (and often relatively) enlarged brain with a normal cortex to bilateral megalencephaly with diffuse cortical dysplasia, as discussed below. Finally, reciprocal copy number changes are known to be associated with brain growth dysregulation (i.e. megalencephaly and microencephaly). Other important overgrowth conditions include Sotos syndrome, CLOVES, fibroadipose hypoplasia, isolated macrodactyly, variable segmental overgrowth digital anomalies, spinal anomalies, cutaneous vascular malformations; also isolated macrodactyly, some ID, and Klippel–Trenaunay syndrome (KTS)Cutaneous VM (capillary, venous, lymphatic), varicose veins, unilateral hypertrophy of bones and soft tissues; also isolated macrodactyly, some ID. Other important overgrowth conditions include Sotos syndrome, CLOVES, fibroadipose hypoplasia, isolated macrodactyly, variable segmental overgrowth digital anomalies, spinal anomalies, cutaneous vascular malformations; also isolated macrodactyly, some ID, and Klippel–Trenaunay syndrome (KTS)Cutaneous VM (capillary, venous, lymphatic), varicose veins, unilateral hypertrophy of bones and soft tissues; also isolated macrodactyly, some ID.
cortex was diffusely thickened with piling up of grey matter and absent laminar organisation. Neurons are disoriented and widely spaced. Nodular heterotopias of grey matter are present in some cases. Giant neurons are frequently present (Salamon et al. 2006), and balloon cells are found in 50% of cases.

Neuroimaging reveals regions of apparent polymicrogyria, pachygyria, subcortical, and periventricular grey matter heterotopia (Fig. 3.3). However, various morphological abnormalities outside the involved cerebral hemisphere have been reported such as ipsilateral cerebral vascular dilatation, ipsilateral and bilateral cerebellar enlargement with dysplastic folia, and ipsilateral olfactory nerve enlargement (Sato et al. 2007). Moreover, contralateral volume loss (or hemimicrencephaly) with white matter abnormalities have been reported (Shiroishi et al. 2010). It is often an isolated congenital abnormality, but there are sporadic associations with neurocutaneous syndromes, epidermal nevi), connective tissue (skin laxity, joint hypermobility), skeleton (polydactyly, syndactyly) and others. Mutations within the PI3K-AKT-mTOR pathway are associated with the most severe brain overgrowth phenotypes including marked brain overgrowth (head circumference more than 4 SD above the mean) and hemimegalencephaly, a serious medical condition typically associated with severe early onset intractable epilepsy and poor developmental outcome. In addition, these mutations in core components of the PI3K-AKT-mTOR pathway are also responsible for classic hemimegalencephaly and a variety of megalencephaly syndromes including the megalencephaly-capillary malformation syndrome (MCAP) and the megalencephaly-polymicrogyria-polydactyly-hydrocephalus syndrome (MPPH). Collectively, these disorders not only overlap molecularly but also share clinical, neuroimaging, and neuropathologic features (for a review see Mirzaa and Poduri 2014).

The differential diagnosis of megalencephaly may be difficult. Hydrocephalus and intracranial collections should be excluded as they may require surgical treatment (Chapter 7). Differentiation of megalencephaly from large heads found in children with normal or near-normal neurodevelopment is usually easy. However, these children constitute a large heterogeneous group. The majority appears to have genetically determined large heads. Lorber and Priestley (1981) found a high incidence of macrocephaly in the parents, especially the fathers, of such children (Lorber and Priestley 1981). DeMeyer (1972) and Day and Schutt (1979) also suggested that ‘simple’ macrocephaly may be dominantly transmitted (DeMeyer 1972; Day and Schutt 1979). Some of these children with macrocephaly have specific learning disorders, the incidence of which may be higher than among children of normal head size. The rate of head growth is particularly rapid in infants under 4 months of age (DeMeyer 1972; Lorber and Priestley 1981). At this stage the diagnosis of hydrocephalus is often suggested, and neuroimaging examination is in order if the rate of increase does not slow down rapidly. In patients without any neurodevelopmental abnormality and a family history of large head, nothing more than careful follow-up is needed.
However, the possibility of presymptomatic glutaric aciduria (Hoffmann et al. 1991) or another organic acid disorder frequently associated with macrocephaly should be excluded. In children with dolichocephaly (sagittal suture synostosis) the shape of the skull is important to consider as patients with marked skull elongation usually have a head circumference 3 SD or more above the mean, but the shape of the skull is suggestive. In young infants with perinatal illnesses or in older infants who had nutritional problems, ‘catch-up’ growth may temporarily represent a diagnostic problem (Sher and Brown 1975a, b). Neuroimaging should be obtained in cases with persistently divergent head curves or when signs of increased intracranial pressure are present.

**DISORDERS OF MIGRATION**

These malformations are extremely important clinically as they are responsible for a considerable proportion of cases of intellectual disability and of epilepsy. In several cases, they are amenable to treatment, especially focal abnormalities, which may respond to surgery (Arzimanoglou et al. 2016). They are more often a part of a more complex process that not only affects cell migration but is variably associated with abnormalities of cell differentiation and of cortical organisation.

Cell migration can be interfered with by acquired or genetic causes (Barkovich et al. 2001; Lambert de Rouvroit and Goffinet 2001; Gressens 2006; Barkovich et al. 2012). Depending on the date, type and severity of the causal process, the spectrum of migration disorders will manifest as a major form (heterotopias, lissencephaly–pachygyria or polymicrogyria) or a minor disturbance (abnormal lamination of cortex, microdysgenesis) (see Table 3.5). Both may be localised, multifocal or diffuse and variably associated (Barkovich et al. 1996). Localised areas of migration abnormalities are often associated with more diffuse brain changes (Sisodiya et al. 1995). An increasing number of genetic migration disorders are being recognised (see below) and may result from chromosomal deletions or gene mutations. These may affect the multiple, yet incompletely known mechanisms, especially the signalling systems that guide cell movements along glial fibres, the adhesion molecules between neurons and glial guides, the recognition signals that control connectivity and the growth of cone function, and the energy required for motion. Multiple genes, only some of them known, are essential for proper achievement of cortical architecture, but other influences are probably operative, in particular the neural activity that contributes to synaptic stabilisation resulting in the organisation of functional neuronal circuits.

Known or suspected acquired causes include intrauterine infections, especially cytomegalovirus and Zika virus disease and circulatory disorders. Any pathological process damaging the glial guides (e.g. haemorrhage, infarction, infection) can be a cause. Some pathological abnormalities formerly thought to be due to aberrations in development of the cortical plate, result in fact from destructive processes that occur after most of the process of corticogenesis has taken place (Marin-Padilla 2000).

**HETEROTOPIAS**

Heterotopia represent malformations of cortical development in which neurons do not migrate to their proper final location (Barkovich et al. 2012). They are broadly classified by location as periventricular nodular heterotopia, subcortical heterotopia and leptomeningeal heterotopia, the latter currently being difficult to detect by neuroimaging (Guerrini and Parrini 2010).

Periventricular nodular heterotopia (PNH) is the most common group, being identified as variably sized nodules of neurons along the surface of lateral ventricles on neuroimaging or postmortem studies. Histological analysis shows these nodules to exhibit rudimentary lamination, resembling that in the cortex (Garbelli et al. 2009). Traditionally, PNH have been considered a result of impaired neuronal migration (Sarkisian et al. 2008); however, recent evidence suggests that the primary cause may be a disruption of the neuroependyma, which impairs postmitotic neurons from attaching to radial glial cells and, therefore, impairs initiation of the migration process (Ferland et al. 2009).

Isolated heterotopias may remain asymptomatic or give rise to epilepsy or neurological signs (Barkovich and Kjos 1992). They may be located subcortically or in the subependymal region. Subependymal heterotopias were found in about 2% of patients with epilepsy, constituting 20% of cases of malformations of cortical development with epilepsy (Raymond et al. 1994). They are preferentially localised in the posterior part of the brain and may be uni- or bilateral (Dubeau et al. 1995; Aghakhani et al. 2005; Tassi et al. 2005). When unilateral, they are usually sporadic and manifest clinically with focal epileptic seizures. The epileptic activity may originate from the nodules themselves or from the nearby cortex. Resection of the area indicated by invasive EEG, whether it is located within the nodules or in the nearby cortex (Tassi et al. 2005), may allow control of seizures.

**Periventricular Heterotopias**

Periventricular heterotopia is one of the most common malformations of cortical development and causes seizures, dyslexia and psychiatric disturbances (Gonzalez et al. 2013). The most frequent symmetrical manifestation of periventricular nodular heterotopia (PVNH) is located along the walls of both lateral ventricles predominantly in females and results from heterozygous loss of function mutations in the X-linked FLNA gene (Sheen et al. 2001, Parrini et al. 2006). It is associated with high intrauterine and perinatal lethality in hemizygous males presumably from excessive haemorrhage, however, on rare occasions boys and adult hemizygous male carriers of FLNA mutations have been reported (Sheen et al. 2001). The gene product Filamin A is a large cytoplasmic

**Posterior predominant (temporal-trigonal) periventricular nodular heterotopia**
- Posterior PNH only
- Posterior PNH with hippocampal dysgenesis, colpocephaly, anomalies of midbrain tectum or cerebellar hypoplasia
- Posterior PNH with posterior PMG

**Periventricular heterotopia, not nodular (unilateral or bilateral)**
- Diffuse periventricular laminar heterotopia
- Frontal predominant periventricular laminar heterotopia
- Posterior predominant periventricular laminar heterotopia

**Ribbon-like heterotopia, bilateral undulating heterotopic band**
- Posterior predominant ribbon-like heterotopia
- Diffuse ribbon-like heterotopia

**MALFORMATIONS DUE TO GENERALISED ABNORMAL TRANSMANTLE**
- **Anterior predominant or diffuse classic (four-layered) lissencephaly (LIS) and subcortical band heterotopia (SBH)**
  - Anterior predominant LIS with abrupt transition and cerebellar hypoplasia
  - Anterior predominant or diffuse lissencephaly (Isolated lissencephaly) or SBH
  - Winter–Tsukahara syndrome
  - Baraitser–Winter syndrome with anterior or diffuse LIS–SBH

**Posterior predominant or diffuse classic (four-layered) and two-layered (without cell-sparse zone) LIS and SBH**
- Posterior predominant or diffuse LIS with brainstem and cerebellar hypoplasia, +/- ACC
- Posterior predominant or diffuse LIS (Isolated lissencephaly) or posterior SBH
- Diffuse LIS with hair and nail anomalies
- Perisylvian (central) pachygyria (Isolated LIS)

**Ribbon-like deep white matter heterotopia +/- ACC, thin overlying cortex**
- Posterior or diffuse LIS with cerebellar hypoplasia
- Miller–Dicker syndrome (four-layered)

**X-linked lissencephaly (three-layered, without cell-sparse zone) with callosal agenesis, ambiguous genitalia (XLAG)**
- XLAG-like syndrome with temporal-posterior predominant LIS, ACC, microphthalmia and midline cleft lip and palate
- XLAG with temporal-posterior predominant LIS and ACC with mutations

**Reelin-type LIS (inverted cortical lamination, without cell-sparse zone)**
- Frontal predominant mild LIS with severe hippocampal and CBLH

**Variant LIS (other rare types exist but are poorly characterised)**

**MALFORMATIONS PRESUMABLY DUE TO LOCALISED ABNORMAL LATE RADIAL OR TANGENTIAL TRANSMANTLE MIGRATION**

**Subcortical heterotopia**
- Curvilinear transmantle heterotopia, with thinning of overlying cortex, decreased volume of affected hemisphere, +/- ACC, +/- basal ganglia anomalies
- Multinodular subcortical heterotopia with thin overlying cortex, +/- PMG
- Transmantle columnar heterotopia +/- PNH

**MALFORMATIONS DUE TO ABNORMAL TERMINAL MIGRATION AND DEFECTS IN PIAL LIMITING MEMBRANE**

**Dystroglycan–laminin complex abnormalities with cobblestone malformation complex, +/- congenital muscular dystrophy**
- Walker–Warburg syndrome
- Muscle–eye–brain syndrome
- Congenital muscular dystrophy (CMD) with CBLH (Italian MEB)
- FCMD or FCMD with retinal abnormality (MEB-like)
- Posterior predominant COB and CMD

**COBBLESTONE MALFORMATION IN CDG SYNDROME**
- Cobblestone malformation with no known glycosylation defect
- Frontal predominant Cobblestone malformation with GPR56 mutations
- Walker–Warburg syndrome secondary to COL4A1 mutations

**OTHER SYNDROMES WITH CORTICAL DYSGENESIS AND MARGINAL GLIONEURONAL HETEROTOPIA**
- Fetal alcohol syndrome
- Galloway–Mowat syndrome

PMG, polymicrogyria; ACC, agenesis of the corpus callosum; CBLH, cerebellar hypoplasia; MEB, muscle–eye–brain; FCMD, Fukuyama congenital muscular dystrophy; COB, cobblestone malformation; CDG, congenital disorders of glycosylation.
actin-binding and cross-linking protein of diverse functions including initiation of cell migration and spreading, coagulation and aspects of vessel wall integrity (Baldassarre et al. 2009). Cellular function of Filamin A is further modulated by dimerisation with the homologous protein Filamin B, which may rescue defective Filamin A, depending upon the cellular environment (Baldassarre et al. 2009). Functional MRI indicates that the FLNA-associated ectopic cortical neurons are functionally integrated into motor circuits (Lange et al. 2004).

Cerebral MRI demonstrate a specific FLNA-associated PVNH phenotype with bilateral, predominantly confluent nodular heterotopias extending along the entire length of the lateral walls of both lateral ventricles. It is often associated with an enlarged pericerebellar cerebrospinal fluid space in the presence of normal cerebellar and fourth ventricle anatomy referred to as ‘mega cisterna magna’ (Parrini et al. 2006) (Fig. 3.4).

The phenotype in females with heterozygous FLNA loss of function mutation is highly variable (Lange et al. 2015). Difficult to treat epileptic seizures are the core clinical finding in about 90% of the patients (Parrini et al. 2006). Age at onset may be within the first years of life, but more typically, individuals present during childhood. The severity of the seizure disorder may range from mild (with rare frequency and remission without need of antiepileptic drugs) to intractable seizures. No correlation exists between the extent and severity of the nodular heterotopia seen radiographically and the clinical manifestations. Additional neurological findings are rather discrete and may include deficits in reading, processing speed and executive functions, only detectable in subtle neurocognitive testing in about 80% of patients (Chang et al. 2005). Penetrance in heterozygous FLNA mutation carriers is reduced and asymptomatic PVNH may be detected through predictive carrier testing or incidentally in cerebral MRI as the only manifestation of a FLNA mutation. Less frequent FLNA-associated extracerebral manifestations include persistent ductus arteriosus Botalli in the newborn, chronic obstruction, an Ehlers-Danlos-like phenotype affecting connective tissues, cardiac valve disease as well as chronic obstructive lung disease and oto-palato-digital spectrum skeletal phenotypes (Robertson 2005; Bernstein et al. 2011; Lord et al. 2014).

From a genetic point of view, patients with PVNH are also a heterogeneous group. The classic X-linked form is usually caused by mutations of the FLNA gene. A rare autosomal recessive form is caused by mutations in the ARFGEF2 gene (Sheen et al. 2003, 2004) and is characterised by microcephaly and delayed myelination in addition to PNH. Very recently, missense mutations in NEDD4L mapping to the HECT (homologous to the E6-AP carboxyl terminus) domain of the encoded E3 ubiquitin ligase have been shown to lead to PVNH associated with toe syndactyly, cleft palate and neurodevelopmental delay (Broix et al. 2016).

PVNH are found in many syndromes; associations with several single gene disorders, chromosomal anomalies (Guerrini and Parrini 2010) including chromosomal imbalances and submicroscopic genomic copy number variations and some presumably disruptive causes have been published.

From a phenotypic point of view, PVNH is a heterogeneous disorder. Apart from the classic group, 13 additional phenotypes represent almost 50% of patients with PVNH not related to FLNA mutation. These include temporo-occipital PVNH with hippocampal malformation and cerebellar hypoplasia, PVNH with frontal-perisylvian or temporo-occipital polymicrogyria, posterior PVNH with hydrocephalus, PVNH with microcephaly, PVNH with frontonasal dysplasia, PVNH with limb abnormalities, PVNH with fragile-X syndrome, PVNH with ambiguous genitalia, micronodular PVNH, unilateral PVNH, laminar ribbon-like and linear PVNH. Periventricular heterotopias may also be associated with cortical dysplasias (Wieck et al. 2005).

Subcortical Heterotopias

Subcortical heterotopias are irregularly lobulated masses of grey matter that are located primarily in the subcortical white matter of the cerebral hemispheres. Subcortical heterotopia have at least two different morphological configurations (1) the subcortical nodular heterotopia; and (2) the subcortical curvilinear heterotopia. A third type is the mixed subcortical heterotopia (Barkovich 1996, 2000). Associated malformations of the brain are common. The most frequent finding is diminution of the size of the ipsilateral hemisphere and thinning of the overlying cortex with shallow sulci. No differences in the clinical manifestations or in the associated anomalies are identified among these three groups of patients. Recently, a new genetic cause has been identified, in EML1 gene, encoding a microtubule-associated protein in ribbon-like heterotopia in humans (Kielar et al. 2014) (Fig. 3.5).
THE SPECTRUM OF CLASSIC LISSENCEPHALY AND SUBCORTICAL BAND HETEROTOPIA

These migration disorders may be considered to represent different degrees of severity of a basic abnormality of neuronal migration, although they are genetically distinct (Palmini et al. 1993) (Table 3.5). Lissencephaly means a smooth brain. The term agyria–pachygyria is better as the brain is not always smooth (Aicardi 1991). In severe lissencephaly the cortex lacks surface folds (agyria) while milder manifestations include abnormally broad folds (pachygyria) or a heterotopic layer of grey matter embedded in the white matter below the cortex (subcortical band heterotopia, [SBH]) (Barkovich et al. 2012). The precise prevalence of lissencephaly is uncertain but estimates range from 11.7 to 40 cases per million births (Dobyns and Das 1993). The pathogenesis of lissencephaly is best understood in the context of normal cortical development. In humans, primitive neurons (neuroblasts) are generated through mitosis of neural stem cells in the ventricular zone of the fetal brain between 5 and 22 weeks of gestation (Wynshaw-Boris et al. 2010). Post‐mitotic neuroblasts undergo radial migration outward from the ventricular zone, guided by radial glial fibres, to populate the cortical plate (Ayala et al. 2007). Slow or arrested migration leads to a thickened cortex with reduced folding (pachygyria or agyria) or the stranded neurons of SBH.

Over the last three decades a growing number of causative genes for lissencephaly has been identified.

Classic Lissencephaly

Classic lissencephaly is distinguished from other forms of lissencephaly by the presence of an abnormally thick (10–20mm), four-layer cortex and, typically, by the absence of other major brain abnormalities (e.g. severe congenital microcephaly, agenesis of the corpus callosum, or cerebellar hypoplasia) (Barkovich et al. 2012; Fry et al. 2014). Classic lissencephaly is sometimes referred to as ‘type 1’ lissencephaly to differentiate it from cobblestone cortical malformation (Forman et al. 2005). Classic lissencephaly is caused by mutations in three genes: *PAFAH1B1* (Reiner et al. 1993), *DCX* (des Portes et al. 1998; Gleeson et al. 1998) and *TUBA1A* (Kumar et al. 2010). More recently, mutations in *DYNC1H1* and *KIF2A* were found to be responsible for classic lissencephaly (Poirier et al. 2013; Cavallin et al. 2016).

The neuroimaging appearance of lissencephaly is often graded using a 6-point grading system based on the severity and anterior-posterior gradient of the abnormalities. Only grade 1 actually deserves the name of lissencephaly; grades 2–4 are cases of pachygyria (Dobyns and Truwit 1995) (Fig. 3.6). At the end of the spectrum, grades 5 and 6 apply to SBH or band heterotopias or ‘double cortex’ (Table 3.6). SBH is a disorder of migration in which a superficial cortex, which may be grossly normal or show an aberrant gyration, is separated by a thin layer of white matter from a band of grey matter whose separation from the underlying white matter is straight (Fig. 3.7).

*PAFAH1B1* (also often called *LIS1*) was the first gene associated with lissencephaly (Reiner et al. 1993). In the 1960s, Miller (1963) and Dieker et al. (1969) reported sibling pairs with multiple congenital abnormalities including lissencephaly (Miller 1963). Patients with Miller-Dieker syndrome (MDS) have severe lissencephaly (grade 1 or 2) associated with dysmorphic facial features consisting of a high forehead, small jaw, short upturned nose, protruberant upper lip and bitemporal narrowing. Developmental delay and intellectual disability are usually severe (Dobyns et al. 1991; Cardoso et al. 2003). Additional structural abnormalities occasionally reported in MDS include heart defects, omphalocele, cleft palate and genital anomalies in males. Cytogenetic testing revealed that patients with MDS had subtelomeric deletions at band 17p13.3 (Dobyns et al. 1983). The deletions found in MDS patients were frequently de novo and encompassed *PAFAH1B1/LIS1* along with several nearby genes including the *YWHAE* (14-3-3ε) gene (Dobyns et al. 1991; Cardoso et al. 2003). Later on, 65% of patients with isolated lissencephaly sequence (ILS, lissencephaly without other major...
congenital anomalies or dysmorphic features) were found to carry deletions (whole gene or partial) or intragenic mutations of \( \text{PAFAH1B1/LIS1} \) gene (Lo Nigro et al. 1997; Cardoso et al. 2000). In ILS, the lissencephaly is usually less severe (grades 2–4) but the majority of patients still experience significant developmental delay and intellectual disability (Dobyns et al. 1992; Saillour et al. 2009). Severe motor impairment is common. Patients often present with neonatal hypotonia, which evolves into spastic quadriparesis with truncal hypotonia. Other common features include delayed visual development, postnatal microcephaly and feeding difficulties (Dobyns et al. 1992; Saillour et al. 2009). The facial features of patients with ILS are less dysmorphic than those with MDS, and the former usually lack malformations outside the brain. The severity of the neurological impairment broadly correlates with the extent of the agyria and cortical thickening (Cardoso et al. 2000). Around 83% of patients experience early-onset seizures, typically infantile spasms, and nearly all will eventually develop epilepsy (Saillour et al. 2009). The epilepsy is often drug resistant with around half of patients having daily seizures despite treatment. The EEG in most cases shows high amplitude fast activity of alpha or beta frequency, which can alternate, even on the same tracing, with high amplitude delta or theta slow rhythms that may simulate slow spike–wave complexes or hypsarrhythmia (de Rijk-van Andel et al. 1992; Mori et al. 1994) (Fig. 3.8).

\( \text{LIS1} \)-related lissencephaly has several distinctive neuroimaging features. These include a smooth, thickened cortex (typically 12–20mm compared with a normal thickness of 3–4mm) with a cell-sparse zone and a ‘posterior to anterior’ (P > A) severity gradient with more severe abnormalities at the back of the brain. Other potential features include enlarged lateral ventricles, mild hypoplasia of the corpus callosum, prominent perivascular spaces and mild hypoplasia of the cerebellar vermis (Pilz et al. 1998; Dobyns et al. 1999; Saillour et al. 2009).

\( \text{DCX} \) (also known as XLIS) was the second major gene to be associated with classic lissencephaly. \( \text{DCX} \) mutations cause the full spectrum of classic lissencephaly in males (grades 1–6) while females tend to have SBH (Fig. 3.9). The high rate of \( \text{DCX} \)-related SBH in females is explained by lyonisation (X chromosome inactivation), that produces two populations of cells in the developing brain of female heterozygotes. \( \text{DCX} \) mutations explain around 10% of ILS (mostly males),

Modified from Dobyns and Truwitt (1995).

‘Grades 1–6 denote the overall severity of the lissencephaly seen on neuroimaging, with grade 1 being the most severe and grade 6 the mildest form. Grade 1a–6a are more severe posteriorly while grade 1b–6a are more severe anteriorly.'
Chapter 3  Developmental Brain Malformations

Figure 3.7 Typical features of subcortical band heterotopia or double cortex. Representative MRI scans in a 14-year-old girl with a thick continuous band around the entire brain (grades 3–4).

85% of females with sporadic SBH and 25% of males with sporadic SBH (des Portes et al. 1998; Gleeson et al. 1998; Pilz et al. 1998; Leger et al. 2008; Bahi-Buisson et al. 2013). Almost all cases of familial SBH are due to DCX mutations. In familial cases affected mothers may have SBH with mild learning difficulties and epilepsy while their affected male offspring have a more severe grade of lissencephaly. Somatic mosaicism can be an explanation for sporadic SBH in both males and females (Gleeson et al. 2000). Patients with DCX-related lissencephaly have clinical problems similar to those found in patients with PAFAH1 (LIS1)-related lissencephaly. The clinical severity of SBH is dependent on the extent of cortical abnormalities (i.e. the grade of lissencephaly), band thickness and ventricular enlargement (Barkovich et al. 1994). Familial mutations are usually missense mutations (Gleeson et al. 1999), whereas patients with de novo mutations are more likely to have truncating mutations (Bahi-Buisson et al. 2013).

Other Forms and Syndromes of Lissencephaly

Several less common variants of lissencephaly are important to recognise because of different genetic and prognostic consequences (Barkovich et al. 2012) (Table 3.5).

Tubulopathies

TUBA1A mutations are responsible for a spectrum of lissencephaly that ranges from microlissencephaly to perisylvian pachygyria (Keays et al. 2007; Poirier et al. 2007; Bahi-Buisson et al. 2008; Kumar et al. 2010; Cushion et al. 2013; Bahi-Buisson et al. 2014).

TUBA1A-related lissencephaly typically demonstrates a P > A gradient and can be associated with hypoplasia of the cerebellum (mild to severe), dysmorphic basal ganglia, thin or absent corpus callosum, congenital microcephaly. TUBA1A mutations account for 30% of patients with a lissencephaly with cerebellar hypoplasia phenotype and a smaller proportion (1%) of individuals with classic lissencephaly (Kumar et al. 2010).

Following the identification of TUBA1A mutations in lissencephaly patients, heterozygous (and usually de novo) mutations in many neuronal expressed tubulin subunit genes have been associated with a spectrum of malformations of cortical development (Fig. 3.10). These include the β-tubulin genes TUBB2B, TUBB3 and the γ tubulin gene TUBG1 (which is highly-expressed in fetal brain) (Jaglin et al. 2009; Poirier et al. 2010; Poirier et al. 2013). The range of cortical phenotypes associated with tubulin gene defects (the ‘tubulopathies’) is broad but also shows significant overlap between genes. For example, a small number of TUBA1A mutations have been linked to polymicrogyria-like brain malformations also referred to as ‘dysgyria’ (Bahi-Buisson et al. 2008; Jansen et al. 2011; Oegema et al. 2015). Similarly, there are reports of pachygyria-associated TUBB2B mutations (Cushion et al. 2013). Extra-cortical features such as dysmorphic basal ganglia and abnormalities of the corpus callosum, absence of the anterior commissure and cerebellar dysplasia or hypoplasia are commonly observed in patients with tubulopathy and are useful diagnostic indicators of tubulin gene involvement (Bahi-Buisson and Cavallin 1993).

X-linked lissencephaly with ambiguous genitalia

X-linked lissencephaly with ambiguous genitalia (XLAG) is a rarer cause of X-linked lissencephaly. XLAG was first described in 1994 in a family with five affected males (Berry-Kravis and Israel 1994). Premature truncation mutations in ARX gene are commonly associated with XLAG. Features in affected males include severe developmental delay, small or ambiguous genitalia, early hypotonia leading to spasticity and early-onset seizures. Other common features include microcephaly, feeding difficulties, growth failure, diarrhoea and temperature instability (Kato et al. 2004). Mortality in the first year is high in affected males, but survival beyond one year has been reported. XLAG can be sporadic or familial. Carrier females may be normal or have intellectual disability, epilepsy and agenesis of the corpus callosum (Bonneau et al. 2002; Kitamura et al. 2002).

Lissencephaly with cerebellar hypoplasia

Lissencephaly with cerebellar hypoplasia is mainly due to de novo mutations in TUBA1A (Kumar et al. 2010). Homozygous mutations in the RELN gene have also been found in a small number of consanguineous families (Hong et al. 2000).
RELN-related lissencephaly with cerebellar hypoplasia has an A > P gradient and is associated with severe abnormalities of the cerebellum and brainstem (Fig. 3.11). Mutations in \( VLDLR \) gene which encodes the very low-density lipoprotein receptor, a component of the reelin signalling pathway, have also been described in lissencephaly with cerebellar hypoplasia, although the cortical malformation mainly consists of gyral simplification rather than lissencephaly (Ozcelik et al. 2008).

**Baraitser–Winter syndrome**

Baraitser–Winter syndrome (BWS) is a rare malformation syndrome first described in 1988 (Baraitser and Winter 1988). Patients with BWS have characteristic facial features, which include hypertelorism, broad nose with large tip and prominent root, congenital non-myopathic ptosis, ridged metopic suture and arched eyebrows. Iris or retinal coloboma is frequently present, as is sensorineural deafness. The majority of patients have a degree of anterior–predominant pachygyria. Intellectual disability and epilepsy are common and their severity correlates with the extent of the brain malformations. Recently, gain-of-function missense mutations in two genes, \( ACTB \) and \( ACTG1 \) have been described in patients with BWS. The typical brain abnormality associated with BWS is pachygyria with an A > P severity gradient (Riviere et al. 2012; Poirier 2015) (Fig. 3.12).

**Microlissencephaly**

Microlissencephaly consists of extreme congenital microcephaly and agyria or pachygyria with a thick cortex. At least five or six types that may be recessively transmitted have been described with variable thickness of the cortex, localisation of any existing sulci, and presence of associated abnormalities such as cerebellar hypoplasia, brainstem atrophy and enlarged ventricles (Ross et al. 2001; Sztriha et al. 2004; Adachi et al. 2011). Some authors separate these cases from oligogenic microcephaly (Hanefeld 1999), which they consider a form of primary microcephaly rather than a disorder of migration. Clinical features of patients with microlissencephaly include profound cognitive impairment, brain atrophy and extreme microcephaly (head circumference more than 10 SD below the mean). Homozygous mutations in the \( NDE1 \) (Nuclear distribution factor E-homolog1) gene have recently been shown to be a cause of microlissencephaly (Alkuraya et al. 2011). Similarly, recessive mutations in \( KATNB1 \), which encodes the noncatalytic regulatory p80 subunit of katanin, cause microlissencephaly (Hu et al. 2014; Mishra-Gorur et al. 2014).

**Cobblestone cortical malformation**

Cobblestone cortical malformation (CCM), also known as cobblestone cortex, cobblestone lissencephaly or ‘type 2’ lissencephaly, is clinically, genetically, histologically and neuro-radiologically distinct from classic lissencephaly. CCM can appear agyric or pachygyric, although with higher quality brain imaging an irregular or pebbled aspect to the cortex becomes visible.
Chapter 3  Developmental Brain Malformations

Figure 3.9  Distinctive MRI pattern of lissencephaly related to LIS1 and DCX mutations. In LIS1 related lissencephaly, the lissencephaly is most prominent in the posterior (parietooccipital regions). By contrast, in DCX related lissencephaly, the lissencephaly is more severe in the frontal and temporal regions.

is typically thinner than in classic lissencephaly (1cm). Irregularity in the grey-white boundary may also be present, similar to that seen in polymicrogyria. Other MRI features include dilated ventricles, white matter abnormalities, brainstem hypoplasia and cerebellar abnormalities including cysts. Histopathologically, cobblestone cortical malformation is due to over-migration of neurons (in contrast to the under-migration of classic lissencephaly). Neurons migrate through breaches in the glia limitans and accumulate in the subarachnoid space giving the cortex a granular surface and a polymicrogyric appearance is frequently visible together with areas devoid of gyri (Haltia et al. 1997). Cobblestone cortical malformation is genetically heterogeneous but is mostly due to autosomal recessive defects in alpha-dystroglycan O-glycosylation. Around half of patients have mutations in POMT1, POMT2, POMGNT1, FKTN, FKRP, and LARGE. Other genes include POMGNT2, TMEM5, POMK, ISP2, GMPPB, GTDC2, B3GNT1 and B3GALNT2 (Vajsar and Schachter 2006; Godfrey et al. 2007; Clement et al. 2008; Mercuri et al. 2009; Chan et al. 2010).

Three major phenotypes are associated with cobblestone cortical malformations: Walker–Warburg syndrome, Muscle-Eye-Brain disease and Fukuyama Congenital Muscular Dystrophy. These disorders demonstrate a combination of eye, muscle and brain abnormalities (Barkovich 1998).

Walker–Warburg Syndrome

Walker–Warburg syndrome (WWS) (Vajsar and Schachter 2006) is a rare form of autosomal recessive congenital muscular dystrophy associated with brain and eye abnormalities. WWS has a worldwide distribution. The overall incidence is unknown but a survey in north-eastern Italy has reported an incidence rate of 1.2 per 100000 live births. It is the most severe form of congenital muscular dystrophy with most children dying before the age of 3 years. WWS presents at birth with generalised hypotonia, muscle weakness, developmental delay with intellectual disability and occasional seizures. It is associated with type II cobblestone lissencephaly, hydrocephalus, cerebellar malformations, eye abnormalities...
Figure 3.10 Tubulinopathies. Distinct MRI pattern associated with mutations in tubulin genes. (a–c): Four-month-old with classic lissencephaly with a more severe posterior to anterior gradient. (d–f): Fetus at 32 weeks gestation with complete agyria, virtually no sulci and complete corpus callosum agenesis. (g–i): Six-year-old with central pachgyria. The basal ganglia are malformed, appearing as large round structures in which the caudate, putamen and globus pallidus cannot be distinguished (h). Associated malformations include partial agenesis of the rostrum and the splenium (g), thin brainstem and dysplasia of the cerebellar vermis (i). (j–l): Six-year-old with polymicrogyria that appears mildly asymmetrical and most severe over the central regions rather than over the posterior pole. The corpus callosum is hypoplastic (l). The superior vermis is dysplastic (arrow in l).
and congenital muscular dystrophy characterised by hypoglycosylation of alpha-dystroglycan. The cortex has the appearance of a double cortical layer due to the presence of the subcortical heterotopic islands, which may be striking (Fig. 3.13). The meninges are thick and have a milky appearance due to massive mesenchymal proliferation, especially around the brainstem. The cerebellum is small and lacks a vermis, with cerebellar cortical and subcortical cysts represent small areas of pia/subarachnoid space herniating inward through gaps in the pial limiting membrane. The hypoplastic/dysplastic brainstem has typically an abnormal Z-shaped configuration on sagittal images.

The pyramidal tracts are usually absent, and in 75% of cases hydrocephalus is present. It is usually due to fibrosis of the abnormal meninges, but aqueductal stenosis has been reported (Vajsar and Schachter 2006; Godfrey et al. 2007; Clement et al. 2008; Mercuri et al. 2009). There is often fusion of the frontal poles and of the molecular surfaces of cerebellar lamellae. Microscopically, there is complete disruption of cortical architecture, the cortical plate consisting of a variable thickness of poorly oriented cells separated by trabeculae of gliomesenchymal tissue in continuity with that of the meninges. Multiple islands of heterotopic grey matter are aligned parallel to the cortical surface, separated from the overlying cortex by a thin layer of white matter in which thin blood vessels are tangentially aligned. Fibrogial tissue isolates

Fibrogial tissue isolates
clinical features include severe neurological dysfunction from birth; eye abnormalities with retinal dysplasia in all cases, and microphthalmia and anomalies of the anterior segment (Peters anomaly, cataracts, persistence of primitive vitreous body) in most; and the presence in some cases of a posterior cephalocele or large posterior fontanelle. Infants with severe neurological abnormalities and hydrocephalus in association with eye anomalies are highly suspect of having CCM, which is a relatively common cause of genetic hydrocephalus.

Prenatal diagnosis is possible on the basis of hydrocephalus, cephalocele and eye abnormalities (microphthalmia and/or retinal detachment) (Rhodes et al. 1992) and may be confirmed by gene study (Chitayat et al. 1995; Gasser et al. 1998). Muscle involvement is an integral part of cases of CCM (Barkovich 1998), although three patients with normal eyes and muscle has been reported (Dobyns et al. 1996).

**Muscle–Eye–Brain Disease**

In this disease, described by Santavuori et al. 1989, 1998), brain dysfunction is usually less severe. Eye abnormalities mainly consist of severe myopia but may also include such complications as glaucoma and visual failure (Pihko et al. 1995; Haltia et al. 1997). The ventricles are widely dilated and the septum is usually absent (Fig. 3.14). The disease is present at birth but is apparently progressive as shown by the flattening of the ERG after infancy. Flash-evoked potentials are of high amplitude in three-quarters of the patients (Chapter 26).

**Fukuyama Congenital Muscular Dystrophy**

Fukuyama congenital muscular dystrophy is from the neurological point of view a less severe presentation of the cobblestone cortex group, although intellectual disability is marked and eye abnormalities are frequent. The clinical presentation is dominated by muscular impairment (Chan et al. 2010) (see Chapter 21).

The prognosis of the CCM is poor, especially that of the Walker–Warburg type. Most affected infants die in a few weeks or months, an occasional patient living to a few years. Patients with severe hydrocephalus should receive a shunt to avoid monstrous growth of the head, but the ultimate prognosis remains dismal. However, the outcome of
muscle–eye–brain disease and of Fukuyama dystrophy is less severe, and a spectrum of severity from lethal cases to cases of congenital muscular dystrophy or even limb–girdle dystrophy with normal brain and cognition may be observed.

**Kallmann Syndrome**

A peculiar migration abnormality is the cause of the Kallmann syndrome, comprising anosmia due to the absence of olfactory bulb stalks and gyri, hypogonadism, and often mild intellectual disability. This syndrome is genetically heterogeneous but usually transmitted as an X-linked recessive trait. Two genes (KALIG1, localised to Xp22.3, and KALIG2, a fibroblast growth factor receptor [FGFR1] gene), confirm the genetic heterogeneity (Sato et al. 2004; Albuisson et al. 2005). The migration defects involve the olfactory axons and gonadotrophin releasing hormone-secreting neurons that originate from the olfactory placode and normally migrate through the ethmoid to the olfactory bulbs, which do not develop if not reached by axons. The migration of these cells in Kallmann syndrome is blocked in the nasal area because of lack of adhesion molecules, which play a major role in olfactory axon development. Absence of the olfactory bulbs can be visualised by MRI (Truwit et al. 1993).

Cobblestone malformations comprise a broad spectrum of clinically and genetically overlapping disorders resulting from defects in the pial limiting membrane and the attachment of radial glial fibres thereto. The Walker–Warburg phenotype represents the severe end of the spectrum with profoundly small and dysmorphic cerebellar hemispheres often with cysts, absent vermis and very small brainstem, as well as other major brain malformations: cerebral cobblestone cortex, abnormal white matter, anomalous corpus callosum, enlarged dysplastic tectum, and hypoplastic/dysplastic brainstem (Fig. 3.13). The cerebellar cortical and subcortical cysts represent small areas of pia/subarachnoid space herniating inward through gaps in the pial limiting membrane. Patients frequently have hydrocephalus, eye abnormalities (microphthalmia, optic nerve hypoplasia, chorioretinal coloboma, cataract, glaucoma and/or high myopia), seizures, hypotonia and/or muscular dystrophy. The muscle–eye–brain phenotype represents more moderately affected patients with cerebellar and brainstem hypoplasia, and Fukuyama muscular dystrophy represents the mild end of the spectrum that still includes brain malformation. Recessive mutations in multiple genes (POMT1, POMT2, POMGNT1, FKTN, FKRP, LARGE, ISPD and GTDC2) can cause overlapping phenotypes across the entire spectrum of disease, but a substantial proportion of patients remain unexplained (Vajsar and Schachter 2006; Godfrey et al. 2007; Clement et al. 2008; Chan et al. 2010; Luo et al. 2012).

**MALFORMATIONS DUE TO ABNORMAL CORTICAL ORGANISATION**

According to the classification of Barkovich (2012), this category also includes some disorders of late migration. As in the other categories, some of the conditions included depend on mechanisms other than disturbed organisation. Many cases of focal cortical dysplasia, e.g. show abnormal cells of both neuronal and glial origin, indicating abnormal cell differentiation.

**POLYMICROGYRIA**

Polymicrogyria (PMG) is one of the most common brain malformations accounting for almost 20% of all MCD (Leventer et al. 2010; Stutterd and Leventer 2014). Polymicrogyria (PMG) refer to an abnormal appearance of cortical gyri that seem to be crowded, too narrow, and form an abnormal convolutional pattern (Fig. 3.15). Synonymous terms include micropolygyria (Haberland and Brunngraber 1972) and microgyria (Crome and France 1959). PMG is not a single entity but a spectrum of cortical malformations with the
be lined by PMG to be called schizencephaly as opposed to porencephalic cysts, which are lined by white matter or gliosis.

There is no uniform system of classification for PMG. It has been classified according to imaging patterns (Barkovich 2010; Leventer et al. 2010), histopathological appearance (Friede 1989), and the presumed timing of the aetiology in cortical development (Barkovich et al. 2012). There is a wide spectrum of both the type and severity of the clinical sequelae. PMG can be caused by both genetic and non-genetic causes, with multiple chromosomal loci and causative genes described in recent years. It can be seen as an accompanying feature in numerous genetic syndromes (Jansen and Andermann 2005) (Tables 3.7 and 3.8). PMG may show a variety of histological patterns, but all show abnormal cortical lamination, excessive folding and fusion of adjacent gyri through fusion of the molecular layer. Both unlayered (also known as two-layered) and layered forms of PMG are described. Occasionally, both forms are found in the same patient, suggesting that they may be variations of the same malformation. The layered form may show either four or six layers (Judkins et al. 2011). At the boundaries of layered PMG there is an abrupt transition to normal cortex (Kuzniecky et al. 1993). The MRI feature of microgyri and microsulci is ‘stippled’ grey–white junction (Leventer et al. 2010). Stippling of the grey–white junction is a specific feature of PMG not seen in other MCD. In younger children the polymicrogyric cortex may appear thinner than at later ages. This is thought to be due to the immature state of myelination in subcortical and intracortical fibres (Takanashi and Barkovich 2003).

Once the myelination is complete follow-up MRI may be required to appreciate the full extent of PMG. T2 signal within the cortex is usually normal, although there may be delayed myelination. High T2 signal in the underlying white matter should raise the question of an in utero infection (such as cytomegalovirus) (Fig. 3.16) or a peroxisomal disorder (Fig. 3.17) (van der Knaap and Valk 1991).

Polymicrogyria has been described in several topographic patterns (Guerrini and Dobyns 2014). The most common by far is bilateral perisylvian polymicrogyria (Leventer et al. 2010), which varies from the posterior perisylvian region only (grade 4), to the entire perisylvian region (grade 3), to the perisylvian region with extension to other brain regions but not the poles (grade 2), to most of the brain including either or both the frontal or occipital poles (grade 1). However, the perisylvian regions are always the most severely affected. Furthermore, perisylvian polymicrogyria can be bilateral symmetrical, bilateral asymmetrical, or unilateral. Other patterns are almost always bilateral and symmetrical, and include generalised (Chang et al. 2004), frontal (Guerrini et al. 2000), posterior (probably), mesial parieto-occipital, and rare diffuse parasagittal polymicrogyria (Guerrini et al. 1997). Polymicrogyria also occurs in overlying periventricular nodular heterotopia (Wieck et al. 2005).

The clinical manifestations of polymicrogyria vary widely, and depend on several factors. The most severe outcomes

| Focal PMG |

**Syndromes with PMG (neuropathology may differ from classic PMG)**

| Adams–Oliver syndrome |
| Joubert syndrome and related disorders with PMG, includes Meckel–Gruber, Arima (cerebro-oculo-renal) |
| Aicardi syndrome |
| Oculocerebrocutaneous (Delleman) syndrome |
| Fronto-parietal PMG, variable ACC and delayed myelination of anterior limb internal capsule |
| Knobloch syndrome with high myopia, vitreoretinal degeneration, retinal detachment, occipital cephalocele and variable PMG |
| Aniridia, variable temporal PMG, absent anterior commissure and pineal gland, and variable CBLH |
| Goldberg–Shprintzen (megacolon) syndrome |
| Generalised (vs perisylvian) PMG, ACC and optic nerve hypoplasia |
| Perisylvian PMG, ACC, delayed myelination of anterior limb internal capsule and cerebellar vermian hypoplasia |
| Wärburg Micro syndrome |

**Cortical Dysgenesis Secondary to Inborn Errors of Metabolism**

| Mitochondrial and pyruvate metabolic disorders |
| Non-ketotic hyperglycinemia |
| Multiple Acyl-CoA dehydrogenase deficiency (Glutaric aciduria type II) |

**Peroxisomal disorders**

| Zellweger syndrome |
| Neonatal adrenoleukodystrophy |
| D-Bifunctional protein deficiency |

PMG, polymicrogyria; CMV, cytomegalovirus infection; ACC, agenesis of corpus callosum; CBLH, cerebellar hypoplasia.

occur in children with severe microcephaly (−3 SD or smaller), abnormal neurological examination, widespread distribution of polymicrogyria and additional brain malformations (especially cerebellar hypoplasia). The best outcomes are in individuals who have localised unilateral polymicrogyria without other malformations. Bilateral perisylvian polymicrogyria with oromotor dysfunction (congenital suprabulbar palsy), intellectual disability and epilepsy were described

PMG, polymicrogyria; ACC, agenesis of corpus callosum; CBLH, cerebellar hypoplasia; CEDNIK, cerebral dysgenesis, neuropathy, ichthyosis and keratoderma.
as congenital bilateral perisylvian syndrome (Kuzniecky et al. 1993). A small group of patients have unilateral perisylvian polymicrogyria and present with mild hemiparesis or seizures. Although their developmental and neurological deficits are typically less severe than those of patients with bilateral disease, they can develop intractable seizures and epilepsy with continuous spikes and waves during sleep (Kuzniecky et al. 1994). A wider spectrum of manifestations with both severe seizures including infantile spasms and milder cases presenting with language disorder (Saletti et al. 2007) has been reported in infants. Arthrogryposis of central origin is present in some patients (Poduri et al. 2010; Kuzniecky et al. 1994) (Fig. 3.18).

The clinical features of schizencephaly are extremely variable, and the severity of clinical features correlates with the importance of anatomical anomalies, being greater with open-lip clefts (Denis et al. 2000; Govaert 2009). Bilateral, open defects give rise to severe involvement (Barkovich and Kjos 1992). Some patients have quadriplegia and profound encephalopathy. Unilateral clefts usually manifest with hemiplegia and/or focal epilepsy (Caraballo et al. 2004). With the use of neuroimaging it has been realised that many cases are much less severe, with mild intellectual disability, congenital hemiplegia, a large head or even isolated partial seizures. The involvement of both sylvian and insular regions can be responsible for a biopercular syndrome with facial apraxia and speech difficulties (Becker et al. 1989). Epilepsy is present in about 80% of patients (Granata et al. 1996).

The pathogenesis of polymicrogyria is not understood and is probably variable in relation to its remarkable causal heterogeneity with evidence of extrinsic (i.e. non-genetic) and genetic causes. The substantial pathological, neuroimaging, and clinical heterogeneity suggest that polymicrogyria is not a single malformation per se, but can be grouped by diverse phenotypes (Guerreiro and Dobyns 2014). Extrinsinc causes include polymicrogyria related to known or presumed vascular or infectious causes. Several of the earliest descriptions of polymicrogyria came from studies of schizencephaly (Levine et al. 1974), which is associated with extrinsic causes such as vascular insufficiency (especially during twin pregnancies) and cytomegalovirus infections (Barkovich and Lindan 1994). Both causes can result in polymicrogyria without clefts. Some copy number variants have been associated with polymicrogyria, but only deletions in 1p36.3 and 22q11.2 are common (Dobyns et al. 2008). Indeed, when these two loci are excluded, copy number variants seem to be rare. The causal gene has not been identified for any of these loci. All types of single gene inheritance have been reported for polymicrogyria, including several families with autosomal dominant inheritance and some families with rare autosomal recessive forms (Guerreiro et al. 2002). Several reports have described X-linked forms, although the lack of substantiation of these findings throws doubt on the role of these loci in polymicrogyria (Guerreiro and Dobyns 2014). Of note, pathogenic variants in the COL4A1 gene have been reported in schizencephaly, expanding the spectrum of the cerebro-vascular disorders related to COL4A1 mutations (Yoneda et al. 2013).

Several syndromes with diffuse or bilateral frontal predominant polymicrogyria have been described. Because pathological changes have not been defined for most of these disorders, it is not clear whether these syndromes are true polymicrogyria or polymicrogyria-like cortical malformations. Polymicrogyria-like cortical malformations have been reported with several metabolic diseases with severe phenotypes, including Zellweger syndrome, neonatal adrenoleukodystrophy, fumaric aciduria, mitochondrial diseases, glutaric aciduria type 2, maple-syrup-urine disease and histidinaemia. However, the histopathology differs from classic polymicrogyria for several of these disorders, especially the peroxisomal disorders and glutaric aciduria type 2 (Guerreiro and Dobyns 2014).

FOCAL CORTICAL DYSPLASIAS

Focal cortical dysplasias (FCDs) are highly epileptogenic brain lesions and are a frequent cause for drug-resistant focal epilepsies in humans. FCDs present with variable histopathological patterns, including architectural, cytoarchitectural or white matter abnormalities (Taylor et al. 1971). Pathomechanisms compromising neuroblast proliferation, migration or differentiation are likely to play a role in the aetiology of FCD variants. FCDs were subsumed, therefore, into the broad spectrum of malformations of cortical development. Such lesions are increasingly recognised
using high-resolution MRI. Tailored surgical resections provide favourable seizure control in many patients. The International League Against Epilepsy (ILAE) therefore initiated an ad-hoc task force to review published work and to redefine clinicopathological FCD subtypes (Spreafico and Blümcke 2010; Blümcke et al. 2011; Blümcke and Spreafico 2011).

The morphological spectrum of FCD variants is broad (Desikan and Barkovich 2016). In 2004, the seminal classification system developed by Palmini et al. (2004) distinguished two subtypes. With this system, however, presurgical neuroimaging, electroclinical assessment, and histopathological examination of surgical specimens have not enabled reliable identification of all FCD variants.

By contrast, Palmini type 1 FCDs are histopathologically less well characterised; they occur as isolated lesions in adults or children, and affect one or more lobes, or are associated with a second type of pathological change. Appearances on MRI might be nonspecific, with some lesions appearing only as a grey–white matter interface abnormality and others only as hypoplastic cortical lobes. Additionally, there is no international consensus on applied terminologies, which means that comparisons between published studies are difficult.

With the advances of neuropathological and MRI techniques, an international consortium from different medical and scientific disciplines redefined clinicopathological FCD subtypes, combining histopathological findings, neuroimaging and electroclinical data as classifying parameters.

The ILAE task force (Blümcke et al. 2011) has proposed a new classification of three FCD subtypes (Table 3.9). Type 1 refers to FCDs that are not adjacent to or associated with any other lesion (isolated subtype). Vertical or horizontal cortical dyslamination affecting one or more lobes is the classifying parameter, whereas dysmorphic neurons or balloon cells are absent. Neither pathogenetic data nor specific neuroimaging findings are yet available. The second FCD variant is identical to that introduced by Taylor and co-workers (Taylor et al. 1971) and was termed FCD type 2. Dysmorphic neurons and balloon cells remain the classifying morphological landmarks for this variant. A novel ILAE type 3 FCD subgroup refers to those variants with cortical dyslamination that are adjacent to or associated with other principal lesions. Prominent examples include hippocampal sclerosis (type 3a), glioneuronal tumours (type 3b), vascular malformations (type 3c) and other brain injuries that are acquired during early life (e.g. trauma, ischaemic injury, encephalitis).

**ABNORMALITIES OFTEN ASSOCIATED WITH DISORDERS OF CORTICAL DEVELOPMENT**

Several deformities often coexist with migration disorders. However, they may also occur in isolation or in association with other malformations. They include agenesis of the corpus callosum, schizencephaly (‘true’ porencephaly), septo-optic dysplasia and colpocephaly.

**AGENESIS AND DYSGENESIS OF THE CORPUS CALLOSUM**

Agenesis of the corpus callosum (ACC) is an exceedingly heterogeneous condition that can result from disruption of numerous developmental steps from early midline telencephalic patterning to neuronal specification and guidance of commissural axons. It can occur as an isolated finding on MRI, but is more commonly associated with a broader disorder of brain development (Schell-Apacik et al. 2008; Tang et al. 2009).

ACC encompasses either total absence (complete ACC) or absence from birth of at least one, but not all, of the anatomically defined regions of the corpus callosum (partial ACC), which results in a shorter anterior–posterior length. Hypoplasia denotes a corpus callosum that is thinner than usual, but has a normal anterior–posterior extent although this may be hard to quantitate (Hetts et al. 2006; Palmer and Mowat 2014). Atypical forms, difficult to separate from holoprosencephaly, may be encountered (Barkovich and Norman 1988). Callosal agenesis is relatively common. Its prevalence
in the general population is incredibly varied and ranges from 0.5 per 10,000 in the general population to 230–600 per 10,000 in children with neurodevelopmental disability which would make it one of the most common brain malformations (Jeret et al. 1987).

The absent callosal commissure is usually replaced by two longitudinal bundles, known as longitudinal corpora callosa or Probst bundles, that course on the inner aspect of the hemispheres (Fig. 3.19). Sulci on the internal aspect have a radial disposition, and enlargement of the occipital horn that maintains their fetal morphology, the so-called colpocephaly, is common (Noorani et al. 1988). Other abnormalities of the corpus callosum have been noted in a variety of neurodevelopmental conditions, e.g. hyperplasia of the corpus callosum, which may result from reduced postnatal axonal pruning. Dysgenesis of the corpus callosum refers to the corpus callosum being present but malformed in some way, including partial ACC and hypoplasia of the corpus callosum.

ACC can be an apparently isolated malformation, or be associated with additional cerebral malformations with potential detrimental effects on neurological function (complex ACC). Other associated abnormalities frequently include the formation of cysts dorsal to the third ventricle, communicating or noncommunicating (Griebel et al. 1995; Barkovich et al. 2001) cerebellar vermis and brainstem anomalies, and a miscellany of CNS malformations such as heterotopia, abnormalities of gyration or cephaloceles (Jeret et al. 1987; Barkovich and Norman 1988). Giant cysts may have a favourable outcome despite their impressive size (Haverkamp et al. 2002). CNS malformations were found in in 33% of patients with complete and 42% of those with partial agenesis in one series (Bedeschi et al. 2006). It is these associated anomalies that are responsible for the clinical manifestations. Lipoma of the corpus callosum is almost invariably associated with agenesis of the structure (Zee et al. 1981; Vade and Horowitz 1992). Peripheral malformations are common. Eye abnormalities are especially frequent (Palmer and Mowat 2014).

It is recognised that genetic factors contribute to ACC in the vast majority of cases. Less commonly ACC can result from antenatal infections, vascular or toxic insults (Edwards et al. 2014; Palmer and Mowat 2014), and it is increasingly recognised that ACC, particularly isolated ACC, may be polygenic in many cases, due to an interaction of a number of ‘modifier’ genetic and environmental factors. All forms of genetic inheritance have been implicated, including X-linked, autosomal recessive and autosomal dominant. Chromosomal aberrations have been identified as an important cause and advanced maternal age is particularly associated with an increased prevalence of ACC due to chromosomal disorders (Glass et al. 2008). Callosal abnormalities can be associated with chromosomal trisomies (e.g. 13, 18 and mosaic trisomy 8), cytogenetically visible structural chromosomal rearrangements (e.g. 8p rearrangements), and an increasing number of submicroscopic copy number variants, detectable by chromosomal microarray. Twelve chromosomal loci are consistently associated with ACC and at least 30 other recurrent loci that may contain genes that cause or contribute to ACC (O’Driscoll et al. 2010; Edwards et al. 2014; Palmer and Mowat 2014) (Table 3.10).

Environmental factors include fetal alcohol syndrome. Several metabolic diseases, especially hyperglycaemia, pyruvate dehydrogenase deficiency, maternal phenylketonuria and other metabolic disorders collectively account for up to 2% of cases of callosal agenesis (Bamforth et al. 1988). Most cases are of unknown origin.

The clinical manifestations of callosal agenesis can be described under two different headings: nonsyndromic and syndromic forms (Davila-Gutierrez 2002). Nonsyndromic or isolated forms are the most common (Jeret et al. 1987; Serur et al. 1988). Neurodevelopmental outcome for individuals with isolated callosal abnormalities is very varied, even when the neuroanatomy appears relatively similar between patients. There is often significant overlap in neuropsychological outcome between patients with total and partial ACC, in that neuropsychological outcome is not clearly worse for patients with isolated total ACC compared to partial ACC. A recent integrative review highlighted that in truly isolated ACC (i.e. no additional neuroanatomical abnormalities identified on postnatal MRI) neurodevelopmental outcome for individuals diagnosed antenatally can range from essentially normal development, in about 75% of individuals, to differing levels of intellectual disability. About 12% of individuals in this series had severe intellectual disability (Sotiriadis and Makrydimas 2012).
Figure 3.20  Aicardi syndrome in a 2-year-old girl with chorioretinal lacunae. Complete corpus callosum agenesis with arachnoid cyst (posterior fossa) with frontal polymicrogyria and nodular heterotopia.

Several ACC syndromes are yet to have causative genetic mutations identified. Many of these syndromes are of interest because of the diversity of organ systems affected, which may allude to their underlying genetic aetiology (Edwards et al. 2014; Palmer and Mowat 2014) (Table 3.11).

**AICARDI SYNDROME**

Aicardi syndrome was classically characterised by a triad of features: agenesis of the corpus callosum, distinctive chorioretinal lacunae and infantile spasms (Aicardi 2005). However, it is now well recognised that several other important findings are typically present in girls with Aicardi syndrome. Neurological examination can reveal microcephaly, axial hypotonia and appendicular hypertonia with spasticity. Moderate to severe global developmental delay and intellectual disability are expected. Many girls with Aicardi syndrome develop seizures prior to age 3 months, and most before age 1 year. Ongoing medically refractory epilepsy with a variety of seizure types develops over time. Costovertebral defects are common and can lead to marked scoliosis in up to one-third of affected individuals. Other features include characteristic facial features, gastrointestinal difficulties, small hands, vascular malformations and pigmentary lesions of the skin, increased incidence of tumours, lower growth rate after ages 7–9 years, and precocious or delayed puberty. Survival is highly variable, with the mean age of death about 8.3 years and the median age of death about 18.5 years.

The diagnosis of Aicardi syndrome is based on clinical features including the pathognomonic chorioretinal lacunae (See Figure 1.28 in Chapter 1) identified on ophthalmological examination, brain MRI findings (Fig. 3.20) (dysgenesis of the corpus callosum, gross cerebral asymmetry with polymicrogyria, periventricular and intracortical grey matter heterotopia, choroid plexus papillomas, ventriculomegaly and intracerebral cysts, often at the third ventricle and in the choroid plexus) and skeletal findings (hemivertebrae, block vertebrae, fused vertebrae and missing ribs). However, the spectrum of severity is wider than previously thought (Menezes et al. 1994). In rare cases, the corpus callosum may be present. Aicardi syndrome appears to be an X-linked dominant disorder with lethality in males, but no gene or candidate region on the X chromosome has been definitively identified. Pathologically, there are multiple areas of heterotopia and polymicrogyria of the unlayered type in the brain, while the so-called lacunae represent thinning of the pigment epithelium and choroid with loss of pigment granules (Billette de Villemeur et al. 1992). Ependymal cysts are frequently found around the third ventricle, and cysts or tumours of the choroid plexus may reach a large size (Aicardi 2005). They may permit prenatal diagnosis when found in association with callosal agenesis.

Other syndromic forms are rare or mostly restricted to certain ethnic groups.

A familial syndrome of callosal agenesis with abnormal genitalia, which may also feature microcephaly and other CNS anomalies, is a part of the much larger spectrum of disorders associated with mutations in the ARX gene on chromosome Xp22.3 (Hartmann et al. 2004).

ANDERMANN SYNDROME

Andermann syndrome was described in French Canadians in the Lake St John region (Larbrisseau et al. 1984) but a few cases have been reported outside Canada. The syndrome features involvement of the peripheral nervous system in addition to callosal agenesis or hypotrophy. Agenesis of the corpus callosum is often a part of oro-facio-digital syndrome type I.

Prenatal diagnosis is possible from 22 weeks (Bennett et al. 1996; Simon et al. 2000). Indirect ultrasound features that may indicate a corpus callosum anomaly include the absence of the cavum septi pellucidi, colpocephaly (dilatation of the atria and occipital horns of the lateral ventricles), abnormal course of the pericallosal artery, widening of the interhemisphere fissure and radial disposition of the sulci on the internal aspects of the hemispheres. The most common brain anomalies associated with corpus callosum include posterior fossa anomalies, interhemispheric cysts and neuronal migration disorders found in 45.8% of cases on a recent review (Sotiriadis and Makrydimas 2012). Fetal MRI is recommended as this allows direct visualisation of the corpus callosum and may identify additional brain abnormalities (Fig. 3.21).

The presence of additional ultrasound/MRI findings suggests a less favourable prognosis but a specific diagnosis is often not possible. Many couples elect to terminate the pregnancy in these circumstances. Many couples choose to terminate the pregnancy even in the absence of additional abnormal findings because of their concerns about a poor neurodevelopmental outcome. There is relatively little data looking at outcome in the context of isolated ACC and PACC although the emerging trend suggests a better outcome than previously expected. A recent review looked at the developmental outcome in 132 fetuses with isolated ACC from 16 studies and suggested that 71.2% have intelligence in the normal range, 13.6% have borderline or moderate disability and 15.2% have severe disability (Sotiriadis and Makrydimas 2012). In many of these cases the neurodevelopmental data, follow-up period and imaging modality varied widely. When limiting the analysis to isolated ACC, prenatal MRI and standardised neurodevelopmental assessment the rates were 75.4% and 11.6% for normal and severe disability, respectively (Sotiriadis and Makrydimas 2012). In a 10-year follow-up study of an original cohort of 17 children with antenatally detected isolated ACC, 27% had borderline intelligence and 73% were in the normal range (Moutard et al. 2012; D’Antonio et al. 2016).

SEPTO-OPTIC DYSPLASIA

Septo-optic dysplasia (SOD) is a rare disorder with postulated genetic and environmental aetiology, initially considered as a very rare disease with a reported incidence of 1 in 10,000, with equal sex distribution (Saranac and Gucev 2014). The diagnosis of SOD is predominantly a clinical one, and made with the presence of two or more features of the classic triad: (1) hypopituitarism, (2) optic nerve hypoplasia, and (3) midline brain defects, typically absence or hypoplasia of the septum pellucidum and/or corpus callosum (Fig. 3.22). Hypopituitarism ranges from isolated to multiple hormone deficits, with diabetes insipidus in a minority. The condition is heterogeneous...
Chapter 3 Developmental Brain Malformations

and may also manifest additional brain defects. Although homozygous mutations in the homeobox gene \textit{HESX1} have been identified in SOD, these are uncommon and genetic diagnosis can be made in only less than 1% of patients with autosomal recessive inheritance. Autosomal dominant inheritance has also been reported. \textit{SOX2}, \textit{SOX3} and \textit{OTX2} mutations have also been identified in some forms of SOD. The aetiology of SOD is uncertain but viral infections, environmental teratogens and vascular or degenerative damage have been postulated to account for its sporadic occurrence. Other factors (endogenous or exogenous) include parental age, parity, smoking, alcohol and substance abuse, antenatal haemorrhage and ethnicity. Cocaine abuse during pregnancy, which is a potent vasoconstrictor has recently been identified as a potential external cause. The phenotype of SOD is highly variable; the clinical picture may include visual impairment, short stature, obesity and sleep–wake inversion.

Approximately 75–80% of patients exhibit optic nerve hypoplasia, which may be the first presenting feature. The clinical features include variable degrees of visual disturbances. The optic discs have a characteristic appearance with a central part of less than half the normal diameter of the papilla, which represents the true disc, and a peripheral ring of about the size of a normal papilla. This double-contour is of great diagnostic value (Ouvrier and Billson 1986). Facial dysmorphism or endocrine abnormalities, especially growth hormone deficiency and diabetes insipidus, may occur (Masera et al. 1994) and should be searched for systematically in infants because they may produce hypoglycaemia with its complications and sequelae. Pituitary insufficiency may evolve over time, and children with possible SOD must be kept under careful endocrine follow-up.

Cases associated with other brain malformations have been termed ‘septo-optic dysplasia plus’ (Fitz 1994). Prenatal diagnosis of septal agenesis is possible (Lepinard et al. 2005) but isolated septal agenesis is difficult to differentiate from complex cases (Malinger et al. 2005) and is only rarely encountered (Belhocine et al. 2005).

Other anomalies of the septum pellucidum include simple agenesis, cyst formation and persistence of the septum beyond the first year of life. Most are asymptomatic but they may be a marker for other brain malformations (Bodensteiner 1995). An occasional cyst may become symptomatic and compress the foramina of Monro with resulting hydrocephalus (Miki et al. 2005).

COLPOCEPHALY

This is an abnormal shape of the lateral ventricles with symmetrical dilatation of the occipital horns and normal frontal horns. It is commonly associated with callosal agenesis and seldom occurs as a primary abnormality of the occipital lobes. Hypoplasia of the optic nerves may be present in the latter cases (Coupland and Sarnat 1990). The diagnosis is easily made by neuroimaging, but periventricular leukomalacia may produce a superficially similar appearance (Bodensteiner and Gay 1990). Colpocephaly does not require shunting even when the dilatation is marked.

Absence of the corticospinal tracts may be a part of various malformation syndromes including congenital stenosis of the aqueduct and Walker–Warburg syndrome. In rare cases it may be an isolated malformation (Roessmann et al. 1990).

The classification of midbrain–hindbrain (MBHB) malformations is based on embryologic, genetic, neuroimaging and pathophysiological information. It allows the distinction of four major groups of malformations (Jissendi-Tchofo et al. 2015).

1. Malformations secondary to early anteroposterior and dorsoventral patterning defects, or to misspecification of mid–hindbrain germinal zones.
2. Malformations associated with later generalised developmental disorders that significantly affect the brainstem and cerebellum (and have a pathogenesis that is at least partly understood).
3. Localised brain malformations that significantly affect the brainstem and cerebellum (pathogenesis partly or largely understood, includes local proliferation, migration and axonal guidance).
4. Combined hypoplasia and atrophy in putative prenatal onset degenerative disorders.

Little population-based data on the prevalence of MBHB malformations exists, due to the rarity of these disorders and substantial under-recognition on brain imaging studies. The postnatal prevalence of Dandy–Walker malformation has been estimated to be approximately 1 in 30,000 and 1 in 5,000 (Parisi and Dobyns 2003). A prenatal prevalence of approximately 1 in 10,000 was estimated from a large birth defects registry in the United Kingdom (Doherty et al. 2013).

MBHB malformations are frequently diagnosed before birth. Prenatal ultrasound can identify cerebellar hypoplasia, abnormal fluid collections in the posterior fossa or poor delineation of posterior fossa landmarks. Fetal MRI allows a better definition of the malformation (Guibaud and des Portes 2006).

Postnatal presentation of patients with MBHB malformations is typically nonspecific features that include hypotonia, motor delay, and in some cases, characteristic cerebellar clinical syndrome with ataxia, dysmetria, nystagmus and oculomotor apraxia. More severely affected patients can present with
apnoea, feeding and swallowing difficulties, spasticity, lack of developmental progress or seizures. Signs of cranial neuropathy, such as abnormal eye movements, ptosis, facial palsy, hearing impairment (with consequent speech delay) and facial/corneal anaesthesia, may also be observed. Ophthalmological evaluation may reveal chorioretinal coloboma or retinal dystrophy in a subset of patients with Joubert syndrome, a variety of structural eye abnormalities in patients with cobblestone malformations, or eye movement abnormalities. Cognitive impairment is common, but not universal, and autistic features are also observed. The range of neurodevelopmental outcome is broad. Mildly affected patients may have relatively isolated cranial nerve dysfunction, as in Duane retraction syndrome and horizontal gaze palsy with progressive scoliosis.

PREDOMINANTLY CEREBELLAR MALFORMATIONS

Cerebellar hypoplasia has many causes including chromosomal disorders, specific genetic syndromes and prenatal disruptions. They include the Dandy–Walker malformation and other types of dysgenesis of the cerebellar vermis, cerebellar aplasia or hypoplasia (Donkelaar et al. 2003) and rare anomalies such as rhombencephalosynapsis and tectocerebellar dysraphia. Chiari malformation has been described above.

DANDY–WALKER MALFORMATION

Dandy–Walker malformation (DWM) is perhaps the most common MBHB malformation. It is a heterogeneous disorder defined by a hypoplastic and commonly anticlockwise rotated vermis, an enlarged fourth ventricle, and an enlarged posterior fossa with an elevated torcular. Typically, the cerebellar hemispheres are less affected than the vermis, and the brainstem is normal to moderately hypoplastic. Subsets of patients have other brain findings such as ACC and hydrocephalus. DWM can be isolated, part of a defined syndrome or associated with extra-CNS malformations that do not fit with a known condition. Neuroimaging is characteristic (Fig. 3.23). In all cases, a huge collection is present that in half the cases extends upwards through the tentorial opening into the trigeminal cistern and/or downwards through the foramen magnum. It represents the greatly dilated fourth ventricle. The hemispheres are small but normal. The vermis is constantly small and rotated, pushed toward the tentorium. Sagittal cuts allow best visualisation of remnants of the vermis, which are pushed upwards toward the tentorium and anteriorly rotated. According to Klein et al. (2003), in most patients there are only two vermicelliform masses and three lobes; such patients have no associated malformation and their cognitive level is almost always within normal limits. In a smaller group, the vermis is malformed and presents only one or no fissure. These patients always have associated abnormalities and are likely to have severe intellectual disability (Boddaert et al. 2003; Klein et al. 2003). Prenatal diagnosis is relatively easy from the 18th to the 20th week.

Detailed evaluation of brain imaging is important to (1) distinguish DWM from more benign entities such as persistent Blake pouch cyst, in which a normal vermis is rotated anticlockwise by the cyst, and (2) identify mass-effect that might result in obstructive hydrocephalus.

The clinical manifestations of the Dandy–Walker syndrome are mainly those of hydrocephalus. Therefore, the diagnosis is made in 75% of cases after 3 months of age and often only by the first birthday, as hydrocephalus usually becomes apparent by 1 year of age. The head may be elongated in the anteroposterior direction, with bulging of the occiput, which may lead to fortuitous discovery of the anomaly. Remarkably, there are no cerebellar signs or disturbances of stance. Some degree of intellectual disability is present in 30–50% of patients and may be the reason for radiological examination (Boddaert et al. 2003).

Treatment involves shunting the hydrocephalus rather than opening the cystic fourth ventricle. Some surgeons advise inserting the shunt into the fourth ventricle but this is not a unanimous opinion. Additional shunting of the trapped fourth ventricle may be necessary when the lateral ventricles have been shunted. Endoscopic surgery can give good results (Mohanty et al. 2006).

The mechanism of Dandy–Walker syndrome was formerly thought to be atresia of the foramina of Magendie and Luschka. However, it is neither constant nor characteristic.
It in 2009, mutations of FOXC1 (Forkhead box C1, mapped to locus 6p25 OMIM 601090), a gene that is expressed in the developing leptomeninges but not in the brain, in humans were identified to cause posterior fossa malformations ranging from hypoplasia of the vermis or entire cerebellum, with or without enlarged fourth ventricle, to mega cisterna magna, all included in the Dandy–Walker spectrum (Aldinger et al. 2009). Precisely how mutations in the leptomeninges cause hypoplasia of underlying parenchyma is not fully established. Therefore, the earlier concept of hindbrain cystic malformations, being a combination of abnormalities including variable increase of the posterior fossa size and cerebrospinal fluid volume (mesenchymal anomalies) on the one hand and variably impaired growth of the cerebellum (neuroectodermal anomalies) on the other hand, seem to be reasonable in light of new genetic mechanisms as mentioned above.

**CEREBELLAR INVOLVEMENT IN MIGRATIONAL DISORDERS**

Cerebellar hypoplasia may be found in patients with cerebral malformations in the lissencephaly spectrum, caused by defects in the RELN pathway or microtubule function. Reported patients with RELN mutations have pachygyria and minimal foliation of a very hypoplastic cerebellum, vermis worse than hemispheres (Hong et al. 2000) (Fig. 3.11). Profound developmental disability, microcephaly, sloping forehead, seizures and congenital lymphedema have also been reported in these patients. In contrast, patients with mutations in VLDLR have a simplified, mildly pachygyric cerebral cortex and milder cerebellar hypoplasia with some degree of cerebellar foliation (Ozcelik et al. 2008).

Similarly, in ‘tubulinopathies’ are caused by mutations in TUBA1A, TUBA8, TUBB2B, TUBB3 and TUBB5 genes, cerebellar hypoplasia is common. Clinical features range from isolated congenital fibrosis of the extracranial muscles to severe intellectual disability, quadriplegic cerebral palsy, seizures, cranial neuropathies and hydrocephalus. Neuroimaging features include cortical dysgenesis (lissencephaly or polymicrogyria), malformation of cranial nerves and basal ganglia, often with cerebellar and pontine hypoplasia, as well as defects in the corpus callosum, anterior commissure and internal capsule (Fig. 3.10). While most occurrences are sporadic and due to de novo mutations, recurrences have been reported due to germline mosaicism and autosomal recessive inheritance (Bahi-Buisson and Cavallin 1993; Bahi-Buisson et al. 2014; Mutch et al. 2015).

Finally, cerebellar dysplasia with cysts (CDC) is an imaging finding typically seen in combination with cobblestone cortex and congenital muscular dystrophy in individuals with dystroglycanopathies. Similarly, cerebellar dysplasia with cysts are also common in GPR56 related fronto parietal polymicrogyria. More recently, CDC was reported in patients without neuromuscular involvement (Poretti-Bolthauer syndrome), caused but LAMA1 mutations (Aldinger et al. 2014).

**CEREBELLAR AGENESIS**

Cerebellar agenesis is an extremely rare condition characterised by near-complete absence of the cerebellum (Bosemani and Poretti 2016). Cerebellar agenesis is defined on the basis of the morphological pattern/neuroimaging findings and does not suggest the pathogenesis. In cerebellar agenesis, the cerebellar tissue is usually not completely absent; remnants of the anterior vermal lobules, flocculus and/or middle cerebellar peduncles may remain. The volume of the posterior fossa is variable, mostly of normal or increased size. Secondary brainstem involvement, with marked pontine hypoplasia and absence of the protuberance of the inferior olives is typically seen.

Cerebellar agenesis appears to result from at least two distinct pathophysiological mechanisms. First is a genetically mediated condition presenting as a primary malformation (e.g. mutations in PTF1A) (Sellick et al. 2004). The other is a secondary/acquired disruption resulting from: (1) pre- or perinatal haemorrhage; (2) vascular insufficiency/compromise in Chiari II malformation with cerebellar herniation; and (3) as a sequela of preterm birth.

Almost all children with cerebellar agenesis are symptomatic. However, the clinical presentation of cerebellar agenesis appears to be quite heterogeneous, ranging from early death in presumed genetically mediated complex cerebellar agenesis to variable degrees of cerebellar dysfunction, including cognitive impairment in cases of isolated cerebellar agenesis following disruption. Motor dysfunction in patients with cerebellar agenesis is characterised by truncal ataxia, limb ataxia with dysmetria, intention tremor, dysarthria and lower extremity spasticity. Dexterity was studied in one adult with cerebellar agenesis who generated greater grasping forces compared to healthy controls, and who showed impairment of the predictive adjustment of grasping forces to the differential loading requirements of movement direction. Ocular motor abnormalities include strabismus and nystagmus (gaze-evoked and periodic alternating nystagmus), saccadic intrusions into smooth pursuit eye movements in three, hypometric saccades.

**OTHER CEREBELLAR HYPOPLASIAS**

While the cause of cerebellar hypoplasia remains unknown in many patients, a number of other rare cerebellar hypoplasia disorders have been identified. Cerebellar hypoplasia, ventriculomegaly, intellectual disability, seizures and mildly dysmorphic facial features are characteristic in males and occasionally in females with mutations in the X-linked OPHN1 gene (Billuart et al. 1998; des Portes et al. 2004; Zanni et al. 2005).

PHACE syndrome is characterised by posterior fossa brain malformations, haemangioma of the head and/or neck, arterial lesions of the head and/or neck, cardiac defects including aortic coarctation and eye abnormalities (Garzon et al. 2016).
Unilateral cerebellar hypoplasia, ipsilateral to the hemangioma and cerebrovascular lesions are the most common brain imaging findings with occasional cerebellar vermis and supratentorial malformations (corpus callosum dysgenesis, polymicrogyria and heterotopia) (Oza et al. 2008).

**RHOMBENCEPHALOSYNAPSIS**

Rhombencephalosynapsis consists of partial or complete absence of the cerebellar vermis with continuity of the hemispheres across the midline, thought to be due to aberrant dorsal–ventral patterning. The severity of rhombencephalosynapsis on MRI correlates with clinical outcome (Ishak et al. 2012). When severe, the fused cerebellar nuclei arch in a horseshoe shape across the midline, with a narrow fourth ventricle; the primary and prepyramidal fissures of the vermis cannot be identified. Rhombencephalosynapsis is often associated with midbrain abnormalities, i.e. aqueductal stenosis and midline fusion of the colliculi, and supratentorial abnormalities such as absent septum pellucidum and corpus callosum dysmorphisms.

Affected patients can be divided into at least three recognisable categories:

1. Gómez-López-Hernández syndrome combining rhombencephalosynapsis with scalp alopecia and trigeminal anaesthesia,
2. Rhombencephalosynapsis plus features of VACTERL association vertebral defects, anal atresia, cardiac defects, tracheo-esophageal fistula, renal defects and limb defects, and
3. Rhombencephalosynapsis with atypical holoprosencephaly, most severely affecting the occipital lobes.

Developmental outcomes vary widely; patients with isolated rhombencephalosynapsis can function independently in adulthood, while patients with VACTERL features or holoprosencephaly are more likely to manifest significant impairments. No genetic defects have been linked to rhombencephalosynapsis.

**CEREBELLAR HYPERPLASIA OR MACROCEREBELLUM**

Cerebellar hyperplasia is a rare neuroimaging finding that can be seen in isolation, or in a variety of disorders including chromosomal abnormalities, Alexander disease and fucosidosis, as well as Sotos, Williams, Costello, MCAP/MPPH syndromes (Doherty et al. 2013). While the developmental mechanisms underlying cerebellar hyperplasia in most of these disorders remains unknown, substantial progress has been made in the understanding of brain overgrowth in MCA/MPPH. MCAP/ MPPH are typically diagnosed due to supratentorial overgrowth and polymicrogyria (Mirzaa and Poduri 2014). Although cerebellar size is normal at birth, many patients develop macrocerebellum with normal posterior fossa size, resulting in cerebellar ectopia/Chiari I malformation and associated symptoms (posterior headache, dysphagia, stridor) and hydrocephalus.

Most patients have pathway activating de novo mutations in components of the PI3K-AKT-mTOR pathway that result in increased cell growth (Riviere et al. 2012).

**CEREBELLAR DYSPLASIA**

Any part of the cerebellum can be dysplastic, from small focal portions of a single hemisphere to abnormal foliation of the entire cerebellum (Demaerel 2002) (Fig. 3.24). Very often, such as in Joubert syndrome and cobblestone malformations, the hypoplastic cerebellum is also dysmorphic. Outside of these conditions, little is known about the causes of cerebellar cortical dysgenesis. One exception is Chudley-McCullough syndrome, in which patients have striking disorganisation of the inferior cerebellar hemisphere folia. Clinically, these patients present with severe sensorineural hearing loss and mild delays, but are not usually dysmorphic and do not have other malformations. Brain imaging reveals additional abnormalities including frontal polymicrogyria with subcortical heterotopia, corpus callosum hypogenesis and arachnoid cysts. All patients to date have biallelic truncating mutations in the GPSM2 gene that encodes a GTPase regulator required for correct orientation of stem cell divisions in multiple tissues (Doherty et al. 2012). It is likely that aberrant cell division underlies the cerebellar dysplasia, but the mechanism remains unknown.

**OTHER UNUSUAL CEREBELLAR MALFORMATIONS**

Tectocerebellar dysraphia (Dehdashti et al. 2004) is a complex anomaly that includes an inverted cerebellum developed inside the fourth ventricle, hypoplasia of the vermis and occipital cephalocele. Of note, there is evidence that at least in some of the patients, tectocerebellar dysraphism is a morphological pattern within the spectrum of Joubert syndrome (Poretti et al. 2011).

Dentato-olivary dysplasia is a very rare cerebellar malformation characterised by a particular form of the inferior
olives which are hook shaped, coarse, and lacking undulations. It is responsible for neonatal tonic seizures reminiscent of Ohtahara syndrome has been found in a few patients. A genetic origin is likely (Barth 2011).

CEREBELLAR AND BRAINSTEM MALFORMATIONS

PONTOCEREBELLAR HYPOPLASIA

Pontocerebellar hypoplasia occurs in a number of disorders that can be distinguished, in part, by neuroimaging findings and associated features.

To date, 10 subtypes of pontocerebellar hypoplasia with different phenotypes and pathogeneses (types 3 and 8 have a non-progressive course) have been identified (Bosemani et al. 2015; Bosemani and Poretti 2016). Pontocerebellar hypoplasia type 1, associated with mutations in EXOSC3 (Wan et al. 2012) and VRK1 (Renbaum 2009), is characterised by moderate pontocerebellar hypoplasia on MRI in combination with spinal muscular atrophy, resulting in substantial global weakness and decreased or absent reflexes. Pontocerebellar hypoplasia types 2, 4 and 5 are now known to be caused predominantly by mutations in genes that encode tRNA splicing endonucleases (TSEN54, TSEN34 and TSEN2) (Rudnik-Schoneborn et al. 2014; Namavar et al. 2011). Patients with pontocerebellar hypoplasia type 2 represent the less severe end of the spectrum with early hyperreflexia, developmental delay and feeding problems, eventually developing spasticity and involuntary movements in childhood, while patients with pontocerebellar hypoplasia type 4 represent the severe end of the spectrum characterised by polyhydramnios, severe hyperreflexia, contractures and early death due to central respiratory failure. Microcephaly is present at birth in patients with pontocerebellar hypoplasia type 4, while microcephaly develops over time in pontocerebellar hypoplasia type 2. Seizures are common in both groups. A typical feature of TSEN-related pontocerebellar hypoplasia is more severe involvement of the cerebellar hemispheres compared to the vermis, with the so-called ‘dragonfly aspect’ (Fig. 3.25). It is noteworthy that this aspect may be seen in preterm infants with disruptive cerebellar development (Poretti et al. 2014).

Pontocerebellar hypoplasia type 3 is associated with optic atrophy and caused by mutations in PCLO gene (Ahmed et al. 2015). Pontocerebellar hypoplasia type 6 is associated with elevated cerebrospinal fluid lactate and caused by mutations in the RARS2 gene (Edvardson et al. 2007).

Other disorders can mimic the TSEN-related pontocerebellar hypoplasias. The severe end of the spectrum of CASK-related disease also presents with progressive microcephaly and pontocerebellar hypoplasia that proportionately affects the vermis and hemispheres (Fig. 3.26) (Najm et al. 2008). The CASK gene is on the X chromosome, so CASK-related pontocerebellar hypoplasia is more common in females, presumably due to lethality in males. Most recently, recessive loss of function mutations in CHMP1A have been shown to cause severe pontocerebellar hypoplasia with proportionate involvement of the cerebellar vermis and hemispheres and preserved foliation pattern (Najm et al. 2008). Described patients...
had moderate to severe developmental delay, acquired microcephaly, increased extremity tone and contractures.

Pontine tegmental cap dysplasia is characterised by multiple cranial neuropathies, particularly hearing loss, trigeminal anaesthesia, facial paralysis and swallowing dysfunction (Barth et al. 2007). Pontine tegmental cap dysplasia can be distinguished from other pontocerebellar hypoplasias by the characteristic ‘cap’ of tissue on the dorsal pons and severe hypoplasia of the inferior and middle cerebellar peduncles (Fig. 3.27). Congenital heart, kidney, vertebral and rib defects are present in subsets of patients. Developmental disability is typically severe, and the degree of impairment may correlate with the severity of brainstem dysplasia, with mildly affected patients having a rounded bump (‘cap’) and those more severely affected having a more angular brainstem kink (‘beak’). Neither familial recurrence nor genetic causes have been reported.

Hypoplasia of the pons and cerebellum with progressive volume loss is characteristic of congenital disorders of glycosylation type 1a (Fig. 3.28) (Feraco et al. 2012). Patients present with hypotonia and developmental delay, but can also display a striking variety of other features including abnormal fat distribution, coagulopathy, retinal degeneration, peripheral neuropathy, stroke-like episodes and seizures. The range of developmental outcome is broad. This disorder is autosomal recessive, caused by biallelic mutations in the PMM2 gene, required for N-glycosylation of proteins (Matthijs et al. 1997).

Many causes of pontocerebellar hypoplasia remain undefined, although atypical presentations of disorders such as VLDLR-related disequilibrium syndrome (Ozcelik et al. 2008) or pre- and postnatal insults (most commonly complications of extreme preterm birth) may explain additional subsets of patients.

JOUBERT SYNDROME/MOLAR TOOTH MALFORMATION

Joubert syndrome is a congenital cerebellar ataxia with autosomal recessive or X-linked inheritance, the diagnostic hallmark of which is a unique cerebellar and brainstem malformation recognisable on brain imaging the so-called molar tooth sign. Neurological signs are present from the neonatal period and include hypotonia progressing to ataxia, global developmental delay, ocular motor apraxia, and breathing dysregulation (Valente et al. 2005). These signs are variably associated with multi-organ involvement, mainly of retinal dystrophy, nephronophthisis, liver fibrosis and polydactyly (Romani et al. 2013). The outcome is variable. Intellectual disability is the rule but is of variable degree (Hodgkins et al. 2004). A normal intelligence may be preserved in some cases. Supportive treatment and physiotherapy and appropriate education are always justified.

Brain MRI is usually diagnostic, revealing cerebellar vermis hypoplasia/dysplasia, long, thick, elevated superior cerebellar peduncles and a thin MBH junction with a deep cerebellar peduncle resulting in the ‘molar tooth sign’ on axial MRI (Fig. 3.29 and Fig. 1.15 in Chapter 1). The spectrum of associated findings in Joubert syndrome is wide. Other brain malformations can be present, including polymicrogyria, brainstem and cortical heterotopia, agenesis of the corpus callosum and/or cephalocele (Poretti et al. 2011).

Diagnosing Joubert syndrome is important, since it is recessive and carries a 25% recurrence risk. In addition,
close monitoring for the progressive retinal, kidney and liver disease is required to reduce complications. Mutations in more than 35 genes can cause Joubert syndrome and related disorders. The gene products function in the primary cilium–centrosome complex making these disorders part of an expanding group of disorders called ‘ciliopathies’ (Hildebrandt et al. 2011; Poretti et al. 2017). Remarkably, neuroimaging does not predict the genetic cause, but may predict the neurodevelopmental outcome. A high degree of vermis hypoplasia correlates with worse neurodevelopmental outcome. This finding is important for prognostic counselling in Joubert syndrome.

**PREDOMINANTLY BRAINSTEM MALFORMATIONS**

**CONGENITAL CRANIAL DYSINNERVATION DISORDERS**

The term congenital cranial dysinnervation disorders refer to abnormalities of cranial nerve development that result in abnormal movement of the face and eyes, (Gutowski et al. 2003) most of which do not have obvious brainstem abnormalities on clinical MRI studies. The exception is horizontal gaze palsy with progressive scoliosis (HGPPS; OMIM 617313), an autosomal recessive disorder associated with a ‘butterfly shaped pons and medulla’ (Jen et al. 2004). Patients typically present with progressive scoliosis during early childhood and congenital eye movement abnormalities and defects in midline axon crossing demonstrated by somatosensory and motor evoked potentials. HGPPS is due to biallelic mutations in ROBO3 which encodes a receptor required for axon guidance (Jen et al. 2004).

**PREDOMINANTLY MIDBRAIN MALFORMATIONS**

Relatively few disorders that predominantly affect the midbrain have been described (Doherty et al. 2013). Of these, the diencephalic–mesencephalic junction dysplasia has been described as a novel recessive brain malformation in several consanguineous Egyptian families (Zaki et al. 2012). On neuroimaging, the patients had rostral–caudal shortening and dorsal–ventral lengthening of the midbrain, with a deep interpeduncular cistern. In two patients, the corticospinal tracks were not detectable at the level of the pons by diffusion tensor imaging. Variable features included cortical calcifications, agenesia of the corpus callosum, ventriculomegaly, brainstem dysplasia and cerebellar vermis hypoplasia. Clinically, the patients had progressive microcephaly, spasticity, intellectual disability and seizures. Inheritance appeared to be autosomal recessive, but the genetic cause(s) remains unknown.

**Prenatal Diagnosis, Treatment and Prevention of Brain Malformations**

The possibilities for active treatment of brain malformations are limited. Those malformations that induce hydrocephalus can be effectively managed by ventriculo-peritoneal shunt or other shunting operations. Even in such cases, however, neurodevelopmental dysfunction may persist after successful operation because diffuse abnormalities are present in addition to hydrocephalus. The drug treatment of epilepsy has significantly progressed over the past decades, and surgery, especially for epileptogenic dysplasias (Chapter 16), has become a practical possibility in some cases and will continue to develop, being as yet under-utilised. For many patients, however, rehabilitation and physiotherapy are the major tools. Special education is needed in many cases, and for the most the most severely affected children may require care in an institution.
Prevention of CNS malformations is one of the major challenges for child neurology in the coming years. In the present state of knowledge, primary prevention is feasible for neural tube defects by administration of folic acid. Short of primary prevention, genetic counselling and prenatal diagnosis are the major preventive means available.

Genetic counselling requires that a precise diagnosis of fixed encephalopathies is made and that the rules of inheritance of the various types are known (Lie et al. 1994). Major advances in neuroimaging (Garel 2004; Gressens and Luton 2004) especially fetal MRI, have permitted visualisation of important malformation syndromes like polymicrogyria and some ‘minor’ malformations that were very difficult or impossible to diagnose previously. Ideally, a diagnosis of CNS malformation should be not only precise but early if genetic counselling is to be effective.

Prenatal diagnosis of several brain malformations is feasible mainly by ultrasonography (Aubry et al. 2003; Barnewolt and Estroff 2004). Improvement in techniques makes earlier and firmer recognition of many malformations possible. Fetal MRI is currently available in major centres and allows a more precise definition of the pathological features of the malformations (Garel 2004; Golja et al. 2004; Gressens and Luton 2004). It is indicated when sonographic diagnosis is uncertain or additional anatomical precision is required. With technical progress the diagnosis has become possible earlier in many conditions, but in others remains relatively late, with the consequence that only late termination is possible, which compares unfavourably with the earlier diagnosis of cases of metabolic diseases. Additionally, the reliability of ultrasonography depends heavily on the skill of examiners. A difficult ethical issue may be raised by some abnormalities such as the

Dandy–Walker syndrome or agenesis of the corpus callosum as these may be unassociated with neurodevelopmental dysfunction in a significant proportion of cases.

For the diagnosis of chromosomal abnormalities, spina bifida and some metabolic disorders, amniocentesis or chorionic villus sampling may be required. These techniques are associated with a risk of fetal loss of approximately 0.5–1% for amniocentesis performed under ultrasound guidance (Seeds 2004) and of 3% for villus sampling (Caughey et al. 2006). The risk of of puncture injury of the fetus is very small but does exist (Seeds 2004).

Several developmental CNS anomalies may be associated with metabolic diseases. Some of these can be prevented by the control of the metabolic abnormality in the mother (e.g. phenylketonuria or diabetes) or by prevention of toxic effects of certain drugs or other toxic substances like alcohol, and several can be detected prenatally (Table 3.12). Several inborn errors of metabolism are a cause of CNS malformations (Nissenkorn et al. 2001). Nonketotic hyperglycinemia, mitochondrial and peroxisomal disorders have been repeatedly indicated.

Metabolic disturbances of environmental origin, whether due to maternal disease or to use of toxic substances during pregnancy, are a significant cause of fetal malformations. Maternal diabetes mellitus (Anderson et al. 2005) is one major metabolic disorder capable of increasing considerably the incidence of certain CNS malformations, especially holoprosencephaly. Moreover, the clear correlation that exists between high levels of glycosylated haemoglobin A1 in early pregnancy and the occurrence of severe defects in offspring supports the hypothesis that malformations in infants of diabetic mothers occur early during the first 7 weeks of gestation. Such findings indicate that strict control of maternal diabetes is essential. Maternal phenylketonuria is another cause of central nervous system malformations.

Maternal alcoholism is an important factor. Fetal effects including CNS malformations have been extensively reviewed and publicised, and the use of any quantity of alcohol during pregnancy is better avoided as no ‘safe’ level can be defined. Callosal agenesis and holoprosencephaly (Cohen and Shiota 2002) are on record.

Malformations resulting from cocaine use have been produced experimentally in mice (Derauf et al. 2009; Lucca and Baldisserotto 2013). The situation in humans is less clear-cut, although the fetal effects of maternal addiction including disturbed head growth and behavioural effects are well recognised.

Careful monitoring of pregnancy is clearly important, and special attention should be given in cases involving higher risk factors such as maternal age over 35 years, multiple pregnancy, oligohydramnios or hydramnios, and to mothers with known disorders or who have previously given birth to an infant with deformities. Fetuses that are small for gestational age are also at high risk. Khoury et al. (1988) found an incidence of malformation (of any type) of 8.0% in small for gestational age infants compared to 3.3% in infants appropriate for their gestational age (Khoury et al. 1988). The discovery at ultrasonography of peripheral malformations, especially of cystic hygromas, is also an indication of high risk, and nuchal lucencies are an important clue to the diagnosis of Down syndrome and other abnormalities.

It is essential to inform future parents that even the best monitoring will miss a significant number of brain malformations whatever the technique used.

Neurocutaneous Diseases
and Syndromes

Eleni Panagiotakaki and Alexis Arzimanoglou

Several diseases affect both the skin and the nervous system, which is probably a consequence of their common ectodermal origin. Most of these disorders are genetically determined and manifest early in life, although late manifestations are frequent as many of the neurocutaneous syndromes are evolutive conditions.

The group of the neurocutaneous disorders is highly heterogeneous and includes conditions completely unrelated pathophysiologically. They are studied together only because they feature clinically both cutaneous and neurological symptoms and signs, however different these can be. The term ‘phakomatosis’ is still sometimes used as a synonym. However, it has come to be applied mainly to those neurocutaneous diseases in which an excessive growth potential, with frequent development of hamartomas or tumours, is present. This applies to neurofibromatosis, tuberous sclerosis, von Hippel–Lindau disease and some other conditions with a proliferative tendency such as Proteus syndrome or nevoid basal cell carcinoma syndrome. In this chapter, the term neurocutaneous syndrome is used for all diseases in which there is a nonfortuitous association of skin and nervous system abnormalities, including those in which the nervous system involvement consists of vascular abnormalities, even though the cutaneous manifestations may not be regularly present in all patients. The grouping used is clearly arbitrary, but it is justified from a clinical point of view as the association of cutaneous and neurological manifestations raises specific problems. Neurocutaneous diseases are much more pleiotropic than suggested by their name as they may involve viscera as well as skin and the central nervous system (CNS). Most neurocutaneous diseases are genetically determined; all three major Mendelian types of inheritance being possible. Sporadic syndromes may be due to somatic mutations or to other, unknown mechanisms.

Although the group of neurocutaneous diseases is heterogeneous, new concepts such as toropathies bring together diseases considered until now as non-related. The term refers to the tuberous sclerosis complex (TSC) disorders (due to mutations in the TSC1 or TSC2 genes), Cowden syndrome (mutations in PTEN) and neurofibromatosis type 1 (neurofibromin 1 mutations). The mammalian target of rapamycin (mTOR) signalling pathway regulates cell growth and differentiation. Loss-of-function mutations in upstream regulators of mTOR give rise to dysplasias, epileptic seizures and neurodevelopmental disorders (Galanopoulou et al. 2012).

NEUROFIBROMATOSES

Neurofibromatosis is not a single disorder and includes a spectrum of disorders that share many features but clearly differ from one another; there is no agreement as to how many entities belong to the neurofibromatoses. Two distinct forms are generally recognised: Type 1 (NF1), also termed von Recklinghausen disease or peripheral type; and Type 2 (NF2), also termed central neurofibromatosis. These two types are distinct diseases genetically and clinically. The gene of NF1 is located in the pericentric region of the long arm of chromosome 17 (17q11.2), while that of NF2 is on the long arm of chromosome 22 (22q11.2). Both genes act as tumour suppressor genes.

The NF1 gene codes for a protein, neurofibromin, that appears to be a GTPase-activating protein. GTPase converts the proto-oncogen p21-ras from active to inactive form, thus downregulating the production of oncogen and having a probable anti-oncogenic function (De Luca et al. 2005). Most patients with NF1 and intellectual disability are associated with large deletions of the gene.

The NF2 gene codes for merlin, a cytoskeletal-membrane linking protein with roles in the suppression of growth-associated signalling pathways (Hamaratoglu et al. 2006; Plotkin et al. 2014). Interestingly, a loss of chromosome 22, and hence of the NF2 gene, is commonly found in schwannomas and meningiomas that occur outside NF2.

Other types of neurofibromatosis exist. Riccardi (1992) has proposed that seven distinct forms may be recognised. However, the individualisation of some of these forms remains
controversial. The terms central and peripheral are better abandoned because both NF1 and NF2 produce CNS lesions, albeit of different types. The diagnosis of patients with neurofibromatosis is essentially clinical and is usually easy. Table 4.1 shows the criteria for the diagnosis of NF1 and NF2. The basic disturbance in neurofibromatosis appears to be an abnormality in development of the neural crest cells with resulting tendency to abnormal, excessive growth of affected tissues and the development of multiple tumours.

### NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis Type 1 (NF1) accounts for at least 85% of all cases of neurofibromatosis. The prevalence of the disease is about 1 in 3000 individuals. NF1 is inherited dominantly with a 98% penetrance but with a high degree of phenotypic variability. According to Huson et al. (1988) and North (1993), approximately half of people with NF1 have only minor manifestations. Paternal transmission is more common than maternal inheritance. Occasional occurrence of a paternal germline mosaicism may account for the rare occurrence of more than one affected offspring of clinically unaffected parents (Lázaro et al. 1994). About one-third of cases involve new mutations, and the mutation rate is approximately one mutation per 10 000 gametes per generation.

### Cutaneous Manifestations of NF1

Skin features of NF1 consist of abnormalities of pigmentation and tumours (Fig. 4.1). Café-au-lait spots are the hallmark of NF1 and are found in virtually all patients. Their size varies with age; they often are absent at birth but are present from an early age, although they are not as readily visible in infancy as they are later. Ordinarily, at least six spots 0.5–1.0 cm are apparent by 1 year of age but an occasional patient may have less. Of 46 children with such spots prospectively followed by Korf (1992), 27 had developed other signs of NF1 (in the majority, within 3 years), six had segmental neurofibromatosis, three received other diagnoses and eight remained without diagnosis. Axillary freckling was present in 84% of 200 children followed by North (1993), and inguinal freckling was found in about half these patients. Diffuse pigmentation may overlie a plexiform neuroma. Xanthomas and angiomas are less common features. Neurofibromas may be intracutaneous and are then of a violaceous colour and a soft consistency, or subcutaneous and presenting as firm tumours along the trunk of peripheral nerves. They vary from a few millimetres to 3–4 cm at their greatest diameter. Of 46 children with such spots prospectively followed by Korf (1992), 27 had developed other signs of NF1 (in the majority, within 3 years), six had segmental neurofibromatosis, three received other diagnoses and eight remained without diagnosis. Axillary freckling was present in 84% of 200 children followed by North (1993), and inguinal freckling was found in about half these patients. Diffuse pigmentation may overlie a plexiform neuroma. Xanthomas and angiomas are less common features. Neurofibromas may be intracutaneous and are then of a violaceous colour and a soft consistency, or subcutaneous and presenting as firm tumours along the trunk of peripheral nerves. They vary from a few millimetres to 3–4 cm at their greatest diameter. Neurofibromas are sometimes found in children under 10 years old, but they increase steadily in number with age, especially around puberty (Riccardi 1992). They can lead to peripheral neuropathy when they affect larger nerves. Plexiform neurofibromas combine cutaneous and subcutaneous elements to form tumours that may become huge and

Modified from National Institutes of Health Consensus Development Conference (1988). Using these criteria a definite diagnosis can be made in 94% of patients. ‘The patient is given points as shown in the table. A diagnosis of definite NF1 is established if the total number of points is 6 or more (Baser et al. 2011).
represent one of the most serious complications of NF1. They may be continuous with intracranial or intraspinal tumours. Plexiform tumours of the periorbital area, which occur in 5% of patients, can produce proptosis and visual compromise. Large plexiform neurofibromas occur in 25–32% of patients (Huson et al. 1988; North 1998; Darrigo 2007) and tend to grow larger with age. The cosmetic burden may be considerable, and large cervical lesions may displace and compress vascular and respiratory structures and be life threatening. Treatment is surgical but difficult so other methods are being studied (Packer and Rosser 2002; Robertson et al. 2012). One case of sudden death secondary to a neurofibroma of the Xth nerve is on record (Chow et al. 1993). Plexiform neurofibromas of the limbs may be associated with partial gigantism. Involvement of the face is possible and may be associated with exophthalmos and rarely with unilateral megalencephaly (Cutting et al. 2002). Such lesions may be associated with bony abnormalities of the orbit; they require rapid treatment if the eyelid completely covers the eye, to avoid secondary amblyopia. Most plexiform neurofibromas appear before 2 years of age and some may be present at birth. Involvement of the iris by pigmented hamartomas known as Lisch nodules is specific for NF1. Lisch nodules are found in 22–30% of patients with NFI by 6 years of age and in virtually all after age 12 years (Flueler et al. 1986; North 1998).

Neurological Manifestations of NF1

Neurological manifestations of NF1 are protean and include intellectual disability, specific learning difficulties and symptoms and signs due to intracranial and intraspinal tumours (North 1998, 2000; Evans et al. 1999; Friedman 2002).

Macrocephaly (>98th centile) is present in only 16–45% of children with NF1 (Huson et al. 1988; North 1997) and is not correlated with neurological or neuropsychological difficulties (Cutting et al. 2002). It is due to megalencephaly and is not accompanied by symptoms of increased intracranial pressure. Headache occurs in over half the patients and may be migraine-like.

Specific learning difficulties are a well-known feature of NF1 (Riccardi 1992). Intellectual disability is relatively uncommon: Riccardi put the frequency at 8% but lower figures have been reported by other authors (North 1997; North et al. 2002). However, the IQ of patients with NFI is on average lower than that of non-affected siblings. Specific learning difficulties are a common problem, being present in 32% (Hofman et al. 1994) to 65% (North et al. 1998) if impaired academic performance is taken as the criterion. Depressed performance in verbal tasks and a high incidence of language deficits are particularly obvious, but all areas of cognition can be affected (Cutting et al. 2000). Attention-deficit disorder without hyperactivity is common and may respond to amphetamine therapy. A study by Templer et al. (2013) suggested that children with NF1 experience problems with executive functioning that are not wholly accounted for by the behavioural features of attention-deficit–hyperactivity disorder without hyperactivity is common and may respond to amphetamine therapy. A study by Templer et al. (2013) suggested that children with NF1 experience problems with executive functioning that are not wholly accounted for by the behavioural features of attention-deficit--hyperactivity.
disorder. A significant association of cognitive deficits with the presence of T2-intense areas on magnetic resonance imaging (MRI) has been reported by several investigators (Denckla et al. 1996; Wang et al. 2000; Goh et al. 2004) but not by others (Moore et al. 1996; Rosenbaum et al. 1999). Although further studies may still be needed there is increasing evidence correlating the presence of unidentified bright objects with cognitive dysfunction (Feldmann et al. 2010; Piscitelli et al. 2012). Social skills have been shown to be frequently affected with resulting difficulties in communication (Barton and North 2004). Behavioural difficulties are also common (Kayl and Moore 2000). A recent population based study reported a prevalence of autism spectrum disorder (ASD) of 30% (Garg et al. 2013).

Epileptic seizures are more frequent in children with NF1 than in the general population, but available figures vary between 3.5% (North 1998), 4.2% (Kulkarnitkorn and Geller 1998) and 7.3% (Huson et al. 1988). All types of seizures including infantile spasms (Motte et al. 1993; Fois et al. 1994; Ruggieri et al. 2009; Ostendorf et al. 2013) may occur. Focal seizures are more often observed than generalised seizures (Hsieh et al. 2011). Electroencephalogram (EEG) abnormalities are seen in 15% of patients (Riccardi 1992).

Epilepsy in NF1 has been reported to be relatively easy to control with antiepileptic drugs (Hsieh et al. 2011) with approximately 60% of patients having good seizure control (Vivarelli et al. 2003). However, in a recent study, only 16 of 47 (33%) patients with NF1 with epilepsy received only one antiepileptic drug, while 77% of individuals with structural abnormalities on MRI needed more than one drugs (Ostendorf et al. 2013).

In NF1 the occurrence of epileptic seizures could be related to intracranial glioneuronal tumours (gliomas and dysembryoplastic neuroepithelial tumours) and malformations of cortical development, but not to neurofibromatosis unidentified bright objects (Hsieh et al. 2011; Barba et al. 2013). Malformations of cortical development are encountered with lower frequency in comparison to other neurocutaneous syndromes and present in the form of polymicrogyria, focal cortical dysplasia, and hippocampal sclerosis (Mastrangelo 2009; Barba et al. 2013). Hemimegalencephaly has been reported (Cusmai et al. 1990). Epilepsy surgery can be performed effectively in patients with NF1 provided a single and well delimited epileptogenic zone is recognised. The high prevalence of dysembryoplastic neuroepithelial tumours (DNETs) in the series reported by Barba et al. (2013) might suggest a nonfortuitous association with NF1.

Optic gliomas (see Chapter 14) are present in 15–20% of patients with NF1 (North 1998). Histologically, they may differ from other optic gliomas by the presence of an arachnoidal gliomatosis surrounding the optic nerve (Seiff et al. 1987) but otherwise they are typical pilocytic astrocytomas. They may be limited to the optic nerve or involve the chiasm and the retrochiasmatic portion of the visual pathway. Between 10% and 60% of optic gliomas are associated with NF1. The proportion tends to increase in the case of bilateral gliomas, which are almost exclusively found in patients with NF1. Clinical manifestations include proptosis and diminished visual acuity, but many gliomas are now discovered by systematic neuroradiological evaluation. Up to 39% of patients present with precocious puberty (Habiby et al. 1995). The proportion of symptomatic patients is 20–30%, and most symptomatic patients manifest before age 6 and often by 2 years of age (Listernick et al. 1994, 2007).

Optic gliomas in NF1 fall into two groups: those that remain stable, and those that are active, increase in size and threaten vision. Only 52% of patients whose optic gliomas were detected by MRI developed symptoms (Listernick et al. 1997). Emergence of symptoms after age 6 years is extremely rare, as is progression beyond age 10, although a few people who show late presentation or late progression are on record (Listernick et al. 2004). Even in symptomatic patients the outcome is often favourable, and this has to be taken into account for therapeutic indications and for those of repeated imaging. Guillamo et al. (2003) found a favourable outcome in a majority of 104 patients with NF1 (88 of whom were children) with CNS tumours, including 88 optic gliomas, 55 of which were symptomatic. This high proportion of symptomatic patients is explained by the surgical origin of this study. Intrabital gliomas only rarely spread intracranially. The evolution of optic gliomas in NF1 may be more benign than in isolated patients (Listernick et al. 1994) but there is no universal agreement in this regard. Tumours anterior to the chiasm frequently remain stable, whereas more posteriorly located gliomas are more often invasive (Hernández Driever et al. 2010). The diagnosis of optic glioma may be suggested by finding an enlarged optic foramen, although this sign is not specific as elongation of the optic nerve and dural ectasia can simulate a tumour (Riccardi 1992; North 1997).

Modern neuroimaging has transformed the conditions of diagnosis of optic pathway tumours in patients with NF1 (Fig. 4.2) There is an ongoing controversy about the indications for imaging in NF1 (Di Mario et al. 1993). Expert physicians agree that symptomatic cases should be scanned. For asymptomatic people with NF1, the National Institutes of Health Consensus Development Conference (1988) did not advise systematic study as no treatment is usually indicated. Riccardi (1992) is of the opposite opinion, as some aggressive gliomas may progress silently for relatively long periods and may cause damage that could be prevented by early diagnosis. Monitoring of visual evoked potentials may permit early detection but there is a high level of false positives. A study by Yerdelen et al. (2011) on 39 adults and adolescents revealed that over half had abnormal visual evoked potentials even with normal MRI. This could represent either an early presentation of optic glioma or be due to an abnormal myelinisation of the visual pathway.

Treatment of optic glioma is still controversial (Riccardi 1992) (see also Chapter 14). Most tumours that appear stable, especially if localised to the anterior optic pathways, should be watched carefully without surgical or other intervention. In a collaborative study, extension to the optic chiasm was seen in only four of 106 unilateral cases (Wilson 1998). For optic
nerve gliomas that are growing and produce marked proptosis with complete unilateral loss of vision, surgical removal gives satisfactory results. For lesions that are not stable, radiotherapy is effective. However, irradiation with doses of 52 Gray, as usually required, is associated in children with intellectual disability and with endocrinological sequelae in one-third of patients. For patients under 5 years of age whose sensitivity to radiation is particularly high, chemotherapy tends to be substituted for radiotherapy. Combinations of vincristine and carboplatin have been found effective and are often used (North 1997).

Other intracranial tumours are less common (Fig. 4.3). They are mostly astrocytomas that can involve the hemispheres, cerebellum, basal ganglia or brainstem. Brainstem tumours accounted for 21% of intracranial tumours in patients with in the large series of Guillamo et al. (2003). These are of special interest because their prognosis is usually much better than that of brainstem tumours unassociated with NF1. Molloy et al. (1995) studied 17 patients. In only six of these was there evidence of progression by imaging, and in only three was progression detectable clinically. The tumours involved the medulla in 14 patients. Fifteen of the patients were alive at
follow-up after several years, although no treatment other than a shunt when required was given. The authors concluded that these lesions are intermediate between hamartomas and classic brainstem tumours, and that aggressive treatment is best withheld unless there is evidence of progression on monitoring. Pollack et al. (1996) came to similar conclusions in a study of 21 patients. Schmandt et al. (2000) reported spontaneous regression of some astrocytomas. A study on gliomas in 100 patients with NF1 (24 of them arose in the optic pathways) concluded that those tend to be lower grade and have a more favourable prognosis than in patients without NF1, with pilocytic astrocytomas and low-grade astrocytomas (subtype intermediate) being most common. However, diffusely infiltrating astrocytomas are also seen in a subset of patients and need to be managed accordingly (Rodriguez et al. 2008). Multiple brain tumours are not uncommon (Hochstrasser et al. 1988). Intracranial calcification involving the central nuclei or the periventricular area is rare (Arts and Van Dongen 1986) and is not of tumoural origin.

Malignant peripheral nerve sheath tumours are also not uncommon in adolescents and adults (lifetime risk 10%) and patients carry a poorer prognosis than patients without NF1 (Porter et al. 2009). They are rare in children but do occur (Drouet et al. 2004). They have been identified as a leading cause of death in adulthood in patients with NF1.

Intraspinal tumours, comprising mainly astrocytomas, are uncommon. Intraspinal neurofibromas occur mainly in the cervicothoracic region. These tumours not uncommonly are both intra- and extraspinal and may be in continuity with a subcutaneous plexiform neurofibroma. Intramedullary tumours such as ependymomas and astrocytomas are not a feature of NF1. Rare cases of spinal neurofibromatosis with multiple symmetrical tumours are on record (Pascual-Castroviejo et al. 2007).

The so-called ‘unidentified bright objects’ are hyperintense areas especially demonstrated by MRI, most frequently on T2 sequences in the thalami, the pallidum, the cerebellar peduncles and hemispheres, but also in the hemispherical white matter in the optic tracts and radiations (Fig. 4.4). The significance of this finding is not fully understood. Such areas, in most patients, do not correspond to tumour extension, although in the past they have been described as ‘hamartomas’ (Braffman et al. 1988) and may remain stable or disappear. They are frequent in patients without, as well as those with, optic pathway gliomas (Duffner et al. 1989; North 1998). North (1997) found high-intensity T2 lesions in 32 of 50 systematically studied 8–16-year-old patients, 24 of whom had no tumour. The lesions were usually multiple, involved the optic tract in 20 patients, the basal ganglia in 24, the cerebellum in eight and the brainstem in six. Hyperintense lesions were seen in T1-weighted sequences in 16 children, usually corresponding with T2 abnormalities. As a result of improvement in magnetic resonance techniques the frequency of these abnormalities has been even higher in recent series, and some authors have proposed them as a diagnostic criterion for NF1 (Curless et al. 1998; DeBella et al. 2000). They were present in 25 of the 29 patients described by Rosenbaum et al. (1999) and in 89% of those of Raininko et al. (2001). The latter authors made a detailed study of these areas. They found them more commonly on proton density (80%) than on T1 (50%) sequences and noted that they occasionally enhanced with gadolinium. In five of their patients they increased in size, with later regression and disappearance in four. They often change with evolution, tending to disappear with age, although they may increase in number at adolescence, as also found by Kraut et al. (2004) who reported a biphasic evolution. They are not more common when an optic pathway tumour is present. Hyperintense areas tend to decrease and often disappear before adulthood (Sevick et al. 1992). Their histological nature is unknown. They are more common in children and adolescents than in adults. Those located in
the optic tracts and the pallidum are larger than those found elsewhere and may give an abnormal signal, although a weak one, on T1-weighted images (Inoue et al. 1997). The abnormally intense T2 areas have been shown in a few patients to represent glial dysplasia or spongiotic changes rather than hamartomas (Di Paolo et al. 1995). Proton MRI of such lesions (Wang et al. 2000) showed initially an increase in chol- line and relatively normal N-acetylaspartate, later followed by a decrease in N-acetylaspartate, suggesting a secondary loss of neurons. Billiet et al. (2014) studied the microstructure of ‘with new in vivo MRI-based techniques. Their results support the hypothesis of intramyelinic vacuolisation, in the absence of demyelination or axonal damage.

Hydrocephalus in a majority of patients is the result of aqueductal stenosis (Afifi et al. 1988; Rivello et al. 1988). It usually develops slowly and is recognised late. It is most commonly due to gliosis, diffuse or membranous, of the aqueduct. Small tumours of the peduncular region may be a cause, and MRI in the sagittal plane using both T1- and T2-weighted sequences should always be performed. An intense signal in T2-weighted scans was present in seven of nine patients (Pou Serradell and Ugarte-Elola 1989; Valentini et al. 1995). Other causes of ventriculomegaly in patients with NFI include Chiari I malformation (Afifi et al. 1988) and tumours of the posterior fossa.

Other Complications of NF1

These include growth retardation, which was reported in about 25% of patients by North (1998). Vassilopoulos-Sellin et al. (2000) found that 122 of 251 children were below the 25th centile and 68 were below the 10th centile for age. Eye disease, especially glaucoma and buphthalmos, osseous dysplasia and arachnoid cysts are classic findings. Abnormalities of the skull are frequent in NF1. Craniofacial dysplasia can affect any portion of the cranial vault, most commonly the occipital regions along the lambdoid suture. Bones contributing to the orbit, especially the greater sphenoidal wing, are a site for election for dysplasia. The greater wing is missing in part, with resulting pulsating exophthalmos when the defect is large. The lesser wing and sella turcica are often involved in the dysplasia. Dural ectasias can produce bilateral enlargement of the auditory canal, which may suggest the diagnosis of NF2, but they are not associated with schwannoma of the VIIIth nerve (Inoue et al. 1997). Calvarial defects adjacent to the lambdoid suture are clinically asymptomatic.

Scoliosis is present in 20% of patients and may be sufficiently severe to warrant surgical correction. It is occasionally associated with paraspinal neurofibromas. Vertebral abnormalities are frequent, and scalloping of the body of vertebrae is a common radiological finding in NF1, as is scoliosis. Lateral ectasia of the thinned dura through the intervertebral foramina (lateral meningoceles) is a rare complication of NF1 (Riccardi 1992). Tibial pseudarthrosis is a common lesion (North 1997). Decreases in bone mineral density, even osteoporosis can be identified in individuals with NF1, perhaps even as early as childhood (Brunetti-Pierri et al. 2008; Stevenson et al. 2008).

Vascular manifestations (Tomsik et al. 1976) include systemic hypertension with or without renal artery stenosis, which should always be looked for, and, rarely, cerebrovascular accidents (Rosser et al. 2005). Multiple stenoses of carotid arteries with the development of a moyamoya pattern has been reported (Rizzo and Lessell 1994). Grill et al. (1999) observed that 13 of 69 children who received X-irradiation for glioma of the optic chiasma developed vascular stenosis of the intracranial carotid arteries.

The incidence of malignancies, the most frequent of which are fibrosarcomas, is higher in persons with NF1 than in the rest of the population, but they are rare in childhood. Leukaemia, especially of chronic myelogenous type, can occur (Clark and Hutter 1982) and may be associated with the presence of cutaneous xanthomas. Visceral and endocrine tumours are relatively common in later life (Huson et al. 1988). Visceral autonomic localisations may be seen. In particular, intestinal ganglioneuromatosis with intestinal obstruction is recognised (Kim and Kim 1998).

Course of NF1

The course of NF1 is very variable and minor forms are common. However, many complications can occur and mortality is not negligible, especially when subcutaneous neurofibromas are present. Khosrotehrani et al. (2005) found 40 deaths in a 2.6 year follow-up of a series of 703 patients, 57.6% of whom were children. In this series, the presence of cutaneous neurofibromas was associated with a significantly higher mortality. In a 10-year follow-up study of 150 patients, Cnossen et al. (1998) showed that 41% of them developed complications during this period; 28% had one complication, 12% had two and 1.3% had three. All patients should, therefore, be followed regularly, even in the absence of symptoms. Life expectancy in NF1 is approximately 8 years lower than the general population (Wilding 2012).

Diagnosis of NF1

The diagnosis of NF1 is essentially clinical and by imaging (Table 4.1) and it is usually easy. Histological study of pigmented spots could show abnormalities in melanosomes (Martuza et al. 1985), but is not usually justified. Imaging diagnosis may be difficult, and MRI is the primary tool for the diagnosis of CNS abnormalities. NF1 genetic testing is reserved for unusual presentations or reproductive decision-making.

Management of NF1

The management of patients with NF1 should start with assessment of the extent of the disease by a complete clinical, ophthalmological and radiological examination. A team
approach, grouping specialists in the many different problems that are often associated with the condition, is important, as it has been shown that many patients are not appropriately diagnosed and treated for all their problems. A thorough search for neurological, visceral and bone abnormalities is essential. Careful clinical follow-up is mandatory. Huson (1999) thinks a consultation every 2 years is reasonable, but closer surveillance and complementary investigations are required when symptoms appear. Members of the United Kingdom Neurofibromatosis Association Clinical Advisory Board recommend that the following should be recorded at each annual visit: development and progress at school; visual acuity and fundoscopy until age 7 years (optic pathway glioma, glaucoma); head circumference (for a rapid increase indicating tumour or hydrocephalus); height; weight; pubertal development (delayed/precocious puberty due to pituitary/hypothalamic lesion); blood pressure (renal artery stenosis, phaeochromocytoma); cardiovascular examination (congenital heart disease, especially pulmonary stenosis); evaluation of spine (scoliosis underlying plexiform neurofibromas); evaluation of the skin and system examination guided by specific symptoms (Ferner et al. 2007).

Whether routine imaging studies of the CNS are required remains disputed, they generally seem to be performed at least on the first examination. Repeated studies should be undertaken according to clinical indications. It is clearly necessary for those patients who have suspected brain tumours. For patients with known optic gliomas, at least an annual ophthalmological examination of visual acuity and fields should be performed, and MRI should be done if vision deteriorates.

Surgical treatment is indicated only for invasive tumours as much of the tumours are either static or slowly growing, but the results are often disappointing. The same applies to radiotherapy, as sequelae are particularly prone to occur in young children. Epileptogenic tumours can be treated surgically, provided that a link is clearly established with the electroclinical presentation of the seizures. Surgery is also indicated for visceral lesions, cosmetic deformities and orthopaedic problems that in many cases amount to a major problem. There is no drug treatment for neurofibromatosis, although several drug trials have been initiated, in an attempt to slow or halt the growth of neurofibromas. Some studies were done to assess the efficacy of statin use in improving cognitive function in children with NF1 but results are contradictory (Krab et al. 2008; Acosta et al. 2011; van der Vaart et al. 2013). Several clinical trials have been initiated, including studies of imatinib (Robertson et al. 2012) or sorafenib for plexiform neurofibromas, bevacizumab and everolimus for malignant peripheral nerve sheath tumours, everolimus for progressive glioma associated with NF1, and mitogen-activated protein kinase/extracellular signal-regulated kinase inhibitors for children with inoperable plexiform neurofibromas (Hirbe and Gutmann 2014; Plotkin et al. 2014).

**NEUROFIBROMATOSIS TYPE 2**

Neurofibromatosis Type 2 (NF2) is transmitted as a dominant autosomal trait. The gene has been mapped to chromosome 22 (Rouleau et al. 1993). Bilateral acoustic neuromas (vestibular schwannomas) are the essential feature, occurring in at least 90% of patients (Evans et al. 1992a). These tumours develop mainly in late adolescence and early adulthood, and NF2 is rarely found in children. Loss of hearing is the first symptom. Cutaneous manifestations are uncommon and most patients have no café-au-lait spots, or only a small number of them. Some of these are schwannomas. Histologically they differ from those in NF1; they are usually less than 2cm in diameter, slightly raised, well circumscribed, and may contain excess hair (MacCollin and Mautner 1998; Ruggieri et al. 2005). Lisch nodules are not found, but posterior subcapsular cataracts occur in 10% or more of patients (Ruggieri et al. 2004). Other intracranial tumours are frequent especially meningiomas, often multiple but optic nerve glioma has not been found in NF2 patients. The occurrence of astrocytoma also seems to be exceptional. Diagnostic criteria are summarised in Table 4.1. Definite diagnosis is based on MRI findings (Fig. 4.5).

Schwannomas of cranial nerves V to XII are common. They are frequently bilateral and multiple. Some authors indicate that atypical NF2 may occur sporadically and often presents with multiple cranial or spinal schwannomas (Purcell and Dixon 1989; Pou Serradell 1991). MacCollin et al. (1996) proposed separating a subgroup of NF2 under the term ‘schwannomatosis’, manifested by peripheral painful nerve schwannomas and often by multiple spinal root tumours. Such cases may be difficult to distinguish from children with NF2 in which peripheral tumours may long precede the appearance of acoustic schwannomas, and indeed have been shown to be a variant of NF2 (Evans et al. 1997).

Spinal cord tumours are of two types: schwannomas, which are of the same histological type as the acoustic neuroma, and ependymomas (Rubinstein 1986). The former may be multiple and lead to serious problems. Hamartomatous lesions resembling meningiomas, termed ‘meningoangiomatosis’ (Russell and Rubinstein 1977), may occur and be responsible for calcification, especially in the choroid plexus, at the periphery of one cerebellar hemisphere (Ruggieri et al. 2005), or as linear subependymal calcification (Arts and Van Dongen 1986), which may be associated with seizures. Involvement of peripheral nerves can occur. Presymptomatic diagnosis is possible with chromosome 22 markers (Ruttleledge et al. 1993).

Ruggieri et al. (2013) described the natural history of three unrelated children with bilateral vestibular schwannomas due to NF2 and detected incidentally on brain MRI at ages 4–5 months. These children had no symptoms for a period of 11–15 years, when their schwannomas became symptomatic. During the period in which their schwannomas remained asymptomatic, these children developed NF2 plaques, mostly
in atypical locations, which spontaneously resolved by the age of 11–15 years. Retinal changes and lens abnormalities were detected in two of these children as early as 3 months of age (Ruggieri et al. 2013).

NF2 is a separate disorder from NF1 and there are a few patients with both NF1 and NF2 inherited separately from each parent (Evans et al. 1992b). The disease may be mistaken for NF1 in the rare patient with bilateral auditory canal enlargement without tumour (Kitamura et al. 1989). The presence of bilateral acoustic neuromas in NF1 has, however, been reported (Pou Serradell 1991).

The management of NF2 should be supervised by a specialist team. It includes regular assessment, looking especially for acoustic nerve tumours. Special attention should be given to monitoring of hearing as acoustic neuromas usually occur relatively late. Surveillance for other tumours and ocular problems should also be regularly performed. Early assessment of siblings may allow effective treatment of oculan abnormalities and should be systematically offered. A first MRI of patients is indicated from 10 to 12 years of age (Evans et al. 2003).

**OTHER FORMS OF NEUROFIBROMATOSIS**

**SEGMENTAL NEUROFIBROMATOSIS**

Segmental Neurofibromatosis (NF5) is closely related to NF1. NF5 is characterised by the unilateral occurrence of features that are typical of NF1 (café-au-lait spots and neurofibromas) in only one or in several dermal segments. The disorder is thought to result from a postzygotic mutation event, and any dermatome may be involved (McLimore et al. 2014). Most cases are sporadic although familial transmission has been observed (Jung 1988). Although NF5 is said to be rare, Listernick et al. (2003) reported 39 patients from three centres. In 29 of these the disease was limited to pigmented tumours and café-au-lait spots; isolated in seven patients or associated with axillary freckling. Other abnormalities are rare but iris nodules or pseudarthrosis may be found in the affected segments (Ruggieri et al. 2005).

Roth et al. (1987) divide segmental neurofibromatosis into four subtypes, only one of which is genetically transmitted. The skin lesions are usually café-au-lait patches but neurofibromas may eventually develop. Other complications of neurofibromatosis do not occur. The prognosis is good.

**OTHER POSSIBLE FORMS**

Forms with only café-au-lait spots and other atypical forms are on record. Charrow et al. (1993) found suggestive evidence of non-linkage to the NF1 locus, but Abelowich et al. (1995) found close linkage to the NF1 gene in a large pedigree. Intestinal neurofibromatosis may occur in isolation (Heimann et al. 1988) or form a part of syndromes related to neurofibromatosis and to the multiple endocrine neoplasia disorders (Fryns and Chrzanowska 1988; Griffiths et al. 1990). Type III or IIB multiple endocrine adenomatosis is characterised by a Marfan-like habitus, a lobulated tongue with multiple submucous neuromas, conjunctival nodules, thick lips, megacolon and multiple endocrine tumours (Moline and Eng 2011).

Legius syndrome concerns patients with a mild NF1 phenotype with pigmented changes. However, these patients do not develop neurofibromas or Lisch nodules and present
mutations in SPRED1 gene (Brems et al. 2007; Messiaen et al. 2009).

A combination of NF1 with features of the Noonan phenotype (short stature, pectus carinatum, cardiac defect, ptosis and low intelligence) has long been known and has been termed ‘neurofibromatosis–Noonan syndrome’ (Borochowitz et al. 1989). Baralle et al. (2003) found that two of six patients had novel mutations in the NF1 gene and no mutation in the PTPN11 gene, thus indicating that some of these people have NF1. The frequency of NF1 mutation in such patients was recently confirmed (De Luca et al. 2005; Ekvall et al. 2014). However, Bertola et al. (2005) and Thiel et al. (2009) found in some patients the coexistence of NF1 mutation and a PTPN11 mutation known to cause Noonan syndrome. Watson syndrome (café-au-lait patches and pulmonic stenosis), which may include CNS involvement in the form of areas of increased T2 signal (Leão and da Silva 1995), is probably allelic to NF1 (Tassabehji et al. 1993).

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex (TSC) is an autosomal dominantly transmitted disorder characterised by hamartomas that can affect many organs including the skin, brain, heart, kidneys and other sites, with a variable expression. TSC has a high incidence of new mutations in the order of 58–68% of recognised patients (Hunt and Lidenbaum 1984). The prevalence of the disease is imperfectly known because of the frequency of paucisymptomatic forms. Population surveys indicate a prevalence of 1 in 6000 to 1 in 10 000 (Kuntz 1988; Webb and Osborne 1995). Occurrence of affected siblings with apparently unaffected parents is rare. Two genes are responsible for TSC. In about 25% of the families TSC is caused by a mutation in the TSC1 gene in chromosome 9q34.3 that codes for the protein hamartin; in the remainder the TSC2 gene in 16p13.3 that encodes the protein tuberin is affected. Both genes probably act as tumour suppressor genes (Au et al. 2004) and are involved in neuronal specification and migration. In 490 people with TSC Sancak et al. (2005) found the TSC2 gene responsible for TSC in 78%, 3.4 times more often than TSC1. TSC1 mutations account for 10–30% of affected families, whereas most cases of TSC2 mutations are observed in sporadic cases. TSC2 mutations, tend to be more severe (Kothare et al. 2014). No mutation is detected in 15–20% of patients, who usually show a milder clinical disease.

The mechanism of the disease involves an abnormality of proliferation and differentiation of embryonic cells, with a tendency to hamartomatous proliferation, and a disturbance of the migrational process of CNS cells resulting from the disruption of either hamartin or tuberin. These proteins act as sensors for growth factors, linking the extracellular cues to the activity of mTOR, a major regulator of protein translation and cell growth. Growth factor receptors activate a cascade regulating a large number of cellular functions (Goh and Weiss 2006). Work in the past few years has considerably increased our understanding of the disorder, especially the role of reduced inhibition of the mammalian target of rapamycin (mTOR) activation factor (Crino et al. 2006). Tuberin and hamartin function together forming a TSC2: TSC1 tumour suppressor complex. This complex is the principal cellular inhibitor of the mammalian target of rapamycin, mTOR (Orlova and Crino 2010).

Pathology and Pathogenesis of TSC

The characteristic lesions found in the brain of patients with TSC are cortical tubers, subependymal nodules and giant cell tumours. Tubers (Fig. 4.6) are hard nodules of variable size that show disruption of normal lamination, increased astrocytic nuclei and a reduction of the number of neurons, which are replaced by bizarre giant cells (Huttenlocher and Heydemann 1984; Yamanouchi et al. 1997) that take both glial and neuronal markers. They may become calcified. Beneath the tubers, enlarged abnormal heterotopic neurons extend all the way to the ventricular walls. Subependymal nodules are small excrescences on the ventricular walls that resemble solidified wax that has dripped down the side of a candle; hence the term ‘candle guttering’ that is traditionally used. They are composed of large round fusiform cells that are thought to be of astrocytic origin. Subependymal giant cell astrocytomas (Fig. 4.7a–f) are found in about 5% of patients (Gomez et al. 1988) and are consistently located to the region of the foramen of Monro. Unlike subependymal nodules, they tend to measure over 5mm and to be less homogeneously dense; they sometimes grow to a large size but rarely, if ever, become malignant. The nature of the giant cells is still uncertain (Sharma et al. 2004).

Visceral tumours arise from various viscera. Rhabdomyomas are found in the heart of 40–50% of patients with TSC and are often multiple. Renal lesions include angiomyolipomas, which may be the only lesion of TSC in some patients, and renal cysts (Robbins and Bernstein 1988). Retinal phakomas are benign astrocytic tumours that tend to calcify. Other hamartomatous lesions are seen less commonly (Gomez et al. 1988).

Clinical Manifestations of TSC

The clinical manifestations of TSC vary considerably with the extent of involvement and age at onset. Table 4.2 groups the findings into those that are highly suggestive and those that are less characteristic of the disease, according to the revised criteria (Gomez et al. 1988; Roach et al. 1998). Because no feature is pathognomonic, involvement of two organ systems or at least two dissimilar lesions in the same organ is required for diagnosis (Roach and Sparagana 2004). The
most recent revision in June 2012 includes genetic criteria and eliminates probable disease as a diagnostic class. The diagnosis now is definite if a pathogenic mutation of TSC1 or TSC2 is identified or if two major features or one major feature with two or more minor features are present. The diagnosis is possible if either one major feature or two or more minor features are present (Northrup and Krueger 2013).

**Epilepsy in TSC**

In infants and children, seizures are the most common presenting symptom, occurring in around 80% of patients. The majority (70%) of patients start under the age of 12 months with lesser occurrence with age: 16%, 1–4 years; 9%, 5–15 years; only 4% begin their epilepsy over the age of 16 years (Cross et al. 2005). Infantile spasms (Gomez et al. 1988; Curatolo and Seri 2003) are the most common type of seizures in infancy. Vigabatrin can be particularly useful in this case, with a response rate of 95% compared to 54% of children with a non-TSC aetiology of spasms (Cross et al. 2005). Other types of seizures are not unusual, especially focal motor seizures. Tonic or atonic seizures are also frequently seen in children who progressively develop Lennox–Gastaut syndrome. Multiple types of seizures are present in 50% of patients, and drug resistance may occur in about 37–62% (Chu-Shore et al. 2010; Vignoli et al. 2013). About 5% of patients, especially those with a TSC2 mutation, can have epileptic spasms, occurring outside the age range of the first 2 years (Hsieh et al. 2013).

Selected individuals should be considered for epilepsy surgery, especially if seizures arise from a single tuber. The decision on type of presurgical evaluation has to be taken by teams with experience in paediatric epilepsy surgery. A stereo-EEG investigation is usually necessary in children with multiple tubers.

A meta-analysis of 20 studies looking at results of epilepsy surgery in TSC, reported the following as statistically significant predictors of good postoperative outcome: absence of generalised seizure semiology, no or mild developmental delay, unifocal ictal scalp EEG abnormality and EEG/MRI concordance (Fallah et al. 2013). Another meta-analysis of 13 studies also found that patients with unilateral focal ictal-interictal EEG abnormalities, with seizure onset later than 1 year of age and extensive resection (lobectomy), had a higher rate of seizure freedom (Zhang et al. 2013). Completeness of resection, focal scalp interictal EEG patterns, agreement of interictal and ictal EEG localisation, one-stage surgery and few tubers were good predictive factors of seizure-free outcome after surgery according to another study in 33 TSC patients (Krsek et al. 2013). The identification of the most active and epileptogenic tubers may be obtained by a multimodal presurgical evaluation, including invasive EEG monitoring. Unfortunately, seizures may persist after tuberectomy and they may arise in the future from other tubers.

A study with intracranial electrocorticography revealed that the epileptiform activity started from the surrounding perituberal cortex while tubers were electrically silent (Major et al. 2009). But the study by Mohamed et al. (2012) exploring intracranial EEG findings, suggested that tubers play a
greater role in seizure genesis than perituberal cortex, and that
tuberectomy may be a sufficient surgical approach in a num-
ber of patients.

Everolimus (the inhibitor of the mammalian target of
rapamycin complex 1mTORC1), with demonstrated benefit
for TSC-related renal angiomyolipoma, lymphangiomatosis
and subependymal giant cell astrocytoma (SEGA), has been
tried in a prospective, multicentre, open label study showing
a median reduction of seizure frequency of 73% in 17 of 20
treated participants (Krueger et al. 2013). A much larger pro-
spective study is currently ongoing.

Neurodevelopmental Difficulties in TSC

Intellectual disability is the rule in hospital-based series and
was present in 82% of children in one study (Monaghan
et al. 1981). However, in the Mayo Clinic experience, only
47% of patients and their affected relatives were judged to have
below normal intelligence, while 44% had normal intelligence
(Gomez et al. 1988). Webb et al. (1991) gave an even lower
figure for intellectual disability (40%) in a population study.
Intellectual disability is found mainly in patients who have
had seizures, and especially where these had their onset before
2 years of age (with an even worse prognosis for a history of
infantile spasms) (Gomez et al. 1988; Chu-Shore et al. 2010;
Humphrey et al. 2014). The prognosis of infantile spasms in
patients with TSC is thus serious compared to other forms
of epilepsy, even though a proportion of these patients may
develop a normal cognition (Rando et al. 2005; Jóźwiak
et al. 2011). Riikonen and Simell (1990) found that infantile
spasms due to TSC have an especially poor prognosis, while
Yamamoto et al. (1987) reported that the outcome in
such patients was significantly better than that of patients
with symptomatic spasms due to other causes. Bolton
et al. (2015) support the proposition that severe, early-onset

of Monroe associated with moderate right obstructive ventriculomegaly.
epilepsy may impair intellectual development in TSC and highlight the potential importance of early, prompt and effective treatment.

In addition to intellectual regression and/or disability other behavioural or cognitive abnormalities such as specific cognitive deficits and hyperkinesia are not infrequently found in patients with TSC (Hunt and Dennis 1987).

Autism is a frequent feature of TSC, especially in those children who had infantile spasms (Bolton 2004). It is present in 25–50% of patients and TSC may be responsible for 1–4% of cases seen in the population (Wiznitzer 2004). Burket et al. (2015) stipulate that the severity of intellectual disability and ASD in TSC may relate more to the underlying metabolic disturbance (over activity of mTOR signalling), as shown by improvement of sociability and other symptoms in mouse models treated with rapamycin. Gipson et al. (2015) described in detail, the neurodevelopmental phenotype of three individuals with TSC and concluded that they shared common characteristics. They identified a distinct profile of ASD order specific to TSC that requires consideration before diagnosis of autism and can help optimise treatment across the life span. But other authors reported that children with TSC and ASD demonstrated a profile of social communication impairment that has complete convergence with children presenting non-syndromic ASD (Jeste et al. 2016). The authors suggest the need for early intervention in toddlers with TSC, with treatment strategies targeting social communication function as well as broader developmental domains, before the onset of autism symptoms. Concerning treatment, everolimus, an mTOR inhibitor, was observed to lower rates of self-injury in one patient (Gipson et al. 2013).

Other neurological deficits in TSC are rare, with the exception of increased intracranial pressure that occurs in less than 3% of patients and results from the development of intraventricular giant cell tumours and becomes symptomatic after the

c A combination of the two major clinical features (LAM and angiomyolipomas) without other features does not meet criteria for a definite diagnosis.
age of 5 years. These giant cell tumours may also be responsible for a hemiplegia.

Cutaneous manifestations in TSC
The classic cutaneous lesions (Fig. 4.8) of TSC are present in 80% of patients. Classic angiofibromas (adenoma sebaceum) that occupy symmetrical areas over the cheeks, nasolabial folds and chin are red papular lesions, found in 50% of patients; they are rare in infants and generally appear between 3 and 15 years of age. Hypomelanotic macules (achromic patches or ash-leaf spots) are the earliest and most frequent cutaneous sign of TSC and occur in 90% of patients (Fryer et al. 1990). They vary in number and size and are often present at birth, although they may become more visible and more numerous within a few months. They may be visible only under Wood’s light in fair-skinned patients, especially infants. Isolated, small hypomelanotic spots are nonspecific. They are present in 0.8% of typically developing newborn infants (Alper and Holmes 1983). The association of white spots with seizures, especially infantile spasms, is characteristic of TSC. A lock of depigmented hair may be an initial sign (McWilliam and Stephenson 1978). It results from the presence of a hypomelanotic spot on the scalp. Other cutaneous signs are seen later in life. They include fibrous plaques, usually on the forehead or scalp, that can occasionally be the sole manifestation of the disease; shagreen patches (20–40% of patients) that consist of a slightly elevated plaque of epidermis with a granular surface and sometimes a yellowish-brown discolouration and appear after a few years of life, commonly in the lumbar region; periungual fibromas that are a pathognomonic lesion but one that seldom occurs before puberty and then only in about 50% of patients; and molluscum pendulum in the cervical and lower facial region — not a specific lesion but quite unusual in childhood outside TSC. Café-au-lait spots are not more frequent in TSC than in the general population (Bell and McDonald 1985).

Eye anomalies in TSC
Eye findings are represented by retinal astrocytomas (phakomas) (Fig. 4.9), which are found in half the patients and may be unique or multiple. They are round or oval in shape and become easy to diagnose when they calcify, assuming a typical mulberry appearance. They are seldom symptomatic and only a handful of symptomatic changes have been reported in the past few decades (Mennel et al. 2007). Other ophthalmological findings in patients with TSC include depigmented retinal areas, hypopigmented iris spots, hyaline or cystic nodules, cataracts and iris coloboma. An increased incidence of association with subependymal giant cell astrocytomas, angiofibrolipoma, cognitive impairment and epilepsy has been noted in the presence of retinal findings (Aronow et al. 2012).

Other findings in TSC
In some patients, the presenting manifestations are visceral rather than CNS ones (Franz 2004). A search for other localisations of TSC is always indicated. Kidney tumours (angiolipomas), usually multiple and bilateral, are present in 60–75% of patients and may precede nervous system manifestations in
infants, while hypertension may be the first feature in children (Robbins and Bernstein 1988). They are often highly vascular and can produce severe haemorrhage.

Patients with TSC may also manifest with autosomal polycystic kidney disease, as the polycystic kidney disease gene, PKD1, is located in close proximity to the \textit{TSC2} accounting for the occurrence of both conditions in case of large deletions (contiguous gene syndrome) (Brook-Carter et al. 1994).

Cardiac rhabdomyomas may be revealed by echography; they may occur prenatally or may only be revealed following administration of drugs such as carbamazepine. About half the cardiac rhabdomyomas are a manifestation of TSC. Conversely, more than 50% of patients with TSC have cardiac tumours. Many are asymptomatic but some may manifest as cardiac failure, although arrhythmia is more common. Contrary to most other manifestations they have a marked tendency to disappear with time. They may be the cause of embolic strokes, although this is disputed by Gomez (1989).

Other visceral manifestations, especially pulmonary involvement frequent in adults, are rare in children. They usually present in women in their third of fourth decade and can be complicated by pneumothorax, hemothysis, chylothorax and respiratory failure. Partial gigantism has been reported in TSC (Franz 2004).

**Figure 4.9 Retinal phakoma** in a patient with tuberous sclerosis. Note tumour overlies retinal vessels.

subcortical areas of decreased attenuation that correspond to tubers and may be associated with widening of the adjacent gyrus; focal areas of increased attenuation corresponding to calcified tubers; in some patients ventricular dilatation or cortical atrophy or both; and occasionally cerebellar calcification. Gyrisform calcification simulating that in Sturge–Weber syndrome may occur (Wilsms et al. 1992). Contrast enhancement is useful if a giant cell astrocytoma is suspected as these take up contrast in 80% of patients.

MRI may not show all the calcified lesions well, but does show cortical and subcortical tubers much better than CT. They present as high signal areas in T2-weighted sequences. These areas are generally much more numerous than hypodense areas evidenced by CT and are located in the cortex (Roach et al. 1991). They vary in number and localisation, and there is some relationship between the number and localisation of tubers and cognitive development and neuropsychological findings (Shepherd et al. 1995; Goodman et al. 1997; Bozzao et al. 2003). Although there is no strict correlation between neurodevelopmental difficulties and the number or density of tubers detected by imaging, there is a trend for patients with more tubers to have more cognitive or behavioural disturbances, and frontal and parietal locations may be more closely related with autism and intellectual disability (Curatolo 2003; Ridler et al. 2004). Deep white matter cystic abnormalities have been rarely reported (Canapicchi et al. 1996). Radial bands or wedge-shaped areas extending from ventricle to cortex or to a cortical tuber (Braffman et al. 1992) are composed of clusters of heterotopic cells and are indicative of a disorder of migration associated with abnormal cell differentiation. According to Gomez et al. (1988), a diagnosis of cerebral TSC can probably be discarded if both CT and MRI are negative for cerebral abnormalities.

The EEG is of interest to better define the type of epilepsy associated with TSC. Atypical hypsarrhythmia, often asymmetrical, is present in one-third of patients early in the course of the disorder, when epileptic spasms are present. Focal signs are present in at least 40% of tracings (Yamamoto et al. 1987). In later childhood, focal paroxysms or bilateral slow spike–wave complexes may be found.

**Management of TSC**

Genetic testing should be offered for family counselling or when diagnosis is doubtful. Careful examination of both parents including Wood’s lamp inspection of the skin should be performed, especially clinical and ophtalmological assessment. The assessment also includes: a search for possible cases in the family, renal ultrasonography and brain MRI. In the usual case of an isolated patient without family history of the disease, a favourable genetic prognosis can be given with very few reservations, provided both parents have been carefully examined and have been found not to have any cutaneous, neurological or visceral features of the disease. Even
so, a small proportion of such cases (<1%) may be missed (Roach and Sparagana 2004). Prenatal diagnosis can be suspected on the basis of a fetal ultrasound examination showing cardiac rhabdomyomas or polycystic kidneys. A prenatal head MRI after the 20th week of gestation can identify large cortical tubers.

Krueger and Northrup (2013), on behalf of the International Tuberous Sclerosis Complex Consensus Conference, provided recommendations on surveillance and management. MRI of the brain every 1–3 years is advised before 25 years of age to monitor for new occurrence of subependymal giant cell astrocytoma (SEGA). Surgical resection or shunt should be performed for acutely symptomatic SEGAs. Either surgical resection or medical treatment with mammalian target of rapamycin complex (mTOR) inhibitors may be used for growing but otherwise asymptomatic SEGAs.

Regular evaluation should be performed for TSC-associated neuropsychiatric disorders (e.g. ASD, attention-deficit–hyperactivity disorder).

Parents should be educated to recognise infantile spasms in infants. EEG monitoring is recommended every month for the first 6 months and then every 6–8 weeks unless there are other abnormalities (Curatolo et al. 2012). Also prophylactic management of patients based on early EEG changes has been shown to improve cognition and seizure control with lesser need for polypharmacy in the long run (Jóźwiak et al. 2011). Further prospective studies, focusing on the overall efficacy of prophylactic treatment are still needed.

MRI of the abdomen should be performed every 1–3 years to assess for the presence of angiomylipoma and renal cysts. Renal function then (including determination of glomerular filtration rate [GFR]) and blood pressure should be assessed at least annually. Embolisation followed by corticosteroids is first-line therapy for angiomylipoma presenting with acute haemorrhage. For asymptomatic, growing angiomylipoma measuring larger than 3cm in diameter, treatment with an mTOR inhibitor is recommended (Krueger and Northrup 2013).

Pulmonary function testing and chest high resolution CT, is indicated, in patients at risk of developing lymphangioleiomyomatosis, typically females 18 years or older. mTOR inhibitors may be used in moderate to severe or rapidly progressing lung disease.

A detailed skin examination should be performed annually. A detailed dental examination should be performed regularly and panoramic radiographs by age 7 years if not performed previously, in order to screen for symptomatic or deforming dental lesions, oral fibromas and bony jaw lesions.

Fetal echocardiography is used to detect individuals at high risk of heart failure after delivery when rhabdomyomas are identified via prenatal ultrasound. Echocardiograms should be performed in children, especially before age 3 years until regression of rhabdomyomas. Electrocardiograms should be obtained in all ages to assess for underlying conduction defects. A complete ophthalmological evaluation including dilated fundoscopy should be performed to assess for retinal lesions and visual field deficits (Krueger and Northrup 2013).

There is no specific treatment for the disease itself, but several of its manifestations are amenable to therapy. Antiepileptic drugs should be given for seizures, and infantile spasms may justify adrenocorticotropic hormone (ACTH) or steroid treatment. Vigabatrin is particularly effective as a first-line drug in the treatment of infantile spasms due to TSC, and to a lesser extent for treatment of focal seizures (Curatolo and Seri 2003).

Removal of a large tuber may be successful in controlling seizures in some patients. Determination of the existence of a single epileptogenic tuber is a prerequisite. This may be achieved by careful EEG and imaging studies (Lachwani et al. 2005). A large tuber containing a nidus of calcification is most likely to be an epileptogenic tuber (Koh et al. 2000; Karenfort et al. 2002). The use of alpha-methyltryptophan, which appears to fixate electively on active tubers, was suggested by one group (Chugani et al. 1998). In this study authors were able to effectively differentiate the epileptogenic tubers from nonepileptogenic tubers using alpha methyl tryptophan (AMT) positron emission tomography (PET) as opposed to glucose metabolism PET scan, which shows cortical areas of hypometabolism corresponding to the location of all the tubers – epileptogenic and nonepileptogenic. AMT PET has been found to be useful in patients with multifocal EEG abnormalities to localise effectively and resect the epileptogenic tuber for a more favourable seizure outcome. Seizure freedom rates may be much lower if tubers are nonlocalisable by AMT PET (Kagawa et al. 2005).

Further confirmation of the epileptogenic tuber and extent of the resection may involve invasive evaluation with depth electrodes (Stereo-EEG) and electrocorticography (ECoG) (Shahid 2013; Arzimanoglou and Kossof 2016). Resection of epileptogenic tubers alone leaving the peritubular cortex intact has been reported with good results (Mohamed et al. 2012). However, a resection of both the tuber and the perituberal cortex results in a more favourable long-term outcome. It remains to be determined whether resection of an epileptogenic tuber may be associated with ‘activation’ of another lesion that could lead to persistence of seizures (Karenfort et al. 2002).

Epileptogenic tubers located in eloquent cortex can be safely removed without any long-term deficits, thus proving the nonfunctionality of these tubers (Moshe et al. 2010). In 2006, Franz et al. showed that rapamycin, an inhibitor of mTOR, can inhibit the growth of astrocytomas in TSC. Further reports of success of rapamycin (sirolimus) and everolimus in renal angiomyolipoma and lymphangioleiomyomatosis have been published (Wienecke et al. 2006; Bissler et al. 2008). Everolimus, an orally administered mTOR inhibitor, is the first pharmacological therapy approved for the treatment of TSC. The therapeutic efficacy and safety of everolimus have been demonstrated in multicentre, international, randomised, double-blind,
placebo-controlled trials. These studies continue in their extension phases with the goal of establishing the long-term safety and efficacy profile of everolimus in patients with TSC. Targeted systemic therapies such as everolimus are particularly useful in that they treat the multiple manifestations of TSC and offer patients both a means of symptom relief and a treatment alternative to invasive surgical procedures (Franz 2013).

**LINEAR NEVUS AND RELATED SYNDROMES**

In its complete form, Classic Linear Nevus or Schimmelpenning-Feuerstein-Mims Syndrome includes a cutaneous nevus with neurological and eye abnormalities. The skin lesion may be of several types. One typical appearance is that of the sebaceous nevus of Jadassohn. This lesion usually involves the head or face, and may be visible at birth or in infancy or become evident only after a few years (Clancy et al. 1985). It is a slightly raised, yellow-orange, smooth, linear plaque that abuts the midline of the forehead, nose or lips and often involves the scalp. It tends to become darker and verrucous as years pass. Early in life there is mainly acanthosis and little pigment, and sebaceous glands are often not prominent. Later, sebaceous glands proliferate, and apocrine glands may be located aberrantly throughout the thickness of the skin.

A second type of nevus is the verrucous nevus, which is formed of discrete papules, slightly darker than the surrounding skin, with a linear organisation. Such nevi are more often located on the body and less on the face than the sebaceous nevus, and histologically there is only acanthosis and hyperkeratosis with abnormal dermis (Prensky 1987). It seems that either type of nevus may be associated with neurological abnormalities (Clancy et al. 1985; Menascu and Donner 2008), although most skin lesions are isolated. Associated cutaneous abnormalities such as ichthyosis, acanthosis nigricans, haemangiomomas and café-au-lait spots are frequent, and linear nevus overlaps with other neurocutaneous syndromes with proliferative skin and subcutaneous tissue lesions (see section on Related Syndromes with Proliferative Skin and Subcutaneous Tissue Lesions).

Neurological manifestations associated with both types of nevi consist of intellectual disability, seizures, cranial nerve palsies, hydrocephalus and asymmetrical macrocephaly (van de Warrenburg et al. 1998; Menascu and Donner 2008). Seizures are often focal, but infantile spasms have been observed in four of 11 patients in one series (Vigevano et al. 1984). From a pathological point of view, the most common brain abnormalities are disorders of proliferation and migration (Prayson et al. 1999). Hemimegalencephaly (Pavone et al. 1991; Boer et al. 2007) is frequent and may be associated with hemihypertrophy of the ipsilateral face and body. Hamartomatous tumours were present in several patients (Clancy et al. 1985). Destructive lesions such as porencephaly have also been found (Baker et al. 1987; Prensky 1987) and may be of vascular origin as arterial aneurysms, arteriovenous malformations and abnormal venous return have been reported (Dobyns and Garg 1991). Similar lesions have been found in the spinal cord. Other CNS abnormalities include arachnoid cysts, subtotal cerebellar agenesis, and callosal agenesis with Dandy–Walker malformation (Dodge and Dobyns 1995).

The most common eye abnormalities are dermoids or epidermoids of the conjunctiva and colobomas of the iris, choroid, retina or optic nerve. Enlargement of the orbit and of the greater wing of the sphenoid on the side of the nevus may be present. Familial cases are rare (Meschia et al. 1992).

The diagnosis may be difficult early on in people without visible nevus. MRI, with diffusion-tensor imaging, is the most sensitive study for diagnosing hemimegalencephaly, which is present in about 50% of children with epidermal nevus syndrome. The most common imaging findings are hypertrophy of one hemisphere, usually on the same side as the nevus, with enlargement of the ipsilateral ventricle, and pachygyria, polymicrogyria or nodular heterotopias (Kruse et al. 1998; Mori 2004). Such an image is consistent with pathological reports of hemimegalencephaly or other migration disorders.

The EEG usually shows paroxysmal activity over the involved hemisphere, sometimes with a hypersrrhythmic pattern. The prognosis is usually serious but mild cases exist with only seizures or mild learning difficulties. Treatment is symptomatic.

Epilepsy, which develops in most children with hemimegalencephaly, is typically refractory to medical management and resective epilepsy surgery (hemispherotomy) remains the treatment of choice (Vigevano et al. 1989; Shimizu 2005; Di Rocco et al. 2006; Luders and Schuele 2006; Salamon et al. 2006; Loddenkemper et al. 2008). Removal of the cutaneous lesion is possible in some patients.

The occurrence of the syndrome is sporadic. Epidermal nevus can result from somatic mosaicism for mutations in the *FGFR3* gene (Hafner et al. 2006), the *PIK3CA* gene (Hafner et al. 2007), and the *RAS* genes (*KRAS, HRAS* and *NRAS*). Linear nevus syndrome can be caused by postzygotic somatic mutation in the *HRAS* gene on chromosome 11p15, the *KRAS* gene on chromosome 12p12, or the *NRAS* gene on chromosome 1p13 (Groesser et al. 2012; Hafner et al. 2012; Levinsohn et al. 2013).

Other neurocutaneous syndromes with presence of nevi are reported in the literature:

- CHILD syndrome is an acronym for an X-linked dominant disorder characterised by congenital hemidysplasia with ichthyosiform erythroderma and limb defects (Happle
et al. 1980). It has been found to be caused by mutation in the gene encoding NSDHL (König et al. 2000).

• SCALP syndrome, which includes sebaceous nevus syndrome, CNS malformations (including hemimegalencephaly), aplasia cutis congenita and limbal dermoid, with pigmented nevus (giant congenital melanocytic nevus) and neurocutaneous melanosis (Lam et al. 2008).

• CLOVE syndrome, congenital lipomatous overgrowth, vascular malformations, and epidermal nevi. There is evidence that CLOVE syndrome can be caused by somatic mosaicism for postzygotic activating mutations in the PIK3CA gene (Sapp et al. 2007; Kurek et al. 2012). Patients were initially mistakenly identified as having Proteus syndrome. The acronym was later expanded to CLOVES to include the association with scoliosis and skeletal and spinal anomalies (Alomari 2009).

RELATED SYNDROMES WITH PROLIFERATIVE SKIN AND SUBCUTANEOUS TISSUE LESIONS

ENCEPHALOCRANIOCUTANEOUS LIPOMATOSIS (HABERLAND SYNDROME) AND OCULOCEREBROCUTANEOUS SYNDROME (DELLEMAN SYNDROME)

Encephalocraniocutaneous lipomatosis (Haberland Syndrome) and oculocerebrocutaneous syndrome (OCCS; Dellemann Syndrome) are rare, closely related, apparently sporadic syndromes characterised by microcephaly, lipodermoids involving the conjunctiva, sclera or eyelids, and lipomatous swelling over the cranium or face along with skin lesions like alopecia. About two-thirds of the patients have normal development or mild intellectual disability only, and half of them have seizures. Forehead lipoma is the most common CNS abnormalities, followed by enlargement of the lateral ventricles, arachnoid cysts, widening of the subarachnoid spaces, dysplastic cortex, and corticopial calcifications, thinning of the corpus callosum and leptomeningeal angioma. Aortic coarctation, progressive bone cysts and jaw tumours may be associated (Pascual-Castroviejo et al. 2005b; Moog et al. 2005, 2007; Moog 2009). The condition may share some clinical manifestations with the Proteus syndrome (McCall et al. 1992).

PROTEUS SYNDROME

This term applies to a complex hamartomatous syndrome consisting of partial gigantism, asymmetry of the limbs, linear verrucous and intradermal nevi, shagreen patches and variable combinations of lymphangiomas, haemangiomas, macrocephaly and hyperostoses. Plantar skin hyperplasia (the so-called mocassin lesion) is a frequent and useful diagnostic feature (Nguyen et al. 2004). Epibulbar dermoids, colobomas, glaucoma and retinal detachment can occur. Some patients may have intellectual disability. Hemimegalencephaly is frequent (Griffiths et al. 1994). The deformities resulting from the syndrome can reach extreme proportions, as in the case of Joseph Merrick, the so-called Elephant Man. The disease is still commonly misdiagnosed as neurofibromatosis.

As the name implies, the Proteus syndrome has a very variable expression (Cohen 2014). Visceral tumours may occur (Gordon et al. 1995). Most proven cases to date have been sporadic. There is evidence that Proteus syndrome is associated with a somatic activating mutation in the AKT1 gene, proving the hypothesis of somatic mosaicism and implicating activation of the PI3K–AKT pathway in the characteristic clinical findings of overgrowth and tumour susceptibility in this disorder (Lindhurst et al. 2011).

The diagnosis is difficult as the limits of the syndrome are not well defined. Turner et al. (2004) found that among 205 patients described in the literature, only 97 (43%) met strict criteria. In a review, Cohen (2014) provided revised diagnostic criteria, noting that the presence of cerebriform connective tissue nevus is a major diagnostic feature, although it is not found in all patients. Patients whose conditions do not meet such criteria are sometimes termed ‘Proteus-like syndrome’ (Zhou et al. 2000) and some of them were associated with germline and tissue-specific somatic mutations in the PTEN gene, responsible for Cowden or Bannayan–Riley–Ruvalcaba syndrome (PTEN hamartoma syndromes).

OTHER SYNDROMES WITH TISSUE PROLIFERATION – PTEN HAMARTOMA TUMOUR SYNDROMES

Cowden syndrome is characterised by the association of various skin lesions especially facial trichilemmomas and other cutaneous abnormalities, with other hamartomas that may include intestinal polyps. In childhood, clinical features include macrocephaly, scrotal tongue and mild-to-moderate intellectual disability, while cutaneous tumours and other characteristic features appear only later in life (Hanssen and Fryns 1995). Busch et al. (2013) concluded that, contrary to previous reports suggesting an association with intellectual disability, the mean intellectual intelligence quotient was average, with a broad range of function. Patients have a risk for thyroid, breast and endometrial cancers. Approximately 80% of cases are due to germline mutations of the tumour suppressor PTEN gene (Blumenthal and Dennis 2008). The most striking neurological feature is the cerebellar hamartomatos hyperplasia of Lhermitte–Duclos disease, also due to mutations in the PTEN gene, which in fact is part of the spectrum of Cowden syndrome (Perez-Nunez et al. 2004; Tan and Ho 2007).
Bannayan–Riley–Ruvalcaba syndrome (BRRS) is associated with PTEN gene mutations in some patients (Hendricks et al. 2003). In its complete form it presents with macrocephaly, intestinal polyps, lipomas, angiomas, mucocutaneous pigmentation and developmental delay or intellectual disability.

Lachlan et al. (2007) concluded that the BRRS and Cowden syndrome represent one condition with variable expression and age-related penetrance, which is common in tumour suppressor disorders, and suggested that it is not helpful to split PTEN related disorders into separate clinical syndromes. Pilarski et al. (2011) tried to describe clinical features that predicted a PTEN mutation and Tan et al. (2011) developed a clinical scoring system for selection of patients for PTEN mutation testing.

NEUROCUTANEOUS SYNDROMES WITH PROMINENT VASCULAR COMPONENTS

Several syndromes are characterised by the association of cutaneous abnormalities and vascular malformations of the CNS. The type of vascular abnormalities is widely variable, and multiple associated anomalies are common.

STURGE–WEBER SYNDROME

Sturge–Weber syndrome (SWS) is by far the most frequent of the disorders of this group. In its complete form it consists of a venous angioma of the leptomeninges, ipsilateral flat facial angiomatous nevus (‘port-wine stain’) (Fig. 4.10) and choroidal angioma. An identical pial angioma may be present in isolation or in association with choroidal angioma without facial nevus in up to 13% of patients (Gomez and Bebin 1987; Roach 1992; Pascual-Castroviejo et al. 1993; Comi 2015). Such cases, for all practical purposes, should be regarded as belonging to the same syndrome. However, some of these cases may represent errors of diagnosis (e.g. cases of the syndrome of intracranial calcification with coeliac disease). On the other hand, patients who have facial nevus without CNS involvement with or without glaucoma are common (Roach 1992).

A recent study showed that 23 of 26 patients with SWS were positive for the c.548G→A somatic mutation in GNAQ gene, in either port-wine–stained skin or brain tissue. The GNAQ gene on chromosome 9q21, encodes Gαq, a member of the q class of G-protein alpha subunits that mediates signals between G-protein–coupled receptors and downstream effectors. The variant is predicted to result in the amino acid substitution p.Arg183Gln (Shirley et al. 2013). The same mutation causes isolated port-wine birthmarks, thus linking pathogenically both the non-syndromic with the syndromic forms of the birthmarks.

Cutaneous Manifestations in SWS

The nevus flammeus (‘port-wine stain’) almost always lies above the level of the palpebral fissure involving the upper eyelid or frontal region or both. Frontal lesions close to the midline are more commonly associated with anteriorly located pial lesions and more external frontal involvement with the more frequent occipitoparietal angiomas, but the correlation between the extent and location of the nevus and that of the pial angioma is poor. In a survey of 310 patients, Tallman et al. (1991) found neurological or ophthalmological involvement in 6% of those with unilateral and 24% of those with bilateral nevi in the territory of the first two divisions of the trigeminal nerve (only three patients had isolated involvement of the second division). These figures are likely to be underestimates as no imaging was performed. Sujansky and Conradi (1995a, b) computed a frequency of between 8% and 33% from a review of the literature. Some children have bilateral nevi with unilateral pial involvement (Gomez and Bebin 1987). Bilateral meningeal angiomas may coexist with either unilateral or bilateral facial nevi. Pascual-Castroviejo et al. (1993) found 13 patients with bilateral nevi in their 40 patients with SWS.
The intracranial angioma is limited to the pia mater that contains dilated and tortuous venules that may form several layers in the subarachnoid space but rarely enter the brain. The calcifications lie in the cortex underlying the angioma and subcortical white matter, tending to appear deeply at first and then extending toward the surface (Comi 2003; Thomas-Sohl et al. 2004). Localised or unilateral brain atrophy is virtually constant. In one severe case, four-layer microgyria was found underlying the angioma, indicating a prenatal origin of cortical damage (Simonati et al. 1994). Localised atrophy of prenatal origin (Portilla et al. 2002) also indicates the possible early repercussions of the angioma on cerebral development.

**Neurological Manifestations in SWS**

Seizures are the major neurological manifestation of SWS, occurring in 75–90% of patients (Gomez and Bebin 1987; Sujansky and Conradi 1995b; Arzimanoglou and Aicardi 1992). They usually have their onset in the first months of life. They are generally focal motor in type and are often prolonged in episodes of status epilepticus. Generalised seizures and even myoclonic and tonic seizures or infantile spasms can occur (Chevrie et al. 1988; Arzimanoglou and Aicardi 1992; Ewen et al. 2007; Barbagallo et al. 2009). Many patients have frequent and repeated seizures (Oakes 1992), but some children have only an occasional seizure, and approximately half the patients in one series responded relatively well to drug therapy (Arzimanoglou and Aicardi 1992).

The EEG shows reduced background amplitude over the angioma in a majority of patients. Associated paroxysmal abnormalities are often found on the involved side, although this may be a late sign. Generalised biphase synchronous discharges can be present in patients with unilateral pial lesions (Chevrie et al. 1988; Ewen et al. 2007) but should not be considered as a contra-indication when considering surgery. Paradoxical predominance of the paroxysmal features on the normal side may be seen. According to Jansen et al. (2004), abnormally small amplitude of the beta rhythm following administration of benzodiazepines may help to localise the area of parenchymal damage. Ewen and colleagues (2009) reported use of quantitative EEG to screen infants with facial port-wine birthmark.

Hemiplegia occurs in at least one-half of patients and is localised to the side opposite the facial nevus, except in a very few patients who probably have bilateral disease (Terdjman et al. 1990). Hemiplegia usually first appears after an episode of seizures and may become more severe with the recurrence of seizures. Hemianopia is virtually constant, isolated or in association with hemiparesis.

Transient hemiplegias not following an epileptic attack and sometimes accompanied by migraine-like headache are observed in many patients with SWS (Arzimanoglou and Aicardi 1992; Jansen et al. 2004). These hemiplegic episodes are apparently not of epileptic nature and may be a consequence of vasomotor disturbances within and around the angioma (Terdjman et al. 1990). Migraine-like episodes can also occur in the absence of hemiplegia (Taddeucci et al. 2005).

Intellectual disability is present in about 40% of the patients and in 75% of those with seizures. It does not occur in patients without epilepsy and is more common and more severe in bilateral forms (Gomez and Bebin 1987; Sujansky and Conradi 1995b). In many patients, there appears to be a definite regression of cognitive abilities parallel to the repetition and severity of the seizures.

Reesman and colleagues (2009) reported that significant hemiparesis correlates with general adaptive dysfunction. This examination finding may be useful for identifying children in need of additional interventions and eventually surgery.

Intracranial hemorrhage is not a feature of SWS. However, elevated spinal fluid protein is commonly found (Skoglund et al. 1978) and may correspond to minimal hemorrhage from the angioma. This interpretation is also consistent with the occasional occurrence of hydrocephalus (Fishman and Baram 1986), as observed also in a personal case, or with protein exudation from the angioma. Macrocephaly not due to hydrocephalus has also been reported (see Cohen 2003).

Glaucoma is present in 30–48% of SWS patients (Sujansky and Conradi 1995b), and 50% have choroidal angioma that may sometimes be visible with the ophthalmoscope. The glaucoma may be the consequence of overproduction of aqueous fluid by the choroidal angioma, or else exudate from the lesion may block the angle.

**Imaging Features in SWS**

MRI is the investigation of choice as it allows a relatively good visualisation of the pial angiomatosis and its limits. With gadolinium enhancement, the pial angioma can be clearly made out (Lipski et al. 1990; Sperner et al. 1990; Benedikt et al. 1993; Vogl et al. 1993). This may permit a preclinical diagnosis of the SWS in patients with an apparently isolated facial nevus, and may indicate the extent of the angioma and the presence or absence of contralateral involvement (Fig. 4.11). High resolution techniques of three dimensional magnetic resonance angiography may show a blush at the site of the angioma, and MRI may demonstrate advanced myelination at this locus. Perfusion MRI may permit an earlier diagnosis and more precise delineation of parenchymal abnormalities (Lin et al. 2003; Evans et al. 2006), and together with spectroscopy can determine the correlations with clinical symptoms and help surgery planning (Lin et al. 2006). Magnetic resonance spectroscopy and susceptibility-weighted imaging may detect abnormalities not seen on standard MRI with contrast (Batista...
et al. 2008; Hu et al. 2008). A recent series of 15 participants demonstrated infratentorial involvement in 40% and suggested that antibody drug conjugate analysis of normal-appearing white matter may reveal distant abnormalities and serve as a useful biomarker of brain tissue injury (Arulrajah et al. 2010). A better definition of the venous abnormalities might also be obtained with blood-oxygen-level-dependent (BOLD) magnetic resonance venography (Mentzel et al. 2005).

CT is a powerful tool for the detection of calcium and can often show its presence in infants of only a few months of age or even in neonates. CT also clearly demonstrates atrophy of the brain, enlargement of the choroid plexus on the side of the pial angioma, and abnormal veins draining into the deep venous circulation (Terdjman et al. 1990). MRI shows calcification less well than CT. Enhancement seen on CT may not represent opacification of the pial angioma but rather cortical injection similar to that occurring in postconvulsive hemiplegia, and it may disappear and reappear with the occurrence and disappearance of seizures (Terdjman et al. 1990; Shin et al. 2002).

Plain skull X-rays show the classic ‘tramline’ calcification most frequently in the parieto-occipital area. Although this has occasionally been detected in the neonatal period, it is often a late sign and may be absent even in adolescents. Angiography is not usually indicated. It does not show the angioma but demonstrates lack of superficial cortical veins, nonfilling of dural sinuses and abnormal, tortuous veins that course toward the ventricle and vein of Galen system.

Examination with PET or single photon emission computed tomography (SPECT) shows hypometabolism or marked underperfusion in the area of the pial angioma and may help to detect latent angioma (Chugani et al. 1989). Ichinose et al. (2003) found in one case decreased blood flow and glucose hypometabolism of the involved hemisphere as shown by SPECT and fluorodeoxyglucose PET respectively on the one hand, and accumulation of 11C-methionine thought to result from gliosis on the other.

SWS: Diagnosis and Course

The diagnosis of Sturge–Weber syndrome is usually straightforward. However, in mild cases and in children who have not had seizures with a facial nevus that has been present from birth it may be very difficult to know whether a pial angioma is associated. MRI after enhancement with gadolinium or with water diffusion studies can answer this but whether it is justified is difficult to decide, as the frequency of cases of cutaneous angioma without seizures is not known. A few cases of TSC mimicking SWS with leptomeningeal enhancement and enlargement of the choroid plexus are on record (Kremer et al. 2005). The differential diagnosis includes other causes of cortical calcification and atrophy. The syndrome of cortical calcification, epilepsy and coeliac disease (Gobbi et al. 1988) is described below. Other causes of calcification mimicking the ‘tramline’ type include neurofibromatosis and rare cases of TSC (Wilms et al. 1992).

The neurological defects seen in SWS are probably the consequence of blood stagnation, hypoxaemia and impaired neuronal metabolism (Comi 2003). The hypoxaemic effects are exaggerated by the increased metabolic rate resulting from epileptic seizures, and probably also by vasomotor changes and thrombotic phenomena that take place in and about the pial lesion (Aylett et al. 1999). Such a mechanism may explain the progressive aggravation of damage all too often
observed in these patients. It would also account for the beneficil effect of early surgery, preventing this cascade of ill effects.

A common embryological origin from the neural crest of the vascular bed of the leptomeninges and optic cup probably explains the Sturge–Weber association. The disease is sporadic. Only a few, doubtful, familial cases are on record, and the genetic prognosis is good.

The natural course of SWS depends on the presence, persistence and resistance to treatment of the seizures (Oakes 1992). In some patients, the disorder may remain static after marked atrophy has developed, and the seizures may subside or be relatively easily controlled. Onset of seizures before 1 year of age, a hypsarhythmic EEG pattern, the occurrence of episodes of status and bilateral involvement predict an unfavourable spontaneous outcome. Cognitive and behavioural development is quite variable. It may be good, especially if control of the seizures is obtained. Intractable epilepsy is an indication for surgical treatment.

**Differential Diagnosis**

Children with epilepsy and intracranial calcification may have an incomplete form of SWS. However, Gobbi et al. (1988) have described a distinctive syndrome of epilepsy with intracranial calcification associated with coeliac disease different from SWS. The syndrome features unilateral images of calcification, similar to those in SWS, whose origin is not known. Calcification is often but not always occipital and is not necessarily bilateral. There is usually no detectable atrophy associated with the calcification and no abnormalities of the cortical veins or choroid plexus, but hypodensity of the white matter is often seen in the vicinity of calcified areas (Gobbi 2005). The pathology of the syndrome is poorly known. In a few patients, vascular abnormalities reminiscent of SWS in the form of foci of angiomatous venous dilatation were reported (Bye et al. 1993); they were not found in another case (Toti et al. 1996). The epilepsy is sometimes associated with progressive cognitive and epileptic deterioration. This syndrome may not be homogeneous. It is characterised by variable types of seizures that may have a severe course but may also occur infrequently and be controllable by drug therapy. The patients may have full-blown coeliac disease; more often, the disorder lacks digestive manifestations and the diagnosis then rests on jejunal biopsy showing typical mucosal atrophy. In some cases, the biopsy may give normal results, so the ultimate diagnostic criterion in such patients is the presence of antibodies against glia is found in the blood. An immunological mechanism seems likely and is supported by the high incidence of certain HLA groups (HLA DQ2 and DQ8). Although calcification resembles that resulting from folinic acid deficiency, administration of this compound has no positive effect. The treatment is suppression of gluten-containing foods, which has to be maintained throughout life. The effect of the diet on epilepsy is variable and may depend on the precocity of its use (Gobbi 2005). When early, there seems to be a positive effect on seizures.

A few rare vascular syndromes may be only variants of SWS. These include cases of SWS associated with macrocephaly and hydrocephalus (Fishman and Baram 1986), which have been attributed to abnormal venous drainage with resulting intracranial hypertension. A syndrome of bilateral facial nevi, macrocrania and anomalous venous return through superficial veins is regarded by some authors (Shapiro and Shulman 1976; Orr et al. 1978) as probably different from SWS. Association with bilateral lymphatic/venous malformation has been reported (Ramli et al. 2003). Klippel–Trenaunay syndrome, which involves mainly the peripheral vascular system, may be associated with cranial anomalies (Williams et al. 1992).

**Treatment in SWS**

Treatment is mainly directed against the seizures, and an aggressive antiepileptic regimen should be established from the first seizure. Control can be obtained with drugs in about half the patients, even in those with early-onset seizures (Arzimanoglou and Aicardi 1992). Arrest of status epilepticus is of utmost importance, as hemiplegia is often postconvulsive.

In patients with uncontrollable epilepsy, especially in infancy, functional hemispherectomy, or classic occipital or parietal lobectomy or resection of the angiomatous area could render the patient seizure-free and possibly prevent cognitive deterioration. Hemispherotomy has also given very good results for the control of seizures (Schrupp et al. 2006). It is indicated for uncontrollable seizures when fine hand movements are absent (Roach et al. 1994) although some authors have advocated it in nonparalytic severe cases (Kossoff et al. 2002). Arzimanoglou et al. (2000) reported excellent control of seizures after hemispherectomy but less favourable results after lobar or incomplete resections. Kossoff et al. (2002) reviewed 32 patients of hemispherectomy for SWS from the world literature; satisfactory control of seizures was obtained in about 26 of these patients without significant increase in hemiplegia. The series by Bourgeois et al. (2007) of 27 patients found that 11 out of 19 (58%) with focal resections became seizure-free, mostly if a complete resection was performed. A review of 55 individuals with SWS indicated that early surgical treatment controlled the seizures but other neurological problems such as hemiparesis and intellectual deficits showed a less satisfactory response. Early onset of seizures and poor response to medical treatment, bilateral cerebral involvement and unilateral severe lesions were indicative of a poor prognosis (Pascual-Castroviejo et al. 2008) fully justifying early referral to paediatric epilepsy teams with experience in epilepsy surgery.

Even bilateral cases may be amenable to surgery provided the seizures consistently originate from one side as shown by
clinical seizure features, repeated EEGs and possibly functional imaging techniques (Tuxhorn and Panneck 2002; Schropp et al. 2006). Clinical experience favours early intervention, preferably in the first year of life, if frequent seizures or status epilepticus occur. However, the results on neurodevelopment may be disappointing even with early control of epileptic activity.

A neuropathological series of six patients after hemispherectomy revealed that all patients either had evidence of polymicrogyria or focal cortical dysplasia type Ia (Maton et al. 2010). Another series of two adult surgical patients reported association with focal cortical dysplasia type IIa (Murakami et al. 2012). Therefore, cortical malformation may be common in patients with SWS and intractable epilepsy intractable seizures, contributing to the severity of their epilepsy. Corpus callosotomy (Rappaport 1988) proposed as an alternative to hemispherectomy is finally limited to a minority of cases in contemporary clinical practice.

The possibility of preventing the occurrence of seizures by early antiepileptic treatment has been studied by Ville et al. (2002). Although they found a significant, if slight, difference favouring the group treated with phenobarbital over controls, the small number of patients and the heterogeneity of cases renders a conclusion difficult in view of the uncertainties about long-term side effects of such therapy.

Some authors studied mostly in a retrospective manner the safety and efficacy of low-dose aspirin and reported positive results (Udani et al. 2007; Lance et al. 2013). More studies are needed to establish whether all patients with SWS should be on low-dose aspirin and how long they should stay on it. A survey indicated that either triptans or daily preventive medication can be used in case of migraines and may be helpful (Kossoff et al. 2007). However, the small sample size precluded any safety analysis, demonstrating that future prospective trials of both treatment options are needed.

Local treatment of the port-wine stain is psychologically important, and good results have been obtained with pulsed dye laser (Léauté-Lebrègue et al. 2002).

**SYNDROME OF HAEMANGIOMAS AND OTHER CARDIOVASCULAR DEFECTS (PHACES SYNDROME)**

PHACE or PHACES syndrome (Frieden et al. 1996) or Castroviejo syndrome II (Pascual-Castroviejo 1985; Pascual-Castroviejo et al. 1996, 2005a) is typically associated with a posterior fossa malformation, haemangiomas, arterial abnormalities, coarctation of the aorta, eye abnormalities and sternal maldevelopment. The angiomas are variably flat or tuberous, usually involve the face or neck, and may be multiple. They may appear only after birth. This syndrome predominates in girls (90%) and has a wide spectrum of manifestations that can involve many organs throughout the body (Metry et al. 2001, 2006). Rare cases have been familial.

Intracranial anomalies are the most common extracutaneous feature of PHACE syndrome (Bracken et al. 2011). The posterior fossa malformation usually resembles Dandy–Walker syndrome but hypoplasia of the vermis or of the whole cerebellum and unilateral absence of a cerebellar hemisphere may be found. Besides cerebellar hypoplasia diverse embryological abnormalities of the aortic arch and of cervical and especially extracranial and intracranial vessels, as well as cortical dysplasia, are often found (Pascual-Castroviejo et al. 1996). Intracerebral haemangiomas and neuronal migration anomalies may be present (Poindexter et al. 2007). The arteriopathy of PHACE syndrome commonly involves the internal carotid artery and its embryonic branches, ipsilateral to the cutaneous hemangioma, with dysgenesia and abnormal arterial course the most commonly noted abnormalities (Hess et al. 2010). Patients can also present arterial occlusions and stenosis, persistent embryonic arteries and saccular aneurysms (Heyer 2008). In addition to posterior fossa CNS anomalies, supratentorial anomalies may be present, and this may correlate with significant clinical sequelae (Oza et al. 2008). Coarctation of the aorta and congenital heart disease, especially septal defects, are frequent.

Variable eye defects may include proptosis, ptosis, cataracts and retinal anomalies (Kronenberg et al. 2005). Involvement of visceral vessels may occur. A malformed sternum is often found. Many patients have intellectual disability or a borderline intellectual level. Vascular and cardiac complications may occur, and fatal cases are on record. Strokes are a possible manifestation (Drolet et al. 2006). Treatment of the haemangiomas with corticosteroids may be effective, and surgery may be required for correction of some of the congenital defects.

Metry et al. (2009) defined diagnostic criteria. Major and minor criteria were determined for cerebrovascular, structural brain, cardiovascular, ocular and ventral/midline defects. Definite PHACE requires the presence of a characteristic segmental hemangioma, or hemangioma 5cm on the face or scalp, plus one major criterion or two minor criteria. The group recognised that it may be possible to have PHACE syndrome with a hemangioma affecting the neck, chest or arm only or no cutaneous hemangioma at all.

**VON HIPPEL–LINDAU DISEASE**

Von Hippel-Lindau (VHL) disease consists of the association of retinal, cerebellar and spinal haemangioblastoma, pheochromocytoma, cysts or neuroendocrine neoplasms of the pancreas, renal cell carcinoma, and endolymphatic sac tumour (Joerger et al. 2005). Cutaneous involvement (hemangiomas) occurs only in some cases, thus VHL is not a neurocutaneous disease in a majority of patients. The condition is transmitted as a dominant trait with a penetrance

The diagnosis is made in patients with at least two of the aforementioned manifestations, or in patients with a known family history or a pathogenic mutation and at least one of the manifestations stated above (Huson et al. 1986; Binderup et al. 2013).

The disease manifests usually after 10 years of age by acute eye complications, (e.g. haemorrhage, or by a posterior fossa syndrome) (Kreusel 2005). Pancreatic and renal cysts are asymptomatic and are detected by abdominal imaging in three-quarters of patients. Renal carcinomas and pheochromocytomas (Opocher et al. 2005) should be detected early if conservative treatment is to be contemplated.

CNS haemangioblastomas are a cardinal feature of VHL disease and are the presenting feature in 40% of patients. Overall CNS haemangioblastomas occur in 60–80% with VHL (Maher et al. 2011). Neumann et al. (1992) found that 44% of gene carriers had haemangioblastoma, multiple in 42% and 44% of those with haemangioblastoma had retinal lesions. The retinal haemangioma has a characteristic appearance. About 20% of patients with retinal angioma develop neurological complications, and 40% of patients with cerebellar haemangioblastoma have VHL disease (Huson et al. 1986). Lonser et al. (2014) analysed the CNS hemangioblastoma burden in 225 patients with multiple haemangioblastomas in the cerebellum (45%), brainstem (7%), spinal cord (36%), cauda equina (11%) and nerve roots (0.3%). Increased tumour burden was associated with partial deletions in the VHL gene and male sex.

Although CNS haemangioblastomas tend to enlarge over time, they are benign tumours and some may be static for a number of years and hence removal of asymptomatic lesions is not usually indicated. The judicious treatment of symptom-producing haemangioblastomas, while avoiding unnecessary treatment of asymptomatic tumours that may not progress, can provide clinical stability.

Patients and at-risk relatives should have annual paediatric examinations and ophthalmological assessment from 5 years of age. From 5 to 14 years, annual plasma-metanephrine and plasma-normetanephrine tests, as well as annual hearing test. Between the ages of 8 and 14 years, CNS and abdominal MRI. After the age of 15 years tests should include: (1) annual ophthalmoscopy, (2) annual neurological examination, (3) every 2 years: MRIs of the CNS, including the inner ear, (4) annual ultrasound/MRI of the abdomen, (5) annual plasma-metanephrine, normetanephrine and chromogranin A tests, and (6) annual hearing examination (Binderup 2013).

Treatment is purely surgical (Vougioukas et al. 2006). The prognosis is dominated by the presence and size of tumours, both intracranial and intra-abdominal. Generally, the results of surgery for a single peripherally located cerebellar lesion are excellent, but surgical management of multicentric tumours and brainstem and spinal tumours can be challenging and patients can benefit from being treated in units with specialised experience and expertise in VHL disease. Stereotactic radiotherapy may be an alternative to conventional neurosurgery (Maher et al. 2011).

**HEREDITARY HAEMORRHAGIC TELANGIECTASIA (RENDU–OSLER–WEBER SYNDROME)**

Hereditary haemorrhagic telangiectasia (HHT) is a familial disorder, transmitted as an autosomal dominant trait, characterised by the presence of multiple dermal, mucosal and visceral telangiectasias associated with recurrent haemorrhage (Mei-Zahav et al. 2006; Govani and Shovlin 2009). The most common manifestations in children carrying a mutation include cutaneous and nasal telangiectasias, and pulmonary and hepatic arteriovenous malformations (AVMs); central nervous system AVMs (CAVMs) or CNS ischaemic lesions complicating pulmonary AVMs were found in 12–16% of children with a mutation (Giordano et al. 2006, 2013).

Hereditary haemorrhagic telangiectasia CAVMs are more likely to be multiple and have a tendency toward small size and cortical location. As such, they are often treated using a single-modality therapy (Woodall et al. 2014).

Due to the debilitating and potentially fatal effects of CAVM rupture and the lack of evidence regarding effectiveness of treatment for asymptomatic CAVMs, the International Guidelines for Diagnosis and Management of HHT recommended screening for them in all patients (including children in the first 6 months of life) with possible or definite HHT (Faughnan et al. 2011). However, this has been a subject of significant debate as most CAVMs never bleed and investigations and treatments carry risks (Govani and Shovlin 2009; Garg et al. 2014). Both family history and early clinical signs are important to prompt further diagnostic testing to avoid intracranial haemorrhage from CAVMs in children (Saleh et al. 2013).

The most common complication of HHT is epistaxis, which, however, is rarely severe before age 35 years. Neurological involvement includes the complications of right-to-left shunt through pulmonary arteriovenous fistulas, responsible for brain abscesses, and thrombosis associated with polycythaemia.

Spinal arteriovenous fistulas were found in infants and young children, whereas AVMs with a nidus were found only in adults in one large series (Krings et al. 2005). Given the lack of data regarding the true incidence and natural history of these lesions, the question is raised of whether spinal cord imaging should be incorporated into screening recommendations (Calhoun et al. 2012). Recurrent alternating hemiplegia has been reported (Myles et al. 1970). Two major genetic subtypes are known (HHT1 and HHT2) due respectively
RARE NEUROCUTANEOUS SYNDROMES WITH PROMINENT VASCULAR COMPONENT

Neurocutaneous syndromes of which vascular abnormalities are an important part are listed in Table 4.3. Several of these are genetically determined. Cutaneous involvement may not be a major feature, and neurological symptoms may be the presenting feature. In all cases of vascular abnormalities of the CNS it is important to make careful enquiries about possible other cases in the lineage. In cases with known genetic origin or where two instances of vascular malformation exist in the family, a thorough examination of all family members is in order. The exact nosological situation of several of these syndromes is unclear.

SNEDDON AND DIVRY–VAN BOGAERT SYNDROMES

Sneddon syndrome consists of the association of generalised livedo reticularis (livedo racemosa) with cerebrovascular accidents due to diffuse abnormalities of the small and middle arteries (Legierse et al. 2008). Two subtypes are recognised: one where antiphospholipid antibodies are present with other features of inflammation (Szmyrka-Kaczmarek 2005), and an idiopathic type (Mascarenhas et al. 2003) that may be familial (Pettee et al. 1994; Lossos et al. 1995). The syndrome can be caused by a compound heterozygous mutation in the CECR1 gene encoding the ADA2 protein (one such family has been reported; Bras et al. 2014). The disorder is a cause of cerebrovascular accidents, mostly in young adults, with a few cases reported in children (Baxter et al. 1993; Wheeler et al. 1998). In Sneddon syndrome, which shares many features with the Divry–Van Bogaert syndrome (Stone et al. 2001) there is noncalcifying leptomeningeal and cortical angiomatosis with secondary white matter sclerosis. The two conditions appear to be closely related (Ellie et al. 1994).

SYNDROMES WITH VARIOUS CUTANEOUS OR SUBCUTANEOUS TISSUE ANOMALIES

Several of these syndromes feature vascular anomalies of a phakomatous type such as angiomatosis, ectatic veins or lymphangiectasias, in association with macrocephaly and/or CNS abnormalities. The syndrome of *cutis marmorata telangiectatica* is clearly heterogeneous and may be accompanied by neurological symptoms (Picascia and Esterly 1989; Garzon and Schweiger 2004; Hinek et al. 2008) and the association of recurrent hemiplegias mimicking alternating hemiplegia has been reported (Baxter et al. 1993). The syndrome of *macrocephaly–cutis marmorata congenita* is probably different and includes dysmorphism and brain malformations (Lapunzina et al. 2004; Nyberg et al. 2005). It is also referred as *mega-lencephaly-capillary malformation-polymicrogyria syndrome* (MCAP) (Conway et al. 2007; Mirzaa et al. 2012) and diagnostic criteria have been proposed by different authors (Martinez-Glez et al. 2010; Mirzaa et al. 2012; Papetti et al. 2012). Some cases of MCAP have been found to have somatic mutations in the PIK3CA gene (Rivière et al. 2012).

Several syndromes associate neurological abnormalities with proliferation of subcutaneous tissues, and in some there is a tendency to the development of tumours. The distinction between rare syndromes such as *Riley–Smith, Bannayan–Zonana* and *Ruvalcaba–Myhre syndromes* is difficult and may be to some extent artificial (Dvir et al. 1988; Gorlin et al. 1992). They are associated with mutations in the *PTEN* gene and patients present intracranial developmental venous anomalies (Tan et al. 2007).

Wyburn–Mason syndrome (also known as *Bonnet–Dechaume–Blanc syndrome* or congenital retinocephalofacial vascular malformation syndrome) consists of a complex vascular malformation including a retinal arteriovenous angioma associated with a unilateral arteriovenous malformation extending along the optic nerve and the optic tract all the way to the cerebral peduncles and sometimes as far as the ipsilateral cerebellar hemisphere (Gomez 1994; Lester et al. 2005). A facial periorbital angioma is often present. Rupture or thrombosis of the malformation is not rare, with ominous consequences (Rizzo et al. 2004).

*Various genetic factors are being studied but most cases are sporadic.
CNS, central nervous system; S, sporadic; AD, autosomal dominant.
The pathological features and course of ataxia-telangiectasia are more closely related to the heredodegenerative disorders, in particular the spinocerebellar degenerations of which this disease represents; however, the second most common type after Friedreich ataxia is discussed in this chapter because, from a purely clinical point of view, its presentation and diagnosis are mainly those of a neurocutaneous syndrome in a majority of patients, even though it can also be regarded as a degenerative genetic condition.

Ataxia-telangiectasia is a heredofamilial disease of DNA instability, characterised by progressive cerebellar ataxia and choreoathetosis, progressive oculocutaneous telangiectasias, immunodeficiency with susceptibility to sinopulmonary infections, impaired organ maturation, hypersensitivity to ionising radiations and a high incidence of malignancies. It is a multisystem genetic disorder with an autosomal recessive inheritance. The responsible gene ATM (AT mutated) on chromosome 11q22–23 (Savitsky et al. 1995; Shiloh 1995) codes for a protein (ATM protein) with similarities to mammalian phosphatidylinositol-3′ kinases. The ATM protein is a nuclear protein that plays a crucial role in the stability and repair of double-stranded DNA and thus in the control of the stability of the cell cycle and in the protection of the genome. Numerous mutations are known, most being null mutations (Gilad et al. 1996). Less severe mutations are encountered, giving rise to less severe clinical cases (Gilad et al. 1998; Taylor and Byrd 2005).

**Mechanisms and Pathology of Ataxia-Telangiectasia**

The abnormal double-stranded DNA maintenance has widespread consequences. The ATM protein, a protein kinase, is thought to be essential for control of the cell cycle, in particular at the checkpoints G1 and G2/M. It plays a major role in signalling defects of double-stranded DNA and in blocking cell cycle allowing repair of the genome (Lavin et al. 2005). Its failure thus allows induced activation of the cell cycle, which may be deviated toward apoptosis. One important consequence is the abnormal sensitivity of ataxia-telangiectasia cells to ionising radiation and certain radiomimetic chemicals but not to ultraviolet irradiation (Barlow et al. 1999). The cell might then incorporate damage into its DNA that leads to chromosome and chromatid breaks. The ataxia-telangiectasia cell resumes DNA synthesis with undue speed after insults, because of defective control of systems of cell damage repair (Chun and Gatti 2004). Mutations in the gene are heterogeneous, and the resulting different degrees of protein kinase activity are correlated to clinical severity with later onset and milder forms. A high proportion (10%) of chromosomal breaks is almost constant. Chromosomal breakpoints are randomly distributed, but nonrandom chromosome rearrangements affect selectively chromosomes 7 and 14 at sites that are concerned with T-cell receptors and heavy-chain immunoglobulin coding and with the development of hematological malignancies (Hecht and Hecht 1985; Aurias and Dutrillaux 1986). These sites include bands 7p14, 7p35, 14q2 and 14qter. Chromosomes 2 and 22 (at bands 2p11, 2p12 and 22q11) are also frequently involved (Gatti et al. 1985). In about 10% of patients, a clone of cells with a 14–14 translocation with breakpoint at 14q32 develops that may be related to the emergence of malignancies.

Such disturbances could account for the frequency of infections and neoplasias, especially of the lymphoid tissues, but they may have a more general effect on the stability of the genome increasing sensitivity to malignancies even in the heterozygous state. The mechanisms responsible for neurological disease, thymus aplasia, telangiectasias, growth retardation and impaired organ maturation have not been elucidated. There is a general disturbance in tissue differentiation that accounts for the frequent elevation of alpha-fetoprotein (AFP), a fetal serum protein of hepatic origin that indicates dedifferentiation of liver cells.

Considerable work suggests that ataxia-telangiectasia may be associated with dysregulation of the immunoglobulin gene superfamily, which includes genes for T-cell receptors (Peterson and Funkhouser 1989). The normal switch from the production of IgM to IgG, IgA and IgE is defective, and the same may apply to the switch from immature T-cells that express the gamma/delta rather than the alpha/beta receptors (Carbonari et al. 1990). Conceivably, absence or mutation of a single protein coded for by chromosome 11 could explain the immunological and perhaps even the neurological features of the disease (Kastan 1995).

The major neuropathological lesion in the CNS is degeneration of Purkinje and granule cells in the cerebellum (De Léon et al. 1976; Paula-Barbosa et al. 1983). Usually, no vascular abnormalities are found except late degenerative gliovascular nodules in the white matter. Lesions of the basal ganglia are found only occasionally (Boder 1985). Degeneration of spinal tracts and anterior horn cells is often present in late cases. Nucleocytomegaly is a feature of several cell types throughout the body, notably in peripheral nerves (De Léon et al. 1976).

**Clinical Features of Ataxia-Telangiectasia**

**Neurological findings**

The main neurological manifestations of ataxia-telangiectasia are cerebellar ataxia and abnormal eye movements, in the form of ocular motor apraxia, which is present in most cases, and choreoathetosis that occurs in 25% of patients (Boder 1985). The ataxia has its onset in infancy, becoming evident when the child begins to walk. From this early stage, ataxia is associated with abnormal head movements, and affected children have a peculiar gait like ‘little clowns’ that is highly suggestive. However, ocular motor apraxia often appears only after some years. The ataxia is relentlessly progressive but the pace is variable
even in the same sibship. Dysarthria of cerebellar type is the rule; intention tremor and myoclonus may be observed. Various movement disorders are often present. Choreoathetosis may be so marked in some patients as to overshadow or mask the ataxia. A dystonic component is possible and may seldom be prominent. Oropharyngeal dystonia may lead to aspiration (Leffon-Greif et al. 2000), and the relatively immobile face with a peculiar slow-spreading smile, which is a suggestive symptom, may be due to extrapyramidal involvement. Late pyramidal signs may be present. Ocular motor signs are diagnostically important because they may precede the appearance of telangiectasias. Saccades are slowly initiated and hypometric, so that fixation of a target is obtained by head rather than eye deviation, often in association with a head thrust or forced blinking as in Cogan ocular motor apraxia (Baloh et al. 1978), but is present in both horizontal and vertical gaze. Eye deviation, when obtained, is saccadic and often halts midway, and optokinetic nystagmus is absent. Other ocular abnormalities include deficient accommodation, nystagmus, frequent blinking and photophobia (Risse et al. 2007). Peripheral system involvement is a late feature first manifested by absence or weakness of the tendon jerks. The peculiar appearance of children with ataxia-telangiectasia is often striking, with a characteristic gait and posture, a dull facies at rest, and abnormal head movements due to oculomotor defect. About 30% of patients have mild intellectual disability. A small head circumference (61%) and microcephaly (17%), both acquired after the second year of life, have been recognised as a major clinical feature (Nissenkorn et al. 2011).

TELANGIETASIAS AND OTHER CUTANEOUS ABNORMALITIES

Telangiectasias are first noticed after 3 years of age, sometimes not until adolescence. They may be absent even later in some patients (Chung et al. 1994). Dilated conjunctival vessels, first noticed in the angles of both eyes, spread horizontally in the equatorial region of the conjunctiva toward the corneal limbus. They may involve the ears, eyelids, and cubital and popliteal fossae. In late childhood and adolescence, progeric skin changes may appear, as well as pigmentedary changes and café-au-lait spots. The skin often has an unusual appearance with evidence of premature ageing, café-au-lait spots (Ortonne et al. 1980), and warts or molluscum pendulum. Multiple skin cancers may develop especially in areas of previous X-irradiation.

SENSITIVITY TO INFECTIONS

Patients with ataxia-telangiectasia are unusually sensitive to infections, mostly bacterial but to a lesser extent viral, in part as a result of immune globulin abnormalities (Nowak-Wegrzyn et al. 2004) and of deficiency of cellular immunity (Schubert et al. 2002) with decreased numbers of B-cell and of T4 and T8 lymphocytes. Nowak-Wegrzyn et al. (2004) found in 100 ataxia-telangiectasia patients that lymphopenia was present in 71%, and that immunoglobulin levels were lowered by 65% for IgG, 63% for IgA, 48% for IgG, 23% for IgE, and only 18% for IgG. Approximately 10% of patients present with decreased serum IgG and IgA with normal or raised IgM levels. These patients are often erroneously diagnosed as hyper-IgM syndrome; thus, ataxia-telangiectasia should be considered in the differential diagnosis of patients with this syndrome (Noordzij et al. 2009; Pietrucha et al. 2010). Rare patients may have no immunodeficiency as a result of specific mutations (Toyoshima et al. 1998). The most common infections are those of the upper respiratory tract.

Repeated sinopulmonary infections were present in 48–81% of patients reviewed by Chung et al. (1994), but in the study of Nowak-Wegrzyn et al. (2004) only 15% of patients had pneumonia. Infections of viral origin in the latter series included warts, molluscum and herpes simplex, but none were severe. In a study by Chun and Gatti (2004), severe infection with progressive lung disease was present in one-third of children, one-third had sinopulmonary infection but not progressive lung disease, and the remaining third had only a normal incidence of infections. There was a good correlation between the occurrence of infections and immunodeficiency as assessed by laboratory tests. Such a correlation was not found in other series (Roifman and Gelfand 1985). Overall, lung disease is thought to exhibit features of one or more of the following phenotypes: recurrent sinopulmonary infections with bronchiectasis, interstitial lung disease, and lung disease associated with neurological abnormalities (McGrath-Morrow et al. 2010).

Retardation of somatic growth is found in most patients, and many do not achieve normal puberty. In girls, this may be related to absence of ovary differentiation that is found in some patients.

Course and Prognosis of Ataxia-Telangiectasia

The neurological features of ataxia-telangiectasia are relentlessly progressive (Chun and Gatti 2004). In addition to the classic early features, older patients tend to develop other signs of spinocerebellar degeneration such as posterior cord involvement with loss of deep tendon reflexes and spinal muscular atrophy (Boder 1985; Kwast and Ignatowicz 1990; Hiel et al. 2006). Most patients are wheelchair dependent by 10–15 years of age, but mild forms are not rare and can be related to specific mutations of the ataxia-telangiectasia gene (Taylor and Byrd 2005). Early death is frequently due to pulmonary disease but malignancies are now the most common cause. The incidence is 60–300 times higher than in non-affected persons, and 49% of patients coming to autopsy had malignant tumours (Swift et al. 1991). The most common tumours are T-cell and B-cell lymphoreticular malignancies, especially non-Hodgkin lymphomas, lymphocytic leukaemia and Hodgkin lymphomas (Boder 1985), but other kinds of tumours also occur. Lymphoreticular neoplasms and leukaemia predominate in patients under 15 years of age, while epithelial tumours predominate in older patients. Malignancies are also thought to be more common in obligate heterozygotes for the mutant ataxia-telangiectasia gene than in the general population (Swift et al. 1991). The frequency of cancers, especially breast carcinomas, is reported to be three to six times greater than in the general population (Thompson et al. 2005), and this information has to be included in genetic counselling.
although it remains a disputed issue (Gumy-Pause et al. 2004; Tamimi et al. 2004). In older patients, insulin-resistant diabetes develops in half the patients but is not responsible for ketosis.

**Diagnosis and Laboratory Markers of Ataxia-Telangiectasia**

The clinical diagnosis of ataxia-telangiectasia is easy when both cardinal features are present. Before the appearance of telangiectasias, the diagnosis of ataxic cerebral palsy is often made. However, ocular motor abnormalities and the ‘little clown’ gait are suggestive of ataxia-telangiectasia.

Laboratory markers are important for both diagnosis and prognosis. The most constant markers are elevated levels of AFP and carcinoembryonic antigen, and chromosomal abnormalities, especially inversions and translocations involving chromosomes 7 and 14 (Hecht and Hecht 1985), which are regarded as pathognomonic for ataxia-telangiectasia. Neither of these abnormalities is always found, however, and their demonstration may require specific techniques available only in a few centers.

The demonstration of humoral or cellular immunological defects may also suggest an early diagnosis, although such defects are nonspecific and less frequently present (Roifman and Gelfand 1985). The dysgammaglobulinemia of ataxia-telangiectasia includes absence or low level of IgA including secretory IgA, normal or low level of IgG, and elevated or normal level of IgM. A deficit in Ig2 and Ig4 subclasses has been demonstrated in several patients, and IgE may also be absent or low (Oxelius et al. 1982; Schubert et al. 2002). Defects of cellular immunity include a low lymphocyte count, a poor response to skin tests for common antigens, low T-lymphocyte proliferation in the presence of mitogens, and deficient antibody production to viral or bacterial antigens. Excessive T-cell suppressor activity and intrinsic B-cell defects have been described in some patients, suggesting disturbances of immunoregulatory mechanisms.

Chromosomal abnormalities, especially the increased incidence of breaks on certain chromosomes, remain of considerable practical value. Survival of cell colonies after exposure of cell cultures to ionising radiation is of definitive diagnostic value (Chun and Gatti 2004) but not a routine procedure. These tests are being supplanted by molecular diagnosis, which is also considered for the prenatal diagnosis although this is difficult and not always possible. Most mutations of the ataxia-telangiectasia gene are truncating or splicing mutations; only about 10% are missense mutations. Other investigations are of less importance. CT and MRI often show evidence of nonspecific cerebellar atrophy. Nerve conduction velocities may be slowed, and denervation of anterior horn cell type may be found in older patients (Dunn 1973).

**Atypical and Variant Forms of Ataxia-Telangiectasia**

Patients with atypical forms of ataxia-telangiectasia have recently attracted interest. Some cases are undoubtedly part of the spectrum of the disease, with a slow course and prolonged survival and incomplete expression, e.g. absence of ocular motor signs (Trimis et al. 2004). Others include markedly abnormal features such as intellectual disability and spasticity (Mescham et al. 1986), peripheral neuropathy as a predominant sign (Térenty et al. 1978), and absence of telangiectasia persisting into adulthood (Byrne et al. 1984). Patients with variant ataxia-telangiectasia tend to present with movement disorders often mimicking forms of primary torsion dystonias (Verhagen et al. 2009; Saunders-Pullman et al. 2012; Charlesworth et al. 2013). Some of these patients lack one or the other of the laboratory markers. They confirm the genetic heterogeneity of the disease, which has been demonstrated by molecular studies (Taylor and Byrd 2005). It seems that there is a clear genotype–phenotype relation, since the severity of the phenotype depends on the amount of residual kinase activity as determined by the genotype. Thus, ataxia-telangiectasia should be considered in patients with an otherwise unexplained movement disorder. Early diagnosis is important given the increased risk of malignancies and the higher risk for side effects of subsequent cancer treatment (Verhagen et al. 2009).

The Nijmegen breakage syndrome (Seemanova et al. 1985) manifested by microcephaly, immunodeficiency, and growth retardation, tends to be considered as a variant of ataxia-telangiectasia (variant-I), with a similar tendency to develop lymphoreticular malignancies, probably because they share defects of the DNA repair systems. It is an autosomal recessive disorder caused by mutation in the NBS1 gene (Carney et al. 1998; Varon et al. 1998).

Other rare conditions that share some features with ataxia-telangiectasia include the dysequilibrium–diplegia syndrome (Hagberg et al. 1970; Graham-Pole et al. 1975) in which immunodeficiency is a major feature. This syndrome is associated with purine nucleotide phosphorylase deficiency (Soutar and Day 1991), caused by mutation in the PNP gene (William et al. 1987). Patients with this disorder have normal immunoglobulins and pyramidal tract signs, and in one case heterotopia and cortical dysplasia were present (Soutar and Day 1991). Other syndromes with neurological features, especially microcephaly, in association with chromosomal instability may have some relationship to ataxia-telangiectasia, especially the tendency to develop lymphoreticular malignancies.

**Management of Ataxia-Telangiectasia**

Although no specific treatment is available, several features of ataxia-telangiectasia are accessible to active therapy. This applies especially to infections, and the lifespan of patients with ataxia-telangiectasia has been clearly prolonged by antibiotic treatment. Prevention of infections by regular injection of immunoglobulins is considered useful. Fetal thymus implants and stimulants of the immunological system have given inconclusive results.

Treatment of neurological manifestations is disappointing. Propranolol and sulpiride may improve fine motor coordination in a few patients. Rehabilitation and adequate educative
support are always necessary. One adult patient had improvement in his gait ataxia with treatment with the GABAergic medications pregabalin and tiagabine (Gazulla et al. 2007). Some improvement in movement disorders has also been reported with the use of amantadine sulphate (Nissenkorn et al. 2013). In a multicentre, double-blind, randomised, placebo-controlled trial, oral betamethasone reduced ataxia as measured by standardised ataxia scales (Zannoli et al. 2012). However, the long-term safety and effectiveness of oral steroid therapy is still being evaluated.

The use of radiotherapy and chemotherapy in conventional doses is contraindicated in ataxia-telangiectasia patients. Reduced doses of X-rays or chemicals, avoiding bleomycin, actinomycin D and cyclophosphamide, have given favourable results in a few patients. Regular surveillance of patients for the emergence of cancers and leukaemia should be strict. This also applies to heterozygotes and should probably be part of the family management.

**DISORDERS RELATED TO ATAXIA-TELANGIECTASIA**

**ATAXIA-TELANGIECTASIA-LIKE DISEASE**

Some patients presenting with features that mimic ataxia-telangiectasia are not associated with mutations in the ataxia-telangiectasia gene. In such cases the disorder seems to be less severe. Increased sensitivity to ionising radiation is present, as are chromosome breakages (Taylor et al. 2004). However, malignancies have not been reported (Delia et al. 2004). The responsible gene responsible is MRE11, whose mutation seems to be present in the family management.

Increased sensitivity to ionising radiation is present, as are chromosome breakages (Taylor et al. 2004). However, malignancies have not been reported (Delia et al. 2004). The responsible gene responsible is MRE11, whose mutation seems to be responsible for absent activation of the ataxia-telangiectasia gene, in conjunction with other genes such as Nb1 (Stewart et al. 1999; Fernet et al. 2005).

**ATAXIA–OCULOMOTOR APRAXIA**

Although ataxia-oculomotor apraxia (AOA) does not feature cutaneous abnormalities, it is mentioned in this chapter because of its striking resemblance to ataxia-telangiectasia. Four distinct entities are recognised: AOA1, AOA2, AOA3, and AOA4 (see also Chapter 22).

AOA1 appears to occur predominantly in children, in contrast with AOA2, which is more frequent in adults (Le Ber et al. 2004). It is an autosomal recessive ataxia associated with ocular motor apraxia, hypoprolactinemia and hypercholesterolaemia, with onset in childhood and even in infancy (Ito et al. 2005). Chorea and peripheral neuropathy are frequent manifestations. AFP levels are normal (Aicardi et al. 1988; Gascon et al. 1995; Le Ber et al. 2003). The responsible gene, APTX on chromosome 9q13, encodes the protein aprataxin.

It is probably important in single-strand DNA break repair. No telangiectasias are seen; there is no increased frequency of malignancies and no chromosome breakages are noted. The course is slowly progressive and may become static. MRI demonstrates marked cerebellar atrophy (Barbot et al. 2001; Shimazaki et al. 2002; Le Ber et al. 2003). The phenotype is variable, some patients having no oculomotor apraxia or presenting with a neuropathy.

In AOA2, the clinical features are similar, with a later onset in early adolescent years. AFP is moderately elevated in three-quarters of the patients (Le Ber et al. 2004). Oculomotor apraxia is inconstant (Le Ber et al. 2004; Duquette et al. 2005). The responsible gene SETX on chromosome 9q34 codes for the protein senataxin whose role is not known. Anheim et al. (2009) retrospectively analysed 90 patients from 15 families with a genetically confirmed diagnosis of AOA2. The median age at onset was 14 years. Clinical features included polyneuropathy (97.5% of patients), cerebellar atrophy (96%), occasional oculomotor apraxia (51%), pyramidal signs (20.5%), head tremor (14%), dystonia (13.5%), strabismus (12.3%) and chorea (9.5%).

AOA3 is caused by a mutation in the PIK3R5 gene on chromosome 17p (Al Tassan et al. 2012); and AOA4 is caused by mutation in the PNKP gene on chromosome 19q13. Bras et al. (2015) reported 11 patients with age at onset from 1 to 9 years. Most patients presented with prominent dystonia and additional features included ataxia, oculomotor apraxia and peripheral neuropathy. Most patients became wheelchair-bound in the second or third decade. All patients had cerebellar atrophy and some of them increased alpha-fetoprotein and cholesterol.

**NEUROCUTANEOUS SYNDROMES WITH ABNORMAL PIGMENTATION**

**INCONTINENTIA PIGMENTI (BLOCH–SULZBERGER TYPE)**

Bloch–Sulzberger syndrome is a rare genetic disorder, observed almost exclusively in girls, probably transmitted as an X-linked dominant trait prenatally lethal in the majority of affected males. The responsible gene, IKBKG (inhibitor of kappa B kinase gamma, previously NEMO), is a modulator of the activation of the nuclear factor kappaB (NF-kappa B) signalling pathway (Fusco et al. 2004; Su et al. 2004) and maps to Xq28. When activated, NF-kappaB controls the expression of multiple genes, including cytokines and chemokines, and protects cells against apoptosis (Berlin 2002).

**Skin Features**

The skin lesions are striking. They consist of four distinct but somewhat overlapping stages (Rosman 1992; Mangano and Barbagallo 1993; Berlin 2002): vesicular, verrucous, pigmented...

Updated by Minić et al. (2014).

Incontinentia pigmenti (IP), CNS, central nervous system; IKBKG, inhibitor of nuclear factor kappa B kinase subunit gamma.

and atrophic scarring. In the first stage, erythematous, papular, vesicular or bullous lesions are present at birth or during the first 2 weeks of life on the trunk and limbs. They are linear in distribution and last from days to months. Most resolve by 4 months of age. In the second stage, between the second and the sixth weeks, the lesions are variably pustular, verrucous or keratotic (O’Brien and Feingold 1985). Most lesions resolve by 6 months of age, but they may recur throughout childhood often during viral or bacterial infections or after routine vaccination (Patrizi 2004; Alikhan et al. 2010). They may disappear without sequelae or are followed by the development of pigmentation, characteristic of the third stage of the disease. Stage 3 occurs in 98% of patients. These pigmented grey-brown lesions are the hallmark of the disease and may be located outside the area of earlier lesions, and in 10% of patients are not preceded by them. The pigmentation persists into adulthood but tends to fade with the passing of time. Some patients can have pale atrophic/hypopigmented stage. Evidence of CNS infection. These are the most frequent neurological manifestations and appear to be the result of an arte-ritis that may be extensive and can be detected by angiography (Fiorillo et al. 2003; Hennel et al. 2003). Siemes et al. (1978), Shuper et al. (1990) and Hennel et al. (2003) found inflammatory lesions in all participants. Other pathological lesions are possible. Patients have been reported with reversible CNS white matter lesions (Bryant and Rutledge 2007; Lou et al. 2008) One patient had involvement of the anterior horn cells of the spinal cord (Larsen et al. 1987); in another case a migrational disorder was found (O’Doherty and Norman 1968).

### Other Symptoms, Evolution and Management

Various eye lesions are present in one-third of patients, the most characteristic of which is a retrolental mass with detachment of a dysplastic retina (Rosenfeld and Smith 1983). This should be looked for systematically in affected infants, as early detection and therapy of the retinitis may protect vision (Wong et al. 2004).

Dental abnormalities (peg-shaped teeth) occur in 70% of patients. Treatment is symptomatic and includes ophthalmological interventions, antiepileptic agents, physiotherapy and corticosteroids. Orthopaedic measures as well as educational support are vital. Genetic counselling is an important part of management. The outcome is not necessarily bad and a normal long-term outcome may be observed in some patients (Steffan et al. 2004). Prenatal molecular diagnosis has been made (Steffan et al. 2004).

Bloch–Sulzberger syndrome is probably different from the Naegeli type of incontinentia pigmenti rather than a subtype of the same disease (Rosman 1992). The latter occurs in boys and girls.

#### INCONTINENTIA PIGMENTI ACHROMIANS (HYPOMELANOSIS OF ITO)

Another condition that should be distinguished from Bloch–Sulzberger disease is hypomelanosis of Ito or incontinentia
pigmented achromians. This disorder is characterised by hypopigmented areas with a peculiar streaked or whorled appearance, often unilateral or with a strong unilateral predominance along the Blaschko lines (Pascual-Castroviejo et al. 1988; Gordon 1994) (Fig. 4.12). The appearance is variable with the possibility of pigmented rather than achromic lesions and more commonly of an association of both. Associated abnormalities are described in 33–94% of patients. CNS involvement is most common, thus justifying the term neurocutaneous syndrome (Steiner et al. 1996; Ruggieri and Pavone 2000). Only about one in four have average or above average IQ, and more than 50% have some degree of learning disability (IQ <70). Seizures are common (about half the group), they can be of several types and infantile spasms occur in about one in 10 individuals with typical skin changes. Patients with hypomelanosis of Ito may present heterogeneous epilepsy phenotypes. At one extreme, there are patients with generalised seizures well controlled by antiepileptic drugs, whereas at the opposite extreme there are patients with severe, pharmacoresistant, focal seizures (Assogba et al. 2010). There is also a wide spectrum of EEG abnormalities from normal records to multifocal paroxysmic features. Fast rhythm may be associated with areas of pachygria (Ogino et al. 1994). Ito disease is one of the causes of hemimegalencephaly (Pascual-Castroviejo et al. 1988; Aurierma et al. 2000). Macrocephalus is present in about one in seven patients. Glover et al. (1989) found psychomotor delay in 14 of their 19 patients, nine had seizures, and two had severe sensorineural deafness.

Many cases of hypomelanosis of Ito are associated with psychiatric disorder including symptoms compatible with the diagnoses of psychosis, autism, atypical autism and Asperger syndrome have been described (Åkefeldt and Gillberg 1991; Zappella 1993; Davalos et al. 2001; Pascual-Castroviejo et al. 1998, 2006). Autism spectrum manifestations are known to occur (Åkefeldt and Gillberg 1991) in up to 10% of patients (Pascual-Castroviejo et al. 1988). Eye abnormalities (Rosenfeld and Smith 1983) include microphthalmia and related structural abnormalities, and were present in three of the 19 patients of Glover et al. (1989). Hemihyper trophy and scoliosis are commonly present. Imaging may show bilateral or unilateral hemispheric atrophy or areas of low attenuation in white matter or cerebellar atrophy (Pini and Faulkner 1995). MRI has shown the presence of neuronal heterotopia (Glover et al. 1989; Malherbe et al. 1993), and Steiner et al. (1996) reported a wide spectrum of major and minor imaging abnormalities. White matter signal abnormalities may be present, which is in agreement with the pathological findings of Fujino et al. (1995).

Most confirmed cases of hypomelanosis of Ito are sporadic, although dominant transmission has been suggested but not demonstrated. Girls seem to be more commonly affected than boys. Mosaicism for miscellaneous chromosome aberrations appears to be a common but not a constant cause of the disease (Taibjee et al. 2004; Lombillo and Sybert 2005).

Chromosome analysis should ideally be performed on keratinocyte cultures whereas lymphocyte and fibroblast cultures are usually negative. Prenatal diagnosis has been made (Steinberg Warren et al. 2001).

There is no treatment for the skin disorder, but cover-up make-up can be used if desired. Neurological, hearing and visual problems should be treated as indicated for those particular problems.

**NEUROCUTANEOUS MELANOSIS**

This rare disorder is characterised by cutaneous pigmented nevi and variable involvement of the meninges and CNS (Makkar and Frieden 2004) (Fig. 4.13). The nevi are of the giant type, often in ‘bath suit topography’ that covers the lower part of the trunk, the pelvis and the upper part of the lower limbs in two-thirds of patients and multiple small lesions in one-third. However, we have seen a child with biopsy-proven meningeal melanosis who had a single nevus of 5×5cm on one arm, and a lesion of similar size was encountered by de Andrade et al. (2004). The nevi are heavily pigmented and hairy. Kinsler et al. (2008) performed a retrospective study of 120 patients. MRI abnormalities were found in 18% of patients and were significantly associated with projected adult size of the largest congenital melanocytic nevus, particularly those greater than 40cm.

More than half the patients with congenital hairy nevi develop early CNS involvement, in the form of progressive hydrocephalus, probably as a result of proliferation of meningeal melanocytes with consequent blockage of CSF reabsorption or circulation or of meningeal or CNS malignant tumours (Di Rocco et al. 2004; Ramaswamy et al. 2012). There is often cystic dilatation of the cisterna magna (Barkovich et al. 1994). Other CNS findings include parenchymal neuromelanosis, and rarely choroid plexus papilloma, astrocytoma and posterior fossa arachnoid cyst (Kinsler et al. 2008). Seizures are common, and variable neurological deficits may result from parenchymal tumoural proliferation of melanocytes.
Chapter 4 Neurocutaneous Diseases and Syndromes

(Rhodes et al. 1991), such as hemiparesis, reduced muscle tone, spasticity, ataxia and global developmental delay (Kinsler et al. 2008).

The prognosis is poor in symptomatic patients, but hydrocephalus should be treated with a shunt (Di Rocco et al. 2004). An occasional patient survives many years but malignant degeneration of CNS lesions is extremely common.

Kinsler et al. (2013) suggested that single postzygotic NRAS mutations are responsible for multiple congenital melanocytic nevi and associated neurological lesions in the majority of patients.

OTHER NEUROCUTANEOUS SYNDROMES WITH ABNORMAL PIGMENTATION

Albinism refers to a group of inherited disorders in which there is a reduction or absence of melanin formation. Many types of albinism are known, and the main features of the condition are cutaneous and ocular rather than neurological. One remarkable finding is misrouting of the optic fibres, with an abnormally high proportion of crossed fibres and projection of only the most peripheral part of the temporal retina to the ipsilateral hemisphere, which may be demonstrated by study of the visual evoked potentials (Collewijn et al. 1985) and by appropriate MRI techniques (Hedera et al. 1994). Using MRI, Schmitz et al. (2003) found that the size and configuration of the optic chiasm in humans with albinism are distinctly different from the chiasms of normal control participants. Albino children also have a special pattern of cognitive function with a much higher score on verbal than on performance items (Cole et al. 1987).

Several rare syndromes of deficient pigmentation variably feature immunodeficiency (macrophagic activation syndrome) and/or neurological signs. Chediak–Higashi syndrome (CHS) associates a peripheral neuropathy with immune and haematological abnormalities. Chediak–Higashi syndrome is caused by homozygous or compound heterozygous mutation in the lysosomal trafficking regulator gene *LYST* (Barbosa et al. 1997). Severe neurological problems affecting the CNS with seizures, intellectual disability and motor deficits are prominent features in Hermansky–Pudlak (*HPS1* gene), Griscelli (type 2, *RAB27A* gene) and Elejalde (or Griscelli type 1, *MYO5A* gene) syndromes (Oh et al. 1996; Pastural et al. 1997; Menasché et al. 2000; Scheinfeld 2003). Griscelli type 2 or partial albinism with immunodeficiency syndrome is characterised by relapsing neurological symptoms, by the presence of demyelination beginning and predominating in the posterior fossa (Brismar and Harfi 1992) and spreading to involve the whole white matter, and the absence of characteristic granulations, and differs from Chediak syndrome by different hair and skin microscopic findings (Mancini et al. 1998).

Some other syndromes in this category are listed in Table 4.5.

<sup>a</sup>Encephalocraniocutaneous lipomatosis and Dellemann syndrome may belong to the same entity.

<sup>b</sup>Sporadic cases are frequent. A mutation of the PTEN gene is frequent.

<sup>c</sup>The dominant form is associated with mutations in the proto-oncogene RET.

<sup>d</sup>Cowden syndrome is often associated with mutations in the PTEN gene.

S, sporadic; AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.
Chapter 4 Neurocutaneous Diseases and Syndromes

**NEUROICHTHYOSIS SYNDROMES**

The term neuroichthyosis refers to the syndromes that associate ichthyosis or ichthyosiform dermatoses to central or peripheral nervous system involvement.

**SJÖGREN–LARSSON SYNDROME**

Sjögren–Larsson syndrome combines intellectual disability and spastic diplegia with congenital ichthyosis (Rizzo et al. 1989). Patients are born preterm in 70% of cases. Spasticity becomes apparent between 4 and 30 months of age, is most pronounced in the legs and fairly slight in the arms. All patients have cognitive impairment, which varies from slight to severe, almost all have a mild-to-moderate dysarthria and one-third of them present epilepsy (Jagell et al. 1981; Gånemo et al. 2009; Fuijschot et al. 2012). Atypical retinitis pigmentosa with macular glistening dots is an almost constant feature but may easily escape detection (Jagell and Heijbel 1982; Willemsen et al. 2001). Peripheral involvement may occur. MRI may demonstrate a leukoencephalopathy with delayed myelin deposition, mild persistent white matter deficit (Hussain et al. 1995) and periventricular gliosis. Magnetic resonance spectroscopy shows accumulation of lipids in the white matter and a normal grey matter (Willemsen et al. 2004). The disorder is transmitted as an autosomal recessive trait. Several mutations in the gene ALDH3A2 encoding the fatty acid dehydrogenase FALDH are known (Rizzo et al. 1999; Carney et al. 2004). A defect of fatty alcohol metabolism is present, with deficiency of nicotinamide–adenine dinucleotide oxidoreductase in skin and leukocytes (De Laurenzi et al. 1996; Rizzo 2014). Prenatal diagnosis is possible (Rizzo et al. 1994). Dietary treatment is not successful (Maaswinkel-Mooij et al. 1994). Gene therapy is being tried (Haud and Braun-Falco 2006). The diagnosis depends on measurements of fatty aldehyde dehydrogenase or of the oxidoreductase complex in fibroblasts from skin biopsies, but now can be confirmed by genetic analysis. Identification of abnormal urinary excretion of leukotriene B4 and its metabolites can also be useful (Gordon 2007). Somewhat similar syndromes have been observed, one without metabolic deficit (Scalais et al. 1992) and one with prominent myoclonus (Amano et al. 1995).

**TRICHOThIODYSTROPHY**

Trichoiodystrophy (TTD) is also known as Tay disease or Pollitt syndrome and it has also been described by several other acronyms: PIBIDS (photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility and short stature), IBIDS and BIDS (Baden et al. 1976). It is one of several related syndromes associated with abnormalities of DNA repair.

TTD is inherited as an autosomal recessive trait and results from mutations in one of several different DNA repair genes (XPB, XPD or TTDA) (Stefanini et al. 1986; Weeda et al. 1997; Giglia-Mari et al. 2004; Morice-Picard et al. 2009) and TTDN1, a gene of unknown function (Nakabayashi et al. 2005). Although XPB and XPD mutations are also seen in xeroderma pigmentosum, a disease with a 1000-fold increase in skin cancer, patients with TTD have not been reported to have an increase in cancer.

Affected children have brittle and sparse hair, eyebrows and eyelashes. Microscopically, the hair shows ‘tiger banding’ and shaft abnormalities on polarised light examination (Liang et al. 2005), and the sulphur content is reduced to about half the usual value, as is the cystine content. Faghri et al. (2008) reviewed 112 published cases and reported that the majority of patients’ present intellectual impairment (86%), short stature, ichthyosis (65%) and ocular abnormalities such as cataracts. Many of them have abnormal characteristics at birth (55%) and maternal pregnancy complications. Recurrent infections in 46% are related with a high mortality rate at a young age, and photosensitivity is present in 42%.

Cerebellar and cerebral atrophy (Yoon et al. 2005), microcephaly, ataxia and calcification of the basal ganglia have been reported.

**OTHER NEUROICHTHYOSIS SYNDROMES**

Some other neuroichthyosis syndromes are listed in Table 4.5.

**MISCELLANEOUS NEUROCUTANEOUS SYNDROMES**

**NEVOID BASAL CELL CARCINOMA**

This is the most important among the rarer neurocutaneous syndromes. It is a complex disease with skin, bone and CNS manifestations, and a tendency to the development of neoplastic lesions, including medulloblastoma (Evans et al. 1993; Shanley et al. 1994; Amlashi et al. 2003).

Basal cell carcinomas are a constant feature of the syndrome but develop before puberty in only 15% of patients and are mainly located on the face, neck and upper trunk. Palmar and plantar cutaneous pits are a frequent feature.
Cysts of the jaw usually develop before 10 years of age. An early diagnosis in infants is possible by taking into account family antecedents and uncharacteristic features such as bone anomalies and malformations (Pastorino et al. 2005). CNS abnormalities include, in addition to posterior fossa tumours, calcification of the falx cerebri and, less frequently, of the tentorium cerebelli and the petroclinoid ligament; agenesis of the corpus callosum, bridging of the sella turcica; and occasionally intellectual disability (Titinchi et al. 2013; Larsen et al. 2014).

Klein et al. (2005) found mutations of the PTCH1 gene on chromosome 9q31 in 44 of 106 patients. In affected members of a Chinese Han family, Fan et al. (2008) identified a heterozygous germline mutation in the PTCH2 gene. In a family exhibiting atypical signs and symptoms, Pastorino et al. (2009), analysed the PTCH1 gene but found no mutations. Analysis of the SUFU gene, which like PTCH1 and PTCH2 is a component of the same signalling pathway, revealed a splice site mutation in the proband and his father. The basic defect is unknown but there is an increased sensitivity of the skin to X-irradiation. Basal cell carcinomas have developed in the scalp and paraspinal area exposed to the radiation portal after treatment of medulloblastoma in some cases.

Patients with this syndrome should be carefully watched for the possible development of an aggressive cancer. Small odontogenic cysts and skin tumours that show ulceration or haemorrhage should be removed. Successful treatment for the basal cell carcinomas with topical imiquinone and wide-area-5-aminolevulinic acid photodynamic therapy (Oseroff et al. 2005) has been reported.

**PROGRESSIVE HEMIFACIAL ATROPHY (PARRY–ROMBERG DISEASE)**

This rare condition is characterised by progressive hemifacial atrophy. The most common early sign is a painless cleft, the *coup de sabre*, near the midline of the face which marks the boundary between the normal and atrophic tissues. Characteristically, the atrophy starts in the first decade of life and progresses slowly for several years.

This cutaneous syndrome may be associated with neurological manifestations (Chung et al. 1995). Seizures, often focal in type and more often arising from the hemisphere ipsilateral to the side of the facial atrophy, are the most frequent symptom. Unilateral or bilateral motor deficit, impaired sensory function, optic atrophy and involvement of cranial nerves may occur. Intracranial calcification is seen in some patients, and hemispheric atrophy has been demonstrated (Terstegge et al. 1994; Doolittle et al. 2015). Vascular abnormalities are present in some cases (Strenge et al. 1996; Taylor et al. 1997). The neurological disease may be progressive and even dementia has been reported. Cortical dysplasia was shown by MRI in four patients (Dupont et al. 1997). The skin and facial atrophy is also progressive over several years but eventually stabilises.

The relationship between *en coup de sabre morphea* and Parry–Romberg syndrome is still unclear. They frequently coexist and are likely both variants of morphea (Tollefson et al. 2007).

**LIPOID PROTEINOSIS (URBACH–WIETHE DISEASE)**

Lipoid proteinosis is caused by mutation in the gene for the extracellular matrix protein 1, *ECM1* (Hamada et al. 2002). It is also known as cutaneous mucous hyalinosis, and is characterised by a peculiar infiltration of the skin and mucous membranes by a hyaline substance resulting in thick skin with yellowish papules, a typical disposition on the margin of the eyelids and infiltration of the tongue and lips. Hoarseness and dysphonia (Van Hougenhouk-Tulleken et al. 2004) linked to an infiltration of the larynx is the most common manifestation at onset and it may be the only sign in early infancy. Imaging of the head may show calcification of the amygdalar region bilaterally (Özbek et al. 1994; Appenzeller et al. 2006). Thus, neurological involvement may occur in the form of focal seizures. A specific disturbance of emotion perception and recall (Siebert et al. 2003) may also be related to this frequent amygdalar involvement. Recently acitretin was used in the treatment of lipoid proteinosis with some effect in cutaneous lesions and hoarseness (Dertlioglu et al. 2014).

Genetic Anomalies and Dysmorphic Syndromes

Karine Pelc and Bernard Dan

The process of medical diagnosis aims to link observable signs to putative factors that underlie or at least facilitate the occurrence of these signs. The notion of phenotype refers to the characterisation of observable properties relating to clinical knowledge. In most chapters in this book, as in much of current clinical practice, this search often targets genetic determinants. The common use of the term ‘phenotype’ thus links it with the notion of genotype, i.e. the genetic basis that is expressed as the phenotype. However, the general concept is much wider than the implied focus on the genotype–phenotype relationship. In any case, careful observation of a patient’s phenotype is the only way to make a clinical diagnosis.

Many genetic syndromes have both physical and behavioural manifestations with distinctive social, cognitive and motor profiles. The course is not static with age, and presentation typically varies according to the level of learning disability and a host of environmental, developmental and therapeutic influences.

The phenotypic approach is a royal road to pathophysiological reasoning, which incorporates the molecular dimension of the genotype where applicable. Observed features can be tentatively explained by known physiology and gene function. For example, the propensity for more severe neurological impairment in patients with Angelman syndrome, associated with 15q11-q13 microdeletion, compared with other molecular causes has been hypothesised to be the result of hemizygosity of GABA$_A$-receptor subunits impairing $\gamma$-aminobutyric acid (GABA)-related neural synchrony (Dan 2009). The phenotypic approach is also important for management planning, because some phenotypic features may constitute targets, constraints or facilitating opportunities, (e.g. self-injury in Lesch–Nyhan syndrome [see Chapter 9]), impaired manipulative function in Rett syndrome or attention seeking behaviour in Angelman syndrome in Smith–Magenis syndrome.

A medical diagnosis is often expressed as a syndrome, i.e. an association of symptoms and signs that reflect physiological dysfunction, which may themselves be the result of different causes. When such an association has previously been typified, the search for the cause of the problems is much easier. When a syndrome has not been recognised previously, the identification of relevant symptoms and signs from the many aspects of the patient’s presentation is much more difficult, and requires an exquisite combination of medical knowledge, intuition and judgement.

Many syndromes have a genetic background, whether a single gene defect (e.g. Apert syndrome; see Chapters 6, 22, 23), chromosomal abnormalities (e.g. Down syndrome), microdeletion (e.g. Prader–Willi syndrome) or polygenic disorders (e.g. the autism spectrum disorder [ASD]; see Chapter 29).

When faced with the description of a syndrome, clinicians have to pay particular attention to dysmorphic features, i.e. congenital defects and abnormalities of body structure that relate to morphogenesis impairment in particular tissues. Some of them are pathognomonic and may lead to the early detection and intervention, for example, pulmonary artery stenosis in Williams syndrome (Ahmad and Vettukattil 2010). Although different processes underlying dysmorphic features may be disrupted by external agents, morphogenesis is highly determined by the interplay of many genetic determinants, which vary widely within the population. Malformations result from a basic alteration of structure, which typically occurs before 10 weeks’ gestation, (e.g. cleft palate, anencephaly, limb agenesis). They may also occur later in pregnancy as exemplified in brain cortex dysplasias (see Chapter 3). Malformations can occur in ‘sequences’ of multiple defects resulting from a single primary malformation, (e.g. talipes) and hydrocephalus can result from a lumbar neural tube defect (see Chapter 1). Malformation sequences differ from ‘associations’, which are groups of anomalies that occur more frequently than would be expected by chance alone, but do not have a unified aetiology, (e.g. VATER-vertebral anomalies, anal atresia, cardiac defects, tracheo-oesophageal fistula and/or oesophageal atresia, renal and radial anomalies and limb defects) association.

In clinical practice it is often difficult to determine whether the observed features indicate a syndrome or represent variations that occur in the general population. Comparison with other family members is useful, as are anthropometric measurements to identify abnormalities quantitatively with reference to growth charts of different parts of the body (including the face), obtained for the appropriate sex and ethnic background. The following elements raise suspicion of a genetic aetiology: congenital anomalies, unusual aspect,
growth deficit (e.g. short stature or failure to thrive),
developmental delay or regression, cognitive impairment,
failure to develop secondary sexual characters or ambiguous

gentialia.

History taking should concentrate on setting up a detailed
pedigree to evaluate an eventual family history and mode of
inheritance. A detailed history of the pregnancy is important,
for example, oligohydramnios may imply an aberrant force
that caused malformation mechanically, and abnormal fetal
position or decreased fetal movements suggest abnormal fetal
tone. Environmental hazards for the fetus may help to exclude
genetic disorders as a cause, for example, maternal conditions
such as diabetes mellitus, hypertension, thyroid problems,
phenylketonuria (see Chapter 9) or myasthenia gravis (see
Chapters 22, 26), infections, use of drugs and other expo­
sures. A large placenta, which may be a feature of Beckwith–
Wiedemann syndrome, could be a valuable hint. The neonatal
history, including birth measurements, is also important.
A history of growth and neurological development should
be investigated carefully, the association of failure to thrive
or early onset obesity with milestone delay may be clues to
genetic disorders, (e.g. a glycosylation defect (see Chapter 9) or
Prader–Willi syndrome, respectively).

Physical examination may record unusual head shape, (e.g.
trigonocephaly or brachycephaly), or abnormal head circum­
fere, i.e. microcephaly or macrocephaly. Synophrys (i.e.
fused eyebrows), is a feature of Cornelia de Lange syndrome.
The inner canthal distance, palpebral fissures (slanting and
length), the eyes themselves, the shape, rotation and position
of the ears, and nose and mouth morphology can all provide
relevant signs, and so can examination of the hands and feet
(e.g. brachydactyly or short fingers or toes, arachno-, clinop­
ely- or syndactyly), skin (pigmentation, scales, appendages)
and hair (amount, texture, hairline), and joints (shape, mo­
bility). The abdomen should be examined carefully for wall
defects (omphalocele, gastrochisis), hepatosplenomegaly and
abnormal genitalia.

Behavioural features should also be observed with respect
to evocative behavioural phenotypes, i.e. distinctive associa­
tions of abnormalities in domains such as cognition, lan­
guage, social skills and motor control, which are known to
be associated with specific biological disorders (e.g. Williams,
Lesch–Nyhan (see Chapter 19), fragile X, Angelman and Rett
syndromes, among others).

Radiological examination highlights bony changes and
neuroimaging highlights brain structures.

Finally, laboratory tests, including genetic testing, which
until recently were essentially used to confirm and refine
the clinical diagnosis, now play a prominent role in a diagnostic
exploration, which has increasingly supplanted directed
exploration of suspected conditions. Laboratory tests can also
contribute to unravelling the cause of an as yet unclassified
syndrome. This journey from phenotype to genotype takes the
clinician through the complexities and singularities of indi­
vidual patients. Apart from targeted genetic testing, which is
still favoured when the clinical presentation strongly evokes a
well-defined neurogenic condition with minimal or no genetic
heterogeneity, technological advances have dramatically in­
creased the diagnostic yield in the last few years. Comparative
genomic hybridisation (CGH) array has replaced conventional
cytotyping as a routine first-line investigation in children with
intellectual disability that is or is not associated with a dys­
morphic syndrome in many settings. It allows for detection
of small chromosomal deletions and duplications (called copy
number variants), with a higher resolution than conventional
cytotyping (down to few dozen kilobases), leading to a sig­
nificant increase in aetiological diagnoses through the detec­
tion of chromosomal deletions and duplications, including
many newly recognised syndromes. Whole-exome sequenc­
ing, which allows for the detection of nucleotide substitutions
and small insertions or deletions, is complementary to CGH
array in the genetic work-up. Its use in a clinical work-up has
drastically increased the diagnostic yield, in both the condi­
tions described in this chapter and a wide range of neurolog­
ical disorders with Mendelian inheritance. These advances
have proved to be extremely useful for patients, families and
clinicians, but, alongside pathogenic variants, CGH array
and whole-exome sequencing inevitably identify many vari­
ants of uncertain significance, posing a great challenge to
effective interpretation (Dan and Baxter 2014). In addition,
customised gene panels are also becoming increasingly avail­
able. These allow screening of multiple known genes associated
with a specific phenotype at much the same cost as single-gene
analysis. Yet, because of decreasing costs, whole-exome sequenc­
ing is expected to replace CGH in many settings in the
near future.

In this chapter, we review selected dysmorphic
syndromes associated with genetic or chromosomal abnor­
malities. The somewhat arbitrary selection is based on epide­
miology or clinical relevance in illustrating the complexity of
neurological and behavioural phenotype and the diagnostic
process.

### DOWN SYNDROME

The presence of an abnormal number of chromosomes, or
aneuploidy, in a cell often results in spontaneous termination of
gestation, except with the sex chromosomes.

Down syndrome (OMIM#190685) or trisomy 21, i.e. an
extra copy of chromosome 21, is the most common genetic
cause of developmental intellectual impairment. The phenotype
may comprise a variety of dysmorphic features including
craniofacial features (Fig. 5.1), intellectual impairment, mal­
formations such as congenital heart disease, and various oth­
er disorders such as immune deficits, Alzheimer disease and
leukaemia. The original description was provided by British
physician John Langdon Down in 1866 (Down 1866), and
the association with trisomy 21 was established in 1959 (Lejeune et al. 1959). A recent monograph reviewed Down syndrome comprehensively (Newton et al. 2016).

Epidemiology

It occurs sporadically in 1 in 700 live births, although the risk increases with maternal age. The birth prevalence has been decreasing due to more frequent elective pregnancy terminations after an antenatal diagnosis (de Graaf et al. 2015). Population prevalence, currently around 1 in 125, has increased dramatically over the past decades owing to longer life expectancy related to better access to medical care (Presson et al. 2013). Whereas in the 1990s few individuals survived beyond age 25, recent figures suggest that 20% of adults with Down syndrome are aged >55 years (Jensen and Bulova 2014).

Clinical Features

Cognitive impairment is mild in 40% of individuals, moderate in 35%, severe in about 25% and absent in around 1%. However, marked individual variability in skills is observed, and as always there are general limitations in using IQ to approach the actual functioning of individuals. Visuospatial perception (Vicari et al. 2005) is often better than verbal skills, although long-term (but not immediate) memory impairments have been documented in visual–object learning tasks (Jarrold et al. 2007). Receptive verbal language is typically better than expressive language, which shows particular deficits in phonology and syntax (Martin et al. 2009). Speech intelligibility is impaired by systematic sound errors, simplification patterns, speech apraxia and dysarthria. Syntax is typically more impaired than vocabulary for both receptive and expressive speech, to lower levels than expected given non-verbal cognitive ability. Specific verbal short-term memory deficits have also been documented (Laws 2002). The risk for developmental verbal impairment may be enhanced by conductive hearing loss, strongly associated with otitis media, which is found in almost all young children with Down syndrome. (In contrast sensorineural hearing loss is more frequent in adolescence and early adulthood.) Social skills are similar to typically developing children in preschool years. Later, patterns of interpersonal relationships remain parallel to typical development, and adults with Down syndrome generally show less antisocial behaviour and aggressiveness than many with other intellectual disabilities. Yet, social skills may markedly decline in patients who develop early onset Alzheimer disease, which is due to an additional copy of the gene encoding amyloid precursor protein and perhaps other genes. The prevalence of Alzheimer disease rises steeply from the fourth decade, reaching 250–800 per 1000 by age 60. The early symptoms seem to affect predominantly behaviour and personality, for example perseveration or apathy, rather than memory as in the general population, perhaps reflecting masking of memory deficits by presymptomatic cognitive impairment. However, early diagnosis is difficult for want of validated diagnostic tools for these patients (Ballard et al. 2016). Although this condition shows neuropsychological, neuroimaging and neuropathological findings that are very similar to late-onset Alzheimer disease, response to treatment, including cholinesterase inhibitors and the N-methyl-d-aspartate (NMDA)-receptor antagonist memantine, shows marked differences.

Hypotonia and associated ligamentous laxity are often marked, particularly in infancy. They contribute to postural control impairment (Rigoldi et al. 2011). Posterior ligamentous hyperlaxity may induce atlantoaxial subluxation, which can provoke cervical myelopathy.

Epileptic seizures occur in about 10% of individuals (Arya et al. 2011). Infantile spasms are frequent and seem to be better controlled by early, appropriate medication that in other patients with symptomatic infantile spasms (Arya et al. 2011). Other epileptic syndromes and seizure types may occur, particularly tonic–clonic and myoclonic seizures, which peak after the third decade. Many patients with dementia develop myoclonic seizures, predominantly on awakening, as part of a condition that has been termed ‘senile myoclonic epilepsy’ (De Simone et al. 2010), in which seizures appear to be associated with rapid cognitive decline.

Arterial ischaemic stroke (see Chapter 15) may occur in children secondary to infection or congenital heart disease. It commonly manifests with hemiparesis, but can also be caused by moyamoya disease, which occurs more frequently in Down syndrome than in the general paediatric population, although this association is poorly understood. Management of stroke or moyamoya in Down syndrome is not specific. Management in the acute phase of stroke is symptomatic, the use of intravenous tissue plasminogen activator being contraindicated because of the risk of intracranial bleeding (Hashimoto et al. 2011).
262 Part II Brain Malformations, Neurocutaneous Syndromes, Genetic Anomalies and Dysmorphic Syndromes

Genes on the X chromosome are involved in many cases of intellectual disability, which contributes to the higher incidence of intellectual disability in males. The 1943 report, by English neurologist James Purdon Martin and geneticist Julia Bell, on 11 members of a family with intellectual disability ‘showing sex linkage’ (Martin and Bell 1943) is consistent with fragile X syndrome. Fragile X syndrome (OMIM#300624) is the most commonly inherited form of intellectual disability and predominantly affects boys. The physical phenotype also comprises recognisable facial traits, macro-orchidism, and a behavioural phenotype that includes features of ASD (see Chapter 29). It was first characterised cytogenetically by a so-called marker X in the late 1960s (Lubs 1969). In the early 1990s, expansion of the CGG trinucleotide in the \textit{FMRI} gene was identified as responsible for fragile X syndrome (Verheij et al. 1993).

**Clinical Features**

Most affected boys have absolute or relative macrocephaly. The face is typically long, with large, prominent ears. After puberty, macro-orchidism develops.

The disease presents with delayed developmental milestones and hypotonia, as well as a spectrum of intellectual disabilities ranging from mild to severe, with an average IQ of 40 in males. The cognitive profile may include impairment of language, executive function, visuospatial abilities, mathematics, and short-term and working memory, with a specifically impaired phonological loop (Baker et al. 2011).

More than 90% of males with fragile X syndrome show some behavioural features typically associated with autism, such as gaze avoidance, hyperarousal, perseverative speech or stereotyped behaviours (Bailey et al. 2000), and 60%, predominantly those with a low IQ, fulfil the diagnostic criteria for the ASD (Clifford et al. 2007; Harris et al. 2008). However, clinical differences between these males and males with non-syndromic ASD (see Chapter 29) have been noted (Thurman et al. 2015). Social affective symptoms, for example, are less severe at age 4 years in boys.
with fragile X syndrome, but worsen with age, perhaps in parallel with non-verbal IQ decline. Motor stereotypes typically include hand flapping. Tics are probably no more prevalent than in the general population (Kidd et al. 2014). Attention-deficit–hyperactivity disorder (ADHD) (see Chapter 30) is reported in up to 74% of males and 30% of females (Tranfaglia 2011) but the relevance of this diagnosis in neurodevelopmental genetic disorders has been questioned (Pelc and Dan 2008).

Seizures occur in 10–18% of patients, predominantly in males, slightly more in the group with ASD (Kidd et al. 2014). They may be partial or generalised, and commonly respond to pharmacological treatment.

Recurrent otitis media is more prevalent than in the general population, possibly because of anatomical factors, poor secretion control, oromotor hypotonia and dyspraxia.

**Genetics and Molecular Biology**

The syndrome results from mutations of the fragile X mental retardation 1 (FMR1) gene, located on the X chromosome (D’Hulst and Kooy 2009). In close to 99% of individuals, these mutations consist of an increase (>200) in the number of CGG trinucleotide repeats in the gene’s 5’-untranslated region. However, they may also result from deletions or point mutations.

In unaffected individuals, FMR1 contains around 30 CGG repeats. Repeats between 55 and 200 are regarded as a ‘premutation’. Boys with premutations are at increased risk of autistic features and seizures (Chonchaiya et al. 2012). Women who are carriers of a premutation may pass on a full mutation to their children, because the number of premutation CGG repeats often increases during meiosis.

In case of a full mutation (>200 repeats), the expanded repeat region is transcribed into the untranslated region of FMR1 mRNA, which binds to the DNA repeat region, inactivating the FMR1 gene (Colak et al. 2014).

The FMR1 gene product appears to play a role in synaptic plasticity, for example in synaptic protein synthesis, interaction with metabotropic glutamate receptor signalling, mRNA transport and dendritic localisation, and selective inhibition of mRNA translation, but these have not been fully characterised. Abnormal synaptic plasticity would impair learning and memory processes.

Males with a full mutation almost always show signs of fragile X syndrome, whereas females with a full mutation generally show a penetrance of about 50% as a result of having another, unmutated FMR1 allele. In females, the symptoms therefore range from mild to severe, although they are commonly less affected than males.

**Diagnostic Criteria and Testing**

Several authors have suggested use of clinical criteria to select patients for DNA testing. Scoring systems may include a long jaw and high, wide forehead, large and protruding ears, hyperextension of the metacarpophalangeal joint of the fifth digit, soft and velvety skin on the palms, macro-orchidism, initial shyness and lack of eye contact, followed by friendliness and echolalic speech, and a family history of intellectual disability (de Vries et al. 1999).

The diagnosis rests on the demonstration of a full mutation, i.e. >200 CGG repeats, of the FMR1 gene. FMR1 sequencing is necessary to identify fragile X syndrome due to deletions or missense mutations rather than excess CGG repeats.

Determination of the number of CGG repeats also allows for risk assessment of premutation carriers.

**Animal Models**

Fmr1 knockout mouse models have provided insights into the role of the gene product in dendritic spine maturation, axonal arborisation synaptic plasticity and its regulation by metabotropic glutamate receptor signalling (Irwin et al. 2000; Bear et al. 2004). Drosophila models of mutant dfmr1 have been designed for testing pharmacological approaches (McBride et al. 2013). However, clinical trials of drugs that were based on the hyperactive metabotropic glutamate receptor 5 were disappointing and are not being continued (Davenport et al. 2016).

### RETT SYNDROME

Rett syndrome (OMIM#312750) is one of the most common causes of complex disability in girls. It is characterised by early neurological regression that severely affects motor, cognitive and communication skills, autonomic dysfunction and epilepsy. It was first recognised in 1954 by Andreas Rett, a Viennese paediatric neurologist (Ronen et al. 2009), who published his observations in an Austrian medical journal (Rett 1946). It was Bengt Hagberg from Sweden, however, who shared his own observations and revealed Rett syndrome to the international medical world in 1983 (Hagberg et al. 1983). In the late 1990s, MECP2 mutations were identified (Amir et al. 1999), characterising Rett syndrome as a monogenic X-linked dominant neurodevelopmental disorder, the first to be related to a defective transcription of methylated DNA. A recent monograph addresses many aspects of the syndrome (Kaufmann et al. 2017).

**Epidemiology**

The prevalence of typical Rett syndrome (see below) is estimated at 1 in 10,000 women aged 32 years (Fehr et al. 2011). Almost all the causes are sporadic.
Clinical Features

Rett syndrome is characterised by neurological regression in infancy of motor, cognitive and communication skills, often leading to microcephaly, a delay in acquiring new skills, absence of speech, emergence of autistic features and loss of purposeful manipulation skills, replaced by distinctive stereotypical hand movements (Fig. 5.2). The time evolution of the phenotype has been delineated in a staging system (Engerström 1990).

Although retrospective analysis of home videos (Marschik et al. 2013) suggests that development may be suboptimal from the neonatal period, it is not obviously disturbed until a change in the girl’s behaviour during the early onset stagnation period (stage I), between 6 and 18 months of age. Sitting may emerge but not crawling or standing up, and bottom shuffling is very common. Transition to the rapid developmental regression period (stage II) occurs between age 1 and 4 years. Regression of acquired motor and communicative abilities is often sudden, evoking acute encephalopathy, but it may be gradual. Eye contact is preserved but babbling, interest in people and objects, words and fine motor skills are lost. This regression period is followed by the pseudo-stationary stage (stage III), during which walking may develop further but the loss of purposeful hand use is obvious, and stereotypical hand wringing or ‘hand washing’ becomes almost persistent in wakefulness. Breathing irregularities, sleep problems and epilepsy may also become more prominent in stage III. Dystonic asymmetrical posture leads to neurogenic scoliosis, often rapidly progressive, requiring surgical treatment. The feet and lower limbs are cold, with or without colour or atrophic changes. Motor regression slowly progresses in this stage, in contrast to a remarkably well-preserved ability to communicate, mainly with the eyes, and to learn. This stage can last for several decades. It is followed by the late motor deterioration (stage IV), when the individual becomes wheelchair dependent or shows muscle wasting and distal musculoskeletal deformity. Remarkable visual contact and eye-pointing behaviour remain present throughout this progression, and this must be recognised to foster communication and participation.

Other motor impairments include abnormal muscle tone (hypotonia, spasticity and dystonia may occur), ataxia and apraxia (Dan and Cheron 2008).

Epilepsy occurs in up to 80% of patients. Many seizure types may be seen, including partial complex, generalised tonic–clonic, tonic and myoclonic seizures (Krajnc 2015). About a third of patients have drug-resistant epilepsy. Convulsive and non-convulsive status epilepticus may occur. Epilepsy tends to decrease after 20 years of age.

Autonomic manifestations include irregular breathing, reflecting abnormal brainstem control of carbon dioxide exhalation (Smeets et al. 2012). This may contribute to sudden death. Low resting cardiac vagal tone and weak vagal response to hyperventilation and breath-holding suggest inadequate parasympathetic control. There is a higher incidence of prolonged Q–T interval and diminished heart rate variability. Extremities tend to be cold as a result of poor perfusion related to altered autonomic control. Secondary vascular changes lead, in the long term, to atrophic changes in the lower limbs.

Genetics and Pathophysiology

Rett syndrome is caused by (mostly de novo) mutations in the MECP2 gene, located in the Xq28 region, usually on the paternal X chromosome. MECP2 encodes the methyl-CpG-binding protein MeCP2 (Amir et al. 1999). Mutations in the coding region can be identified in approximately 90% of patients with typical Rett syndrome (Philippe et al. 2006).

MeCP2 binds specifically to 5-methyl-cytosine throughout the genome, resulting in deacetylation of histones and chromatin condensation, which leads to repression of transcription. MeCP2 is particularly abundant in the brain (Amir et al. 1999), where it is thought to suppress the transcription of other tissue-specific genes, the activity of which is not required. Loss of MeCP2 function may therefore lead to inappropriate overexpression of these other genes, with potentially damaging effect during CNS maturation (Ellaway and Christodoulou 2001). There is strong evidence that excitatory glutamate activity is too high in Rett syndrome, and some new therapies are being tested based on this (Johnston et al. 2015). Also trials of insulin-like growth factor are being conducted (Khwaja et al. 2014). However, the pathophysiology underlying the manifestations of Rett syndrome remains unclear.

Some variant phenotypes initially thought to be very similar to Rett syndrome are now known to be caused by mutations in other genes. The congenital variant is related to FOXG1 and the infantile seizure-onset variant (Hanefeld variant) is related to CDKL5. Other disorders with overbreathing include Pitt–Hopkins syndrome, related to TCF4 haploinsufficiency, and the CNTPAP2- and NRXN1-related disorders with severe intellectual disability, autism and breathing abnormalities, resembling the Pitt–Hopkins syndrome. The use of CGH array and whole-exome sequencing has provided new insights into Rett syndrome-like phenotypes (Lopes et al. 2016).
Rett syndrome was long thought to be lethal in hemizygous males. However, males with MECP2 mutations show the typical phenotype in case of somatic mosaicism or X polysomy. In other individuals, a variety of phenotypes can be seen from severe congenital encephalopathy, to severe intellectual disability with various neurological symptoms, to isolated mild cognitive impairment.

**Diagnostic Criteria and Testing**

Clinical diagnostic criteria have been suggested for Rett syndrome (Neul et al. 2010). The diagnosis should be made in the presence of a period of regression followed by recovery or stabilisation, and all the following main criteria: loss of purposeful hand use and spoken language; impaired (dyspraxic) or absent gait; and stereotypical hand movements such as hand wringing, clapping, mouthing and rubbing. These features characterise typical Rett syndrome. Diagnosis of atypical or variant Rett syndrome can be made if only two of the main criteria are present together with at least five of the following supportive criteria: intense eye contact or eye-pointing communication, diminished response to painful stimuli, breathing disturbances or bruxism when awake, inappropriate screaming or laughing, impaired sleep, abnormal muscle tone, growth retardation, scoliosis, small cold hands and feet, and peripheral vasomotor disturbances.

Analysis of the coding regions of the MECP2 gene using sequencing techniques yields >90% mutation detection in typical Rett syndrome. Additional analysis using multiplex ligation-dependent probe amplification raises the detection rate to >95% by highlighting gross rearrangements in the coding region (e.g. deletions or duplications such as those involving exons 3 and 4).

In atypical Rett syndrome, the rate of detectable mutations in MECP2 is lower, and in some of these patients the cause is another genetic abnormality (Lopes et al. 2016).

Among other investigations commonly carried out, EEG is usually normal during stage I but background activity slowing and epileptiform discharges occur in later stages (Glaze 2005), none of these changes being specific.

**Animal Models**

Mecp2−/− female mice, which are homologous to human patients with Rett syndrome (Lombardi et al. 2015), show no abnormalities when they are young (they are even fertile), but later they show hindlimb clasping and breathing irregularities. There seems to be an effect of McCP2 dosage. Half the Mecp2 protein expression is associated with altered social behaviour (Samaco et al. 2008). Conversely, a twofold increase in Mecp2 expression results in a progressive neurological disease with cognitive impairment and social problems, reminiscent of the human condition associated with MECP2 duplication (Van Esch et al. 2005). Promising results of targeted-therapy in mouse models may soon have an application in Rett syndrome (Johnston et al. 2015).

---

**ANGELMAN SYNDROME**

Angelman syndrome (OMIM#105830) is characterised by developmental delay with intellectual impairment, a typical happy, exuberant behaviour, absent speech contrasting with eagerness for social interaction, motor impairment and epilepsy. It is caused by a lack of UBE3A expression, which normally occurs in the brain through the chromosome 15 inherited from the mother. The syndrome was first described in 1965 by British paediatrician Harry Angelman in three unrelated patients, whom he described as ‘puppet children’ in an attempt to encapsulate their behaviour (Angelman 1965). In the 1980s, distinctive non-epileptic rhythmic EEG features were documented, and abnormalities of chromosome 15q11-q13 similar to those found in Prader–Willi syndrome were described; the factor determining the phenotypic outcome was the parental origin of the chromosome defect, i.e. genomic imprinting. In 1997, the absence of expression of the UBE3A gene was recognised as the single cause of Angelman syndrome. A monograph covers many aspects of the syndrome (Dan 2008).

**Epidemiology**

Prevalence estimates are between 1 in 10,000 and 1 in 0,000 (Petersen et al. 1995; Thomson et al. 2006). The vast majority of cases are sporadic. Familial recurrence depends on the underlying molecular mechanism. The recurrence risk is very low (<1%) where there is a new 15q11-q13 deletion or uniparental disomy. Situations involving UBE3A gene mutations or imprinting defects may be more complex, because members of the mother’s extended family are also at increased risk. Most mutations occur anew and are associated with a very low recurrence risk, although mutations inherited from the mother are associated with a 50% recurrence risk.

**Clinical Features**

All individuals have developmental delay with severely impaired cognitive skills, although accurate assessment is often difficult because of confounding factors, such as adaptive skills, and behavioural and motor features. Intellectual disability is statistically more severe in individuals with a chromosome 15q11-q13 deletion, but abilities show a great deal of overlap across the different molecular classes (Mertz et al. 2014). Speech impairment is consistently severe, presumably due to combined oral dyspraxia, pragmatic factors and intellectual disability. Receptive verbal language and non-verbal language are relatively preserved. In addition to pointing, nodding and other gestures, expressive skills typically include facial expressions,
those seen in the ASD (see Chapter 29), they correlate with a low developmental profile rather than being specific of autism (Bonati et al. 2007).

Sleep problems are seen in up to 90% of patients, including difficulties in initiating or maintaining sleep, irregular sleep–wake cycles, and sleep-related seizures or movement disorders, none being distinctive (Pelc et al. 2008a). As in other neurodevelopmental conditions, they appear to be more severe in early childhood.

Muscle tone abnormalities include moderate axial and limb hypotonia, or sometimes distal spasticity (Dan and Cheron 2008). Despite varying degrees of ataxia, most children develop independent walking after age 3 or 4 years. Gait is distinctive, with a wide base, lower limb extension and lateral rotation, and associated elbow flexion and wrist pronation. A crouch-gait pattern may also be seen, as well as dynamic equinus or equinovarus, potentially leading to fixed contractions as in spastic cerebral palsy. Mild action tremor is common in children and adults. Day-long clusters of disabling, prominent, quasi-clonic myoclonus, or resting tremor of unclear pathophysiology, may occur in adolescents or adults. Response to treatment, whether antiepileptic or modulating adrenergic or dopaminergic pathways, is often poor.

More than 90% of patients have epilepsy, with onset often between age 1 and 3 years (Pelc et al. 2008b; Leyser et al. 2014). Many seizure types, both generalised and focal, have been reported, including epileptic spasms, myoclonic absences and myoclonic, atomic, tonic and tonic–clonic seizures, but atypical absences and myoclonic seizures have been particularly emphasised. As in other developmental conditions with epilepsy, the seizure disorder often improves in late childhood, although epilepsy can persist or reappear in adulthood and be difficult to control. Both convulsive and non-convulsive status epilepticus may occur. The latter is particularly common during childhood, but it can occur in infancy and adulthood.

**Genetics and Molecular Biology**

Angelman syndrome illustrates genomic imprinting, in which expression of imprinted genes is monoallelic and dependent on the parental origin (but not on the sex of the offspring). It is caused by lack of expression of the imprinted UBE3A gene, located on the long arm of chromosome 15; this gene is specifically imprinted in the brain, where it is expressed through the allele inherited from the mother with silencing of the paternal allele. The role of UBE3A in the pathophysiology of the phenotype is currently unclear. The gene product, UBE3A, is a ubiquitin ligase involved in labelling proteins for trafficking to their proper destinations, for example, selective destruction along the ubiquitin–proteasome pathway. Several potentially relevant UBE3A substrates have been identified, including activity-regulated, cytoskeleton-associated protein (Arc) and ephexin-5, which have roles in synaptic plasticity. Effects on inhibitory (chiefly GABAergic) neurons have been documented (Dan and Boyd 2003; Judson et al. 2016; Santin and Klann 2016).
In about 70% of patients, lack of UBE3A expression is caused by a new 15q11-q13 deletion on the chromosome 15 inherited from the mother. In 10% of patients, there is a mutation in the maternal UBE3A gene. Most of such mutations occur anew, but around 20% are carried by the mother. The 15q11-q13 deletions and UBE3A mutations are commonly associated with a more severe phenotype than other molecular classes. About 5% of patients have an imprinting defect, resulting in a lack of the typical maternal pattern of DNA methylation. Imprinting defects may be caused by (possibly inherited) mutations in the ‘imprinting centre’, a small region in chromosome 15q11-q13 that regulates gene expression. Fewer still have paternal uniparental disomy, i.e. both copies of chromosome 15 inherited from the father and none from the mother. In very rare cases, maternal UBE3A gene inactivation results from chromosome 15 rearrangements. Finally, in less than 10% with a typical phenotype for Angelman syndrome, no genetic abnormalities can be found.

Diagnostic Criteria and Testing
The clinical diagnosis is based on a set of physical and behavioural features (Williams et al. 2006). The consistent features comprise functionally severe developmental delay, happy, excitable demeanour with frequent laughter and smiling, severe speech impairment and motor disturbances, usually mild ataxia or tremor. Frequent features, present in more than 80% of patients, include delayed, disproportionate growth in head circumference, usually resulting in microcephaly by 2 years of age, epilepsy and characteristic non-epileptic EEG rhythmic patterns. These patterns may contribute to diagnosis, particularly before the clinical features become obvious (Boyd et al. 1988; Clayton-Smith and Laan 2003; Leyser et al. 2014). Features seen in more than 20% of patients include prognathia, tongue thrusting, feeding problems in infancy, excessive mouthing behaviours and abnormal food-related behaviours with obesity later in childhood, fascination with water, scoliosis, and hypopigmented skin, hair and eyes (the last only in those with 15q11-q13 deletions, as in Prader–Willi syndrome, due to hemizygosity of the OCA2 gene, the mutations of which are known to cause oculocutaneous albinism type 2).

Genetic confirmation is important for adequate counseling, because the recurrence risk depends on the underlying genetic mechanism. Deletions, which are usually not detected by a routine chromosome study, can be identified by CGH array analysis, or multiplex ligation-dependent probe amplification (MLPA), which on top of microdeletions will also detect uniparental disomy. UBE3A gene sequence analysis can detect mutations. Imprinting defects may be detected by DNA-methylation analysis, but additional testing is required to exclude a deletion. Uniparental disomy can be detected using DNA-methylation analysis or DNA-polymorphism testing. Genetically distinct conditions, including Rett syndrome, may show some phenotypical overlapping with Angelman syndrome (Luk 2016).

The value of EEG has been underlined above. There have been neuroimaging reports of abnormal myelination, which require confirmation in larger series.

Animal Models
Animal models of the different mechanisms underlying the syndrome have facilitated the progress in understanding the molecular pathogenesis and provided bases for experimental attempts at restoring functions disrupted in these animals, hopefully leading to effective therapeutic strategies. Most current murine models replicate features described in patients (Jana 2012). Drosophila models have also been promising.

---

**PRADER–WILLI SYNDROME**

Prader–Willi syndrome (OMIM#176270) is characterised by typical facial, cognitive, behavioural, neurological, endocrine and psychiatric features. It was first described in 1956 by Swiss paediatricians Andrea Prader, Heinrich Willi and Alexis Labhard, based on nine children with small stature, small hands and feet, a history of neonatal hypotonia, early onset severe obesity, insatiable hunger and intellectual disability (Prader et al. 1956). Genetic findings in the late 1980s revealed it as the first human condition related to genomic imprinting. Different mechanisms can lead to the absence of expression of the paternally imprinted genes, including SNRPN, in the 15q11-q13 region.

**Epidemiology**

Prader–Willi syndrome occurs in about 1 in 15000–30000 individuals. The prevalence is high among newborn infants with hypotonia, being higher than 10% in some series (Tuysuz et al. 2014).

**Clinical Features**

The early presentation includes reduced fetal movements, neonatal hypotonia, poor sucking and feeding difficulties, leading to initial failure to thrive. The face commonly shows a narrow forehead, almond-shaped and upsplanting palpebral fissures, and full cheeks.

Gross motor development and language are delayed, (e.g. sitting achieved around 12 months, walking around 24 months, first words around 2 years). Most patients have mild cognitive impairment (IQ 60–70), although the range goes from severe impairment to normal intelligence. Expressive and receptive language abilities are typically lower than non-verbal intelligence, with some group differences according
to the molecular mechanism underlying the syndrome (Dimitropoulos et al. 2013). Problems have been described in interpreting emotional facial expressions, understanding personal space and in theory of mind development (Rice and Einfeld 2015).

The behavioural phenotype includes temper tantrums, stubbornness, obsessive–compulsive behaviours, skin picking, difficulty with changes and the hallmark abnormal food-related behaviour: an extreme unsatisfied drive to consume food, (i.e. hyperphagia). Children start developing an insatiable appetite with rather aggressive food-seeking behaviour at around 8 years (3–15 years) of age. This behaviour results in obesity and lasts into adulthood, when it usually improves significantly. Obesity is a major cause of morbidity and mortality in adulthood. Sleep disorders include excessive obstructive and central sleep apnoea, hypoventilation, abnormal circadian rhythms in rapid eye movement (REM) sleep, reduced REM latency and abnormal response to hypercapnia, as well as excessive daytime sleepiness. Obesity can worsen the sleep disorder. An increased risk of psychosis has been particularly highlighted in those with maternal uniparental disomy (Rice and Einfeld 2015).

Another characteristic feature is hypogonadism of hypothalamic origin, with genital hypoplasia, delayed or incomplete pubertal development, and infertility. Short stature is due to growth hormone insufficiency and exacerbated by the lack of a pubertal growth spurt. Osteoporosis and increased fracture risk may be complications of hypogonadism. Obesity caused by hyperphagia and hypometabolism (secondary to hypothalamic origin) is a risk factor for cardiorespiratory failure, sleep apnoea and type 2 diabetes mellitus.

Growth hormone therapy has been shown to improve a number of phenotypic features in individuals with Prader–Willi syndrome (Fig. 5.4), including decreasing body fat, increasing muscle mass, and improving muscle strength and cognitive functioning (Grugni 2016).

Genetics and Molecular Biology

Three main molecular mechanisms cause Prader–Willi syndrome through lack of expression of the imprinted genes that are normally expressed from a region on the chromosome 15 inherited from the father. This 15q11-q13 region also contains a number of genes that are expressed only through the maternal copy of the chromosome. Therefore, deletions in this region result in Prader–Willi syndrome if they involve the paternal copy and in Angelman syndrome if they involve the maternal copy. A mother with Prader–Willi syndrome can thus have a child with Angelman syndrome (Schulze et al. 1992).

In about 70% of cases the mechanism is a new 15q11-q13 deletion. A maternal uniparental disomy of chromosome 15 is found in >25% of patients, resulting in silencing imprinted genes. Maternal uniparental disomy is most commonly due to maternal meiotic non-disjunction followed by mitotic loss of the paternal chromosome 15. In <5%, the syndrome is caused by an imprinting defect, which is commonly regarded as a chance error occurring during spermatogenesis, although it may result from a microdeletion in the Prader–Willi syndrome imprinting centre region at the 5′-end of the (paternally expressed) SNRPN gene, also located in the 15q11-q13 region. Other nearby (mostly paternally expressed) genes may contribute to the phenotype, such as SNORD116.

Diagnostic Criteria and Testing

Diagnostic criteria have been suggested, based on points attributed to major, minor and supportive features (Gunay-Aygun et al. 2001). Major criteria include characteristic facial features, neonatal hypotonia, developmental delay, feeding problems in infancy, rapid weight gain between age 1 and 6 years, hypogonadism and 15q11-15q13 deletion. Minor criteria include decreased fetal movements, weak cry in infancy, sleep disturbances, small hands and feet, and behavioural problems such as temper tantrums, skin picking, obsessive–compulsive or oppositional behaviour and stubbornness. There are also supportive findings, such as reduced response to pain, altered temperature control, scoliosis and/or kyphosis, early adrenarche, osteoporosis and unusual skill with jigsaw puzzles.

Multiplex ligation-dependent probe amplification has become standard for identifying 15q11-q13 deletion, uniparental disomy and imprinting defect. Deletion is now rarely diagnosed using an SNRPN fluorescence in situ hybridisation (FISH) probe. Chromosome analysis should be included in testing when a deletion is found, because occasionally this may result from a chromosomal translocation.

In the neonatal period, the differential diagnosis of severe hypotonia includes spinal muscular atrophy and myotonic dystrophy type 1 (see Chapter 26).

Animal Models

There are mouse models, based on large deletions, that show some similarity with the most common human deletions, and
a number of models based on targeted inactivation of single genes, although it must be borne in mind that several genes present in the human critical region are not found in the murine one (Bervini and Herzog 2013). These have confirmed that the phenotype of Prader–Willi syndrome results from loss of expression of multiple genes.

THE 22q11.2 DELETION SYNDROME

The 22q11.2 deletion syndrome (OMIM#188400) is one of the most common multiple anomaly syndromes. It is also known as DiGeorge sequence, velocardiofacial syndrome, Shprintzen syndrome, Sedlacekova syndrome and CATCH22 (cardiac abnormality/abnormal facies, T-cell deficit due to thymic hypoplasia, cleft palate and hypocalcemia caused by hypoparathyroidism from the 22q11 deletion). The pattern of inheritance was confirmed to be autosomal dominant in the early 1980s (Shprintzen et al. 1981), and the causative microdeletion was identified in the early 1990s. The expression is highly variable. The clinical features can involve many systems and organs, resulting in craniofacial features, palatal defects, congenital heart defects, hypocalcemia (resulting from parathyroid hypoplasia), immunodeficiency, cognitive impairment and various neuropsychiatric disorders.

Epidemiology

The prevalence based laboratory-confirmed 22q11.2 deletion is approximately 1 in 6000 live births (Botto et al. 2003). As in other developmental disorders, some clinical findings do not appear until later in life. It must also be noted that some phenotypic conditions are incompatible with life, for example, pulmonary atresia associated with a major heart defect.

Clinical Features

More than 180 distinct clinical phenotypes of the 22q11.2 deletion syndrome have been described, with features involving almost every organ system and developmental function. The neurocognitive profile is also highly variable (Shprintzen 2008). Early hypotonia and developmental delay are often present. Speech impairment is frequent, particularly hypernasal speech and severe articulation impairment. Speech onset is usually mildly delayed. Receptive language abilities are often better than expressive ones (Golding-Kushner et al. 1985), although part of the expressive disorders are probably amenable to effective remediation. Most patients have borderline cognitive abilities (IQ 70–84), and about a third have mild-to-moderate intellectual disability (Swillen and McDonald-McGinn 2015). Individuals have an increased risk for several psychiatric disorders including ADHD (see Chapter 30), ASD (see Chapter 33), anxiety disorders and psychotic disorders.

Congenital heart disease occurs in about 70% of individuals, particularly conotruncal (i.e. bulbus cordis) heart anomalies, including interrupted aortic arch, persistent truncus arteriosus, tetralogy of Fallot and ventricular septal defects. Vascular anomalies may involve chest, neck and brain arteries. Palatal anomalies such as submucous and occult submucous cleft palate are also common, resulting in hypernasal speech. Other possible abnormalities that have been reported in the context of the syndrome include brain, spinal, ocular, skeletal (including cranial, vertebral and limb) and renal anomalies, as well as increased platelet size, hyperthyroidism and hypoparathyroidism.

Early feeding problems can result from hypotonia, congenital heart disease, endocrine disorders, and airway obstruction secondary to the combination of retrognathia and hypotonia.

Genetics and Molecular Biology

In the large majority of patients, the 22q11 deletion involves more than 40 genes. The syndrome is commonly regarded as a contiguous gene syndrome.

Among the possibly relevant genes, TUPLE1 has been suggested as a candidate for explaining a number of features, as it encodes a transcription factor expressed at a critical period in the development of the outflow tract of the heart and the neural crest-derived aspects of the face and upper thorax (Halford et al. 1993). Hemizygosity for the COMT gene has also attracted attention, because its product, catechol-O-methyltransferase, is one of the enzymes that degrade catecholamines such as dopamine, adrenaline and noradrenaline. However, no (or little) effect of COMT polymorphism has been demonstrated on IQ and various aspects of executive function in children with 22q11.2 deletion syndrome (Glaser et al. 2006).

In addition, the penetrance of the deletion as a facilitator for the emergence of the defects has been suggested as depending on copy-number changes outside the deleted region, according to a ‘two-hit’ model where the deleted region would act as a modifier at the level of the affected organ systems (Hiroi et al. 2013; Mlynarski et al. 2015).

Diagnostic Criteria and Testing

As a result of the extreme variability in phenotypic expression of 22q11.2 deletion syndrome, the reliability of diagnostic criteria or a probability approach has been disputed (Shprintzen 2008). Whatever the presentation, the diagnosis relies on demonstrating a 22q11.2 deletion. CGH has become the first-choice diagnostic test, although other testing may be preferred when a fast confirmation of the clinical diagnosis is required. This may be raised, for example, by the presence of interrupted aortic arch, tetralogy of Fallot and truncus arteriosus in newborn infants. Hypernasal speech or cleft palate may also raise suspicion if associated with other anomalies in the
context of a multiple anomaly presentation. Features such as characteristic ears, asymmetrical facial animation, hypotonia or any of the other anomalies consistent with the syndrome would also be evocative.

Specific testing is indicated on the basis of the clinical manifestations. MRI may show reductions in both grey and white matter volumes, as well as abnormalities in the corpus callosum, amygdala, caudate nucleus and temporoparietal regions of the brain (Shprintzen 2008).

Animal Models
The syntenic region on murine chromosome 16 shows a high degree of conservation with respect to the human 22q11.2 region. Mouse models, whether based on deletions or single gene inactivation, have been used to characterise molecular function of a number of genes in 22q11.2 and in the study of genotype-phenotype correlations (Hiroi et al. 2013). Zebrafish, drosophila and worm models could also prove useful in studying these molecular mechanisms (Guna et al. 2015).

WILLIAMS SYNDROME

Williams syndrome (or Williams–Beuren syndrome, OMIM #194050) also affects multiple systems, resulting in distinctive facial features, and a characteristic behavioural phenotype that includes cognitive impairment, pulmonary artery or aortic stenosis, and infantile hypercalcaemia. Several of these features were described as distinct entities (Fanconi et al. 1952; Williams et al. 1961; Beuren et al. 1962) before the syndrome was recognised in the early 1960s. Williams syndrome is associated with a new chromosome 7q11.23 deletion.

Epidemiology
Williams syndrome is almost always sporadic, with a prevalence around 1 in 7500 (Strømme et al. 2002).

Clinical Features
In young children the face typically shows a wide forehead, periorbital fullness, depressed nasal bridge and bulbous nasal tip, full cheeks, a long philtrum, a wide mouth and a thick lower lip (Fig. 5.5). Older children and adults usually have a thinner face but still show the full nasal tip, malar flattening, wide mouth and thick lips.

Children present with developmental delay. Hypotonia may be marked in infancy and early childhood. Later in life, hyperreflexia, clonus, extrapyramidal signs and cerebellar signs commonly occur. Average full-scale IQ is 55, but a distinctive distribution of cognitive abilities is often (but not always) found, with better language and face processing than visuospatial, memory and number processing. This discrepancy emerges gradually, and performance is often regarded as atypical rather than impaired, suggesting weak central coherence (Van Herwegen 2015) making global processing of information difficult. Sensorineural hearing loss at high frequencies is common. The behavioural phenotype includes overfriendliness and empathy, attention problems, anxiety and sleep disturbances (Mervis et al. 2000).

Cardiovascular problems include elastin arteriopathy, supravalvular aortic stenosis is found in about 70% of patients. Arterial stenosis can be isolated or occur in multiple locations (aortic arch, descending aorta, and intracranial, coronary, renal, mesenteric and pulmonary arteries). Sleep disturbances are common. There is also an increased risk for urinary tract structural anomalies and diverticulosis. Hypertension may occur; the pathophysiology is often unclear.

Hypercalcaemia may occur, which is often asymptomatic and commonly resolves in the first few years of life. Eventual manifestations may include irritability and gastrointestinal symptoms. Unrelated feeding difficulties and failure to thrive may also occur. Joint laxity in early childhood may be followed by gradual tightening of hamstrings and heel cords (Gagliardi et al. 1997).

Genetics and Molecular Biology
Chromosome 7q11.23 deletions (or rarely duplications or inversions) result from meiotic recombination between highly similar, duplicated sequences. The deletion (0.2–2.5 Mb) associated with Williams syndrome always induces ELN (elastin gene) haploinsufficiency. Longer deletions are associated with a more severe phenotype. Those with deletions including
MAGI2 have a higher risk for severe cognitive impairment and infantile spasms (Marshall et al. 2008). Similar to most conditions in this chapter, CGH has acquired a major role in the diagnostic approach.

Recent findings of markedly altered DNA methylation in Williams syndrome suggested that epigenetic mechanisms related to binding and chromatin regulation probably contribute to the complex neurological phenotype (Strong et al. 2015).

Diagnosis of cardiovascular complications is important because these are the main cause of death. In the first 3–5 years of life, hypercalcaemia and progression of vascular stenosis (e.g. supravalvular aortic stenosis) may require close follow-up. Signs of diverticulosis, diabetes mellitus and sensorineural hearing loss, which commonly develop in adolescence or young adulthood, may also call for careful evaluation.

Brain MRI may show a type I Chiari malformation, although this is often asymptomatic (see Chapter 6).

Animal Models
A mouse model with a deletion of the whole region analogous to that commonly deleted in Williams syndrome shows growth retardation, cardiovascular abnormalities, increased sociability, anxiety and motor coordination deficits (Li et al. 2009). It also shows reduced brain volume and increased density of neuronal packing in layer V of the somatosensory cortex, possibly correlating with that observed in layer IV of the visual cortex in Williams syndrome (Galaburda et al. 2002). Models with targeted inactivation of single genes such as analogues to ELN, BAZ1B, CLIP2 and GTF2IRD1 are potentially informative about their contribution to the syndrome, although hemizygosity for some of these genes in mice does not necessarily imply similar levels of haploinsufficiency to humans (Osborne 2010). These models are also being used for testing therapeutic interventions.

CORNELIA DE LANGE SYNDROME

Cornelia de Lange syndrome (OMIM#122470) includes distinctive facial features, intellectual impairment, growth retardation and organ anomalies. It was first extensively described by the Dutch paediatrician Cornelia de Lange in 1933 (de Lange 1933), although she acknowledged Franz Bruck's 1889 report as the original description, and German physician Winfried Brachmann published an independent report in 1916, hence the alternative eponyms Bruck–de Lange syndrome and Brachmann–de Lange syndrome. It is caused by (usually de novo) mutations in NIPBL or other genes encoding components of cohesin, which has a role in cell division.

Epidemiology
Cornelia de Lange syndrome is typically sporadic. In familial cases, the phenotype seems to be consistent within a family. A large European population-based study found a prevalence of 1 in 81000 live births for the classic form and estimated the overall prevalence between 1 in 45000 and 1 in 65000 (Barisic et al. 2008).

Clinical Features
The phenotypic expression is variable. It is typically characterised by multiple malformations including cardiac, gastrointestinal and musculoskeletal systems, characteristic facial features, hirsutism, pre- and postnatal growth retardation (affecting weight, height and head circumference), developmental delay and a peculiar behavioural phenotype.

The craniofacial features are pathognomonic. They include micro-brachycephaly, webbed, short neck and low hairline. The eyebrows are bushy and arched (possibly compensatory to ptosis), joining at the midline (i.e. synophrys). The eyelashes are long and curly. The palpebral fissures are narrow. The ears are thick, dysplastic and low set. The nose is short with nasal bridge depression. The midface is flat with a long, smooth philtrum, thin upper lip and down-turned corners of the mouth (described by some as a carp mouth). High-arched palate, widely spaced teeth and micrognathia are common.

In about 70% of patients, intellectual disability is profound or severe (Oliver et al. 2008), but the range of intellectual functioning is wide and there are individuals with no cognitive impairment. Impairments are typically more marked in expressive than receptive communication. Communication, mood and socialisation skills tend to worsen with age (Srivastava et al. 2014). The behavioural phenotype includes behaviours seen along the autism spectrum, although eye contact is commonly better preserved and there are often fewer stereotypies than in non-syndromic autism. Tools developed for symptom evaluation in ASD have been useful in Cornelia de Lange syndrome, including the Childhood Autism Rating
Noonan syndrome (OMIM#163950) is an autosomal dominant disorder characterised by short stature, distinctive facial dysmorphism, developmental delay and congenital heart defects. The first clinical descriptions in the 1960s emphasised similarity with Turner syndrome (see below). The American paediatric cardiologist, Jacqueline Noonan, reported the first series of patients (Noonan 1968). Mutations that cause Noonan syndrome alter genes encoding proteins with a role in the Ras–mitogen-activated protein kinase (Ras–MAPK) signal transduction pathway, through which extracellular ligands (e.g. cytokines, growth factors, hormones) affect cellular functions such as proliferation, differentiation, survival or metabolism.

Epidemiology
The incidence is estimated to be between 1 in 1000 and 1 in 2500 live births (Tartaglia et al. 2001).

Clinical Features
The distinctive facial features in infancy consist of a broad forehead, hypertelorism, downsloping palpebral fissures, low-set, posteriorly rotated ears and a high-arched palate. They change with age. The face becomes more triangular in childhood and it often appears coarse or myopathic (see Chapters 24, 26), with ptosis, prominent eyes and nasolabial folds, and thick lips. In adolescence and adulthood, the eyes become less prominent and the neck less short. There may be neck webbing.

About 90% of patients have cardiac abnormalities, such as pulmonary stenosis and hypertrophic cardiomyopathy. Short stature present in childhood can be attenuated by a delayed pubertal growth spurt. Multiple skeletal defects can be present (chest and spine deformities), as well as cryptorchidism and bleeding diathesis. Auditory deficit occurs in about 10% of individuals.

The full-scale IQ is within the normal range in 80% of individuals, but a significant difference between verbal and performance IQ often occurs, without a consistent pattern (Verhoeven et al. 2008). Executive function may be impaired. Deficits in decoding of emotional expressions may lead to alexithymia, (i.e. inability to express emotions verbally). There may also be more general communication and social difficulties. Children and adolescents with language impairments have a particularly high risk of reading and spelling difficulties (Pierpont et al. 2012).
Chapter 5 Genetic Anomalies and Dysmorphic Syndromes

Genetics and Molecular Biology
Noonan syndrome may be sporadic or follow an autosomal dominant pattern of inheritance. About half the patients have a (missense) mutation in the \textit{PTPN11} gene, resulting in gain of function (Tartaglia et al. 2001). The gene product is involved in intracellular signalling cascades along the Ras-MAPK pathway, downstream of receptors for cytokines, growth factors and hormones, and is active in a number of developmental processes. Mutations in a number of genes can also cause the syndrome, (e.g. \textit{KRAS} and \textit{SOS1}), which also have a role in the Ras-MAPK pathway.

Diagnostic Criteria and Testing
Clinical diagnostic criteria were suggested before causative mutations were discovered (van der Burgt et al. 1994) but it is still useful for identifying patients for genetic testing. The scoring system takes into account the typical facial dysmorphology, cardiac abnormalities such as pulmonary stenosis or hypertrophic obstructive cardiomyopathy, short stature, pectus carinatum or excavatum, the family history, intellectual disability, cryptorchidism and lymphatic dysplasia. \textit{PTPN11} mutation should be looked for. In \textit{PTPN11} mutation-negative cases, other mutations along the Ras-MAPK pathway can be searched, for example, by means of dedicated gene panels.

Animal Models
Mouse models have been engineered, most of them based on \textit{PTPN11} mutations. Insights have thus been gained into craniofacial, cardiac and growth abnormalities.

TURNER SYNDROME

Turner syndrome is the only known viable chromosomal monosomy. It is characterised by the complete or partial (small arm) absence of an X chromosome. It is the most common chromosomal abnormality in females. The phenotype includes characteristic dysmorphic features described in 1938 by the American endocrinologist Henry Turner (Turner 1938). German paediatrician Otto Ullrich had reported on a girl in 1930. The 45,XO karyotype was demonstrated in 1959.

Epidemiology
The incidence is about 1 in 2500 female births.

Clinical Features
The main characteristic signs are present from early in life, most of them at birth. They include short stature, scoliosis, low posterior hairline, hypertelorism, high-arched palate, micrognathia, short and webbed neck, lymphoedema of the hands and feet, fourth/fifth metacarpal or metatarsal hypoplasia and hypoplastic nails. There is also gonadal dysgenesis with hypogonadism. Cardiac malformations include coarctation of the aorta and ventricular septal defects. The risk for stroke is increased. Renal anomalies include horseshoe kidney, ureteral duplication and unilateral kidney agenesis. Additional health conditions may comprise hearing and visual impairment, arterial hypertension, osteoporosis, obesity and diabetes mellitus (Santos et al. 2012). IQ is usually normal, but visuospatial and mathematical skills are often impaired (Knickmeyer 2012). Epilepsy is rare. There is an increased risk for psychiatric disorders, such as ASD, anxiety disorders and schizophrenia. However, many women with Turner syndrome marry and lead well-adjusted lives in adulthood.

Genetics and Molecular Biology
It seems that deletion of the short arm of the X chromosome is sufficient to result in Turner syndrome. Monosomy of the X chromosome is found in about 50% of individuals with Turner syndrome. The other cases may be caused by mosaicism or structural alterations of the X chromosome, including isochromosome, i.e. one rearranged X chromosome containing two mirror images of the long arm, whereas the short arm is missing.

Individuals with Turner syndrome who have a maternally inherited X chromosome tend to have more social interaction problems than those whose X chromosome is paternally derived (Skuse et al. 1997).

Among the genes that might account for phenotypic features, \textit{SHOX} (short stature homoeobox gene), a transcription factor, may relate to short stature and some limb abnormalities (Binder 2011). Other regions in Xq may cause ovarian failure, including the \textit{FMR1} and \textit{BMP15} genes.

Diagnosis
The diagnosis can be confirmed by CGH array analysis, which can identify whole X-chromosome loss as well as small Xp deletions. Conventional karyotyping can be complementary to characterise possible chromosomal rearrangement, or detect low mosaicism (if a sufficient number of cells are analysed). Hormonal dosages may also be useful.

Animal Models
Models based on the 39,XO mouse, in which the parental origin of the single X chromosome can be varied, can provide insights into neurobiology, keeping in mind important differences between rodents and humans. One such model suggests that several features of the behavioural phenotype may be replicated in the mouse (Lynn and Davies 2007).
Klinefelter syndrome is the most common non-autosomal aneuploidy in live births. It is characterised by the presence of one (or more) X chromosome(s) in boys. The 47,XXY karyotype was demonstrated in 1959 (Jacobs and Strong 1959), whereas the original 1942 clinical report described it as an endocrine disorder characterised by small firm testes, gynaecomastia, hypogonadism and higher than normal concentrations of follicle-stimulating hormone (FSH) (Klinefelter et al. 1942). It is the most common genetic cause of human male infertility.

**Epidemiology**

Klinefelter syndrome has an estimated prevalence of 1 in 600 live male births (Morris et al. 2002). Many patients with Klinefelter syndrome remain undiagnosed.

**Clinical Features**

The characteristic phenotype includes microcephaly, tall stature (due to advanced long bone growth from age 2 years) and hypogonadism (requiring testosterone replacement therapy). The full-scale IQ is often in the normal range, but the verbal IQ is commonly low, with occasionally marked speech delay, severe reading and writing difficulties, and impairment of executive functions (Bryant et al. 2012). Boys may appear withdrawn and hypoactive. ASDs may occur.

**Genetics and Molecular Biology**

In about 80% of cases, Klinefelter syndrome is caused by 47,XXY. In other patients the syndrome may be caused by higher-grade chromosome aneuploidies (48,XXXY, 48,XXYY, 49,XXXXY), mosaicism (46,XY/47,XXY) or structural abnormalities of X chromosomes. Aneuploidy arises through non-disjunction, during meiotic divisions in germ-cell development or less commonly in early embryonic mitotic cell divisions. It appears that the extra X chromosome inhibits fetal brain growth, although the mechanisms are not clear.

**Diagnostic Criteria and Testing**

A suspected diagnosis can be based on the combination of typical clinical findings, for example, intellectual difficulties in a boy with speech, executive and attentional problems in the context of a (near-) normal full-scale IQ, withdrawn behaviour, tall stature and very small, firm testes. Karyotyping in lymphocytes can confirm the diagnosis. If negative, chromosome analysis can be performed on skin fibroblasts or testicular biopsy samples to confirm mosaicism. Hormonal dosages may also be useful.

MRI confirms reduced total brain volume, although specifically reduced frontal and temporal grey matter and spared parieto-occipital grey matter may be found (Bryant et al. 2011) and has been tentatively related with the observed cognitive and behavioural strengths and weaknesses (Giedd et al. 2007).

**Animal Models**

There are several mouse models. When interpreting findings, it is important to appreciate the existing differences in mechanisms that lead to sexual differentiation of the brain between rodents and humans.

Smith–Magenis syndrome (OMIM#182290) is characterised by dysmorphic features, intellectual disability, distinctive behavioural features, early onset obesity and severe sleep disturbances, mainly related to an inversion in the circadian secretion of melatonin. It is caused by a 17p11.2 deletion. The syndrome was characterised clinically and then cytogenetically in the 1980s by Anne Smith and Ellen Magenis (Smith et al. 1986).

**Epidemiology**

The prevalence is about 1 in 25 000 live births (Juyal et al. 1996).

**Clinical Features**

Craniofacial features include brachycephaly, upslanting palpebral fissures, epicantal folds, wide nasal bridge, midface hypoplasia and prognathism. Short stature, brachydactyly and scoliosis are also common. Congenital heart disease occurs in up to 30% of individuals, including pulmonary or aortic stenosis, valve stenosis or insufficiency, interventricular or interatrial communication, and tetralogy of Fallot.

Most patients have moderate intellectual disability (IQ 40–54), although normal cognition has been reported (Osório et al. 2012). Severity seems to relate to the size of the deletion (Madduri et al. 2006). Children typically have speech delay, with a hoarse voice, and better receptive than expressive skills. Short-term memory, sequential information processing, and visuomotor, attentional and executive abilities are often particularly impaired.

Hypotonia and feeding difficulties are common during infancy, but later behavioural features include propensity towards food, which may lead to obesity in most adolescents (Burns et al. 2010). They also include self-aggression (e.g. biting, head banging, picking at wounds). Children may have frequent temper tantrums and aggressiveness with destructive behaviour (Sloneem et al. 2011). Self-injurious and aggressive behaviours often occur when levels of adult attention are low and lead to increased levels of attention following the
behaviours (Taylor and Oliver 2008). Stereotypies are also common, particularly self-hugging and hand sucking. Anxiety and major depressive disorders have also been reported. ASDs have been reported in a high proportion of patients (Laje et al. 2010), although ascertainment remains an open issue.

Sleep disorders are a hallmark of Smith–Magenis syndrome, particularly the abnormal chronology of the light–dark cycle related to inverted secretion of melatonin (Potocki et al. 2000). Physiologically, secretion of this hormone is triggered by variations in lighting and peaks in the middle of the night. Individuals with Smith–Magenis syndrome have a 12-hour phase shift of this peak, so that they only have residual secretion of melatonin at night. Pharmacological treatment of the sleep disorder may include melatonin in the evening (2–6mg) and beta blockers in the morning (e.g. 10mg/kg acebutolol) (De Leersnijder 2006).

Hyporeflexia is often observed but alterations of nerve conduction velocity are rare. When the deletion involves the PMP22 gene, hereditary neuropathy with a liability to pressure palsy (see Chapter 25) may occur. Reduced response to pain may increase the risk of self-mutilation. About 30% of patients have epilepsy (Goldman et al. 2006).

Genetics and Molecular Biology

Most of the features of Smith–Magenis syndrome are due to haploinsufficiency of the RAI1 (retinoic acid induced 1) gene, whereas the variability and severity of the disorder are modified by other genes in the 17p11.2 region (Elsea and Girirajan 2008). The syndrome can, therefore, be caused by point mutations in RAI1, although it is usually caused by a deletion of about 3.5Mb on chromosome 17p11.2. Other genes that potentially play roles in the phenotype include PMP22, which is involved in hereditary neuropathy with liability to pressure palsy and Charcot–Marie–Tooth-type 1A neuropathy, TNFRSF13B, which may cause IgA deficiency, MYO15A, associated with hearing deficits, and COP9, subunit 3 of the COP9 signalosome, for which a role in melatonin regulation has been suggested (Potocki et al. 2000).

Diagnostic Criteria and Testing

The diagnosis has long relied on demonstration of the 17p11.2 deletion by FISH but this approach has been supplanted by CGH, relative abundance index (RAI), sequencing or whole-exome sequencing. In the case of clinical suspicion without a deletion, RAI1 should be analysed for mutations.

Animal Models

The human chromosome 17p11.2 is syntenic to the 32–34-cM region of murine chromosome 11. The number and order of the genes are highly conserved. A mouse model with a deletion of this region shows phenotypic features that are reminiscent of Smith–Magenis syndrome, such as abnormal circadian activity and being overweight, but normal behaviour, learning and memory (Carmona-Mora et al. 2009). Mice with targeted inactivation of the Rai1 gene have also been studied. The phenotype has been shown to depend on the genomic background, which is, therefore, thought to act as a modifier (Molina et al. 2008).

Sotos syndrome (OMIM# 117550) is an autosomal dominant, developmental, overgrowth syndrome identified since 1964 (Sotos et al. 1964). It is caused by inactivation of the NSD1 gene by mutations or deletions (Kurotaki et al. 2002).

Epidemiology

Sotos syndrome is a common overgrowth condition, although it is apparently less prevalent than Beckwith–Wiedemann syndrome. There have been reports of several hundred individuals affected. The prevalence has been estimated at around 1 in 14,000 live births.

Clinical Features

The craniofacial features appear to be distinctive. They are often fully present at age 6, and include receding hairline, apparent hypertelorism with downslanting palpebral fissures, prominent jaw, malar flushing, anteverted nostrils, mild micrognathia, high-arched palate and large ears (Tatton-Brown et al. 2005). The head circumference is above the 98th centile in infancy, childhood and adulthood in the vast majority of individuals.

Most children show early onset overgrowth, which is particularly marked in the antenatal period and the first year of life (Tatton-Brown et al. 2005), despite feeding difficulties which may be severe in infancy (Cole and Hughes 1994). The length commonly increases more than the weight, with advanced bone age in virtually all individuals. Between age 2 and 6 years, the height is consistently above the 97th centile. Growth tends to normalise at puberty, probably due to physiological fusion, so that adult height is often in the (high) normal range. Large hands and feet are also consistent features.

Learning difficulties are present in almost all patients (Tatton-Brown et al. 2005), although the mean IQ is 76 (de Boer et al. 2004). Most individuals have a delay in expressive verbal language. Attention-impaired, placid behaviour and social inhibition are features of the behavioural phenotype. Most patients show a coordination disorder.

Neonatal hypotonia is common (Cole and Hughes 1994). Congenital heart defects occur in about 20% (Tatton-Brown et al. 2005). Urogenital anomalies, such as renal malformation,
occur in 15% and orthopaedic problems, such as congenital hip dislocation and scoliosis, in 30% of patients.

**Genetics and Molecular Biology**

Mutations of the NSD1 gene are found in up to 90% of patients, whereas chromosome 5q35 deletions that involve NSD1 cause Sotos syndrome in about a further 10% of patients (Kurotaki et al. 2002). This gene encodes the nuclear receptor SET domain-containing protein-1, which is a histone methyltransferase that plays epigenetic regulatory roles during embryonic development, and perhaps during fetal development and adult brain organisation. It has, therefore, been suggested that Sotos syndrome results from a genome-wide alteration of the DNA methylation of genes that have key roles in cellular morphogenesis and neuronal differentiation (Choufani et al. 2015).

Recently, a homozygous frameshift APC2 gene mutation was demonstrated in two siblings with features of Sotos syndrome (Almuriekhi et al. 2015). The gene product is a downstream partner of NSD1.

**Diagnostic Criteria and Testing**

Clinical diagnostic criteria were suggested before the molecular basis for the syndrome was identified, based on a thorough assessment of data from 41 typical patients (Cole and Hughes 1994). The criteria are organised into the following four major aspects: overgrowth with advanced bone age, macrocephaly, characteristic facial features and intellectual disability. Currently, as a mutation or deletion can be demonstrated as a cause for NSD1 haploinsufficiency in almost all patients, the diagnosis ultimately relies on genetic testing. In NSD1-negative cases, the possibility of an APC2 gene mutation should be considered.

**Animal Models**

Despite a high level of homology between human NSD1 and murine Nid1 genes (83% at amino acid level), heterozygous Nsd1 knockout mice do not display any of the typical phenotypic features of Sotos syndrome (Rayasam et al. 2003). More recently, chromosome engineering to generate segmental monosomy in mice, leading to a heterozygous 1.5-Mb deletion of 36 genes on mouse chromosome 13, syntonic with 5q35.2–q35.3 in humans, showed surprisingly decreased postnatal growth, in contrast to Sotos syndrome. However, these mice showed impairment in long-term memory retention and dilatation of the pelvicalyceal system, which may in part model the learning difficulties and renal abnormalities observed in patients. An Apc2-deficient mouse model seems to recapitulate some cognitive and facial features of Sotos syndrome (Almuriekhi et al. 2015).

---

### CRI-DU-CHAT SYNDROME

**Epidemiology**

Incidence ranges between 1 in 15 000 (Higurashi et al. 1990) and 1 in 50 000 (Niebuhr 1978) live-born infants.

**Clinical Features**

Low birthweight, microcephaly and the typical facial features are present at birth. The last includes round face, hypertelorism, epicanthal folds, downward-slanting palpebral fissures, low-set ears, wide nasal bridge, down-turned corners of the mouth and micrognathia. Dermatoglyphics show excess arches on fingertips and transverse flexion creases. The characteristic cat-like cry is probably due to laryngeal and epiglottal anomalies as well as neurological factors (Niebuhr 1978). There may be additional malformations, such as congenital heart defects, brain dysplasia, urogenital malformations and syndactyly.

In the neonatal period, there is marked hypotonia, weak sucking and respiratory problems. Failure to thrive is almost always present, height being less affected than weight. The developmental delay is severe, although a proportion of children eventually walk. Hypotonia is gradually replaced by hypertonia. Verbal development is also slow but almost all children make short sentences by 10 years of age (Cerruti Mainardi 2001). Epilepsy is rare.

**Genetics and Molecular Biology**

Cri-du-chat syndrome is a contiguous gene syndrome. The 5p deletions can vary in size from involving only band 5p15.2 to affecting the whole short arm of chromosome 5. Numerous repetitive sequences may account for the instability of this region. The deletion occurs on the paternally inherited chromosome in most cases. Most deletions occur anew but about 10% result from unbalanced segregation of translocations or recombination involving a pericentric inversion in one of the parents. Comparison of the observed deletions identified chromosomal regions that were associated with specific clinical features. A region involved in the characteristic cat-like cry is proximal to 5p15.3. A separate region at p15.3 appears to be involved in speech delay. A region of about 2Mb involved in the other manifestations of the syndrome maps to central 5p15.2 (Overhauser et al. 1994).

Among the possibly relevant genes in these regions, SEMAF, encoding semaphorin F, might be implicated in some...
features through its role in guiding axons or migrating neuronal precursors during cortical development. CTNNND2, which is also located in 5p15.2, encodes δ-catenin, which is involved in cell motility and expressed early in neuronal development (Medina et al. 2000). Another candidate gene, encoding the telomerase reverse transcriptase, maps to 5p15.33.

Diagnostic Criteria and Testing

The diagnosis is made by demonstration of the 5p deletion, commonly by CGH. It has been suggested by some that the characteristic facial features are pathognomonic (Corcuera-Flores et al. 2016). However, recognition of the syndrome based on facial features has been shown to be inaccurate, particularly with respect to other dysmorphic syndromes, such as fragile X syndrome, Cornelia de Lange syndrome, Williams syndrome, Prader–Willi syndrome, Sotos syndrome, 22q11.2 deletion syndrome or Noonan syndrome, perhaps because of the greater variation in facial appearance with age (Boehringer et al. 2006).

Animal Models

Mouse models with knockdown of Ctnnd2, resulting in overall loss of δ-catenin or selective loss of δ-catenin in pyramidal neurons, has yielded early promising results for understanding of the role of δ-catenin in synaptic architecture and neural circuit formation (Yuan et al. 2015).

KABUKI SYNDROME

Kabuki syndrome (OMIM#147920) is an example of condition related to mutations in the methylation enzymes involved in epigenetic marking, for which research in animal models suggested possible treatment with histone deacetylase inhibitors, such as sodium valproate or ketogenic diet. It is recognizable clinically based on its distinctive facial features, postnatal growth retardation, intellectual disability, skeletal abnormalities and unusual dermatoglyphic patterns. It was first identified in 1969 in a child with cognitive impairment by the Japanese geneticist Norio Niikawa who noted that the unusual facial features were reminiscent of the make-up that is typical in traditional Kabuki theatre. The first reports underlined this aspect, referring to the condition as Kabuki make-up syndrome (Niikawa et al. 1981), though the term 'make-up' is no longer used because it is considered potentially derogatory.

Epidemiology

Initially, Kabuki syndrome was believed to be specific to the Japanese population, although the condition has now been reported in a wide variety of ethnic types. Prevalence estimates in Japan are about 1 in 30,000 (Niikawa et al. 1988).

Clinical Features

Patients often have long palpebral fissures with eversion of the lower eyelid, arched eyebrows with sparseness in the lateral part, prominent ears and depressed nasal tip. The facial features tend to become more pronounced as the child grows. Skeletal anomalies include spinal deformity and brachydactyly of the fifth digit. Dermatoglyphic abnormalities are typical. Most individuals have postnatal growth deficiency and mild-to-moderate intellectual impairment.

Genetics and Pathophysiology

Kabuki syndrome is caused by heterozygous mutations in KMT2D on chromosome 12q13 (Ng et al. 2010). A wide spectrum of new, mostly private mutations can be found in up to 80% of individuals with a clinical diagnosis (Banka et al. 2012). Familial occurrence has also been reported, with an autosomal dominant inheritance pattern (Bogershausen and Wollnik 2013). Most of these mutations result in haploinsufficiency. The gene product, a histone H3 lysine 4 (H3 K4)-specific methyltransferase, is involved in making chromatin marks that are crucial for the inheritance of active transcriptional states (Muramoto et al. 2010). In patients in whom no KMT2D mutation is found, mutations are occasionally identified in KDM6A on chromosome Xp11.3 (Lederer et al. 2012; Miyake et al. 2013), which also encodes a histone modifier that interacts with KMT2D (Schuettengruber et al. 2007).

Diagnostic Criteria and Testing

Clinical diagnostic criteria were suggested by Adam and Hudgins (2004), based on the presence of facial features, skeletal abnormalities, dermatoglyphic features, intellectual disability and postnatal growth deficiency. As for the other conditions in this chapter, CGH (and possibly whole-exome sequencing) plays a prominent role in the diagnostic approach.

Animal Models

A mouse model was engineered with a heterozygous deletion in the Kmt2d gene (Bjornsson et al. 2014). The animals show an impaired methyltransferase function and reduced histone acetylation. However, administration of a histone deacetylase inhibitor to young or adult mice was demonstrated to reverse both structural and functional deficits (Bjornsson et al. 2014). These promising results suggest that patients with Kabuki syndrome could be treated by agents modulating epigenetic processes.

Osseous Malformations of the Skull and Craniovertebral Junction

Richard Hayward and Dominic Thompson

This chapter reviews the abnormalities of the osseous skull and craniofacial syndromes (RH) and the disorders of the cervicovertebral junction (DT), as well as their consequences on the underlying central nervous system and associated malformations.

**OSSEOUS MALFORMATIONS OF THE SKULL**

**CRANIOSYNOSTOSIS**

Craniosynostosis is defined here as the premature closure of one or more of the skull vault sutures. While advances in molecular genetics have revolutionised our understanding of the various syndromes that may include craniosynostosis, and improved imaging techniques have provided new information about not only the calvarial sutures but also changes affecting the skull base and facial skeletons, the initial diagnosis (or more accurately the initial suspicion) of craniosynostosis still depends primarily on the patient’s – usually a child’s – appearance.

The aim of this chapter is to provide for the paediatric neurologist a broad overview of this complex subject. For convenience craniosynostosis affecting a single vault suture (sometimes referred to as ‘simple’ synostosis) will be dealt with separately from the various complex/syndromic forms in which premature closure of several – sometimes all – of the skull sutures is usual although overlap between the two groups is not uncommon. Johnson and Wilkie have provided a useful overview from a craniofacial surgeon and geneticist’s perspective (Johnson and Wilkie 2011).

The various causes of craniosynostosis (or conditions with which it may be associated) can be broadly classified as shown in Table 6.1.

**SINGLE SUTURE SYNOSTOSIS**

The direct consequences of premature fusion of a single skull vault suture are for the most part cosmetic – the result of a usually characteristic alteration in head shape. Effects on the facial skeleton, if any, are modest and severe functional consequences affecting vision, breathing and feeding, for example, are rare. This is in marked contrast to the complex/syndromic forms of craniosynostosis in which such issues are common.

---

### Table 6.1 Classification of causes of craniosynostosis

| Primary | Idiopathic | No genetic cause either known or suspected  
|-------------------------|--------------------------|------------------------------------------------------------------------------------|
| Genetic cause known or suspected | Gene mutation  
| Secondary | Metabolic | Vitamin D deficient rickets  
| Disorders of bone metabolism | Cranio-meta/diaphyseal dysplasia  
| Storage disorders | Hurler syndrome  
| Drug induced | Morquio syndrome  
| Physical distortion | Post-CSF shunting positional scaphocephaly  

*The majority of single suture synostosis fall into this category – in particular those affecting the sagittal and metopic sutures.  
*This includes not only the syndromes once described eponymously (Crouzon, Apert etc.) but also many previously labelled as non-syndromic that have now had their underlying gene mutation mapped.  
*The metopic suture appears to be the most vulnerable when craniosynostosis forms part of a chromosomal abnormality – a deletion of part of the short arm of 7, for example.  
CSF, cerebrospinal fluid.
Aetiology

While the majority of cases of single suture synostosis arise as isolated events the possible genetic implications of the diagnosis should not be overlooked particularly for unicoronal synostosis (Moloney et al. 1997) (see Unicoronal [and Fronto-Sphenoidal] Synostosis). Whereas no common candidate genes are presently known for isolated sagittal and metopic synostosis, it is essential that all children with unicoronal synostosis are referred for evaluation by a geneticist (Johnson and Wilkie 2011).

Pathogenesis of Single Suture Synostosis

The first ‘modern’ explanation for the head shape that results from single suture synostosis is attributed to Virchow (quoted by Alden et al. 1999) who described restricted growth at 90° to the affected suture and exaggerated growth parallel to it. Add a palpable and sometimes visible ridge along the suture itself and, though this analysis can be considered simplistic in the light of more contemporary studies of suture biology, it still serves as a convenient model for discussions with parents.

Modern interest (Cousens et al. 2007) in the biology of premature suture closure was initiated by Moss who introduced the concept of the Functional matrix in which both morphogenic and functional forces combine to produce the final anatomical result (Moss 1975). Since then there has been great progress in the actions of various genes [e.g. TCF12 (Sharma et al. 2013) and ERF (Twigg et al. 2013)] on the biology of osteogenesis in general and suture formation in particular (see The Molecular Genetics of Syndromic Craniosynostosis).

Diagnosis of Single Suture Synostosis

The diagnosis of single suture craniosynostosis is primarily one of pattern recognition. The various types produce head shapes so characteristic that confirmation by some form of imaging is rarely required by those with craniofacial shapes so characteristic that confirmation by some form of imaging is rarely required by those with craniofacial experience. For those without this advantage the following imaging modalities can be useful.

1. **Plain X-rays** can be diagnostic for sagittal, unicoronal and lambdoid synostosis. The metopic suture closes so early in life (during the first year) that its absence on an X-ray is no proof that it might have closed early. The hypotelorism and vertical medial orbital walls associated with metopic synostosis are however recognisable on an antero-posterior skull X-ray.

2. **Computerised Tomography (CT)** can be diagnostic by revealing not only the skull shape (visible on clinical examination) but by demonstrating the absent suture – particularly on three-dimensional reconstructions. They will also reveal any associated cerebral abnormalities.

3. **Magnetic resonance imaging (MRI)** does not show bone with sufficient resolution to have a role in the routine diagnosis of craniosynostosis. It is only indicated when neurological/developmental concerns suggest a possible brain abnormality.

Natural History of Single Suture Synostosis

The natural history of most forms of single suture synostosis is that the abnormality of head shape for which they are responsible commences well before birth – as shown by their occasional presence in the preterm infant. The change in head shape may become more obvious over the first year of life but major changes are unusual. The parents of an affected child can, therefore, be told that without intervention their child’s head shape is likely to remain much as it is when first seen.

Implications of Single Suture Synostosis

Parents need to be warned that single suture synostosis does carry implications for the affected child’s neurodevelopmental progress (Starr et al. 2012). Although the majority of affected children are likely to be unaffected a significant proportion will manifest a degree of delay. This is most frequent when there is an associated chromosomal abnormality (seen most in children with metopic synostosis) or gene mutation (e.g. unicoronal synostosis due to Muenke or FGFR3-associated synostosis). Fetal valproate syndrome also combines developmental delay/learning difficulties with metopic synostosis (Lajeunie et al. 2001).

The cause of such cognitive impairment in most cases, however, remains unknown. Although it has sometimes been attributed to occult raised intracranial pressure (ICP) the evidence remains weak (see Functional Complications of Syndromic Craniosynostosis section for a discussion of raised of ICP in children with complex/syndromic forms of craniosynostosis). Reviewing single suture synostosis in general, Kapp-Simon et al. (2007) stated that, ‘Surgical intervention on morphologic [appearance] grounds remains the only absolute indication’. And single ‘Suture fusion may serve as an indicator of neurodevelopmental concern’. In other words, the relationship between single suture premature fusion (such as the metopic) and neurocognitive problems may not be causal. Finally, Hankinson et al. (2010) concluded that, ‘Taken as a whole, the current literature suggests that cognitive impairment in children with SSC [single suture craniosynostosis] occurs despite early surgical intervention’.

Nevertheless, there remains a body of opinion amongst those involved in the management of children with single suture synostosis that a certain percentage will, if left untreated, develop otherwise avoidable cognitive/developmental problems (Eley et al. 2012).

In brief, however, although raised ICP as confirmed by the discovery of papilloedema can occasionally occur in children with single suture synostosis (particularly in older children with sagittal synostosis regardless of whether or not they have had surgery), the premature closure of a single skull vault suture remains primarily a cosmetic issue when the benefits and risks of intervention are discussed with parents.
Management of Single Suture Synostosis

Decisions concerning treatment for a primarily cosmetic condition in a child usually too young to have an input to the decision-making process involves a delicate discussion between parents and specialist in which they (the parents) have to weigh the severity with which they view the abnormality of their child's appearance (and its possible consequences – e.g. teasing at school) against the benefits (in terms of appearance change) and the risks (to the brain from some unexpected complication of surgery such as haemorrhage or infection) never absent from what is never a minor cranial operation.

The various surgical interventions (and their timing) currently employed in the management of each single suture synostosis are here briefly described. For a more detailed summary, see the review by Garza and Khosla (2012).

SAGITTAL SYNOSTOSIS

Premature closure of the sagittal suture is the most frequent form of craniosynostosis and leads to a characteristic scaphocephalic (boat-shaped) deformity of the skull. A prevalence of approximately 1 in 5000 children has been estimated and the condition is more frequently seen in boys. Six per cent of cases are familial with transmission following an autosomal dominant pattern with a penetrance of 38% (Lajeunie et al. 1996).

The affected skull has an increased antero-posterior diameter, but its bi-parietal diameter is reduced (Fig. 6.1) and a bony ridge can often be both seen and felt along the line of the fused suture (victims of teasing may be called 'peanut head'). The synostotic process does not always involve the entire suture and even when it does the severity with which the child's head shape is affected is very variable, with a mild prominence of the forehead at one end of the spectrum to gross elongation (frontal and occipital bossing) plus narrowing (particularly in the pterional regions) at the other.

The variety of surgical treatments presently employed for the correction of sagittal synostosis (for those children whose parents have opted for intervention) suggests either that all are equally effective – or equally non-effective. The operations vary in scale from removal of the fused suture (suturectomy) combined with internal springs (de Jong et al. 2013) or external (helmet/orthesis) manoeuvres (Proctor 2012) designed to induce a more round shape (all of which need to be performed before six months of age to be most effective) to increasingly major forms of skull reconstruction for which there are no age limits.

UNICORNAL (AND FRONTO-SPHENOIDAL) SYNOSTOSIS

Craniosynostosis of a single coronal suture produces a characteristic asymmetry of the forehead: frontal plagiocephaly. The supra-orbital ridge on the affected side is recessed as is the forehead above while the temporal region is unusually prominent. On the contralateral side the frontal region is often bossed, accentuating the asymmetry and the nose is set an angle, its root 'pointing' towards the side of the affected suture. The net result is to give the face a characteristic 'scoliosis' or curve convex to the affected side. The anterior skull base is also curved – but concave to the affected side (Fig. 6.2).

The elevation of the lateral wing of the sphenoid bone on the affected side is responsible for the characteristic 'harlequin eye' appearance on an antero-posterior skull X-ray. The
deformation of the orbit results in a subtle malposition of the extra-ocular muscle attachments that may in turn cause a complex abnormality of eye movement and a secondary compensatory head tilt (Gosain et al. 1996). All children with unicoronal synostosis should, therefore, be referred to a paediatric ophthalmologist.

Although the cause of unicoronal synostosis is in many cases unknown it can result from a variety of genetically mediated disorders. Most prominent amongst these is the Muenke (or FGFR3-associated synostosis) (Muenke et al. 1997). Saethre–Chotzen syndrome (Readon and Winter 1994) and cranio-frontonasal dysplasia (Cohen 1979) may also involve premature closure of a single coronal suture but their other features are usually sufficiently characteristic to suggest the diagnosis.

It is unusual for children with isolated non-genetically mediated unicoronal synostosis to have impaired neurocognitive development. Such problems are, however, well described for children with the FGFR3 mutation (Wilkie et al. 2010; Johnson and Wilkie 2011).

Treatment of unicoronal synostosis consists of a fronto-orbital reconstruction, a procedure that for the most satisfactory result may require attention to both the affected and contralateral sides. Although a gratifying immediate result can usually be obtained with abolition of the previous frontal plagiocephaly, there is over the years that follow a tendency for some element of the previous deformity to reassert itself. This is seen at its greatest extent in those children harbouring the FGFR3 mutation (Wilkie et al. 2010).

A rare cause of unilateral frontal flattening that can be confused with unicoronal synostosis is premature closure of the fronto-sphenoid suture. It can be recognised clinically by the degree of frontal plagiocephaly being particularly severe and the nose angled in the opposite direction – its root away from the affected side. Its treatment, however, is the same as for unicoronal synostosis. CT reveals a normal coronal suture with an absent fronto-sphenoidal suture.

METOPIC SYNOSTOSIS

The metopic suture is the first of the major calvarial sutures to close, a process often completed by the end of the first year. Mild vertical ridging along the line of the suture is not uncommon and should be considered a normal variation for which investigation in the absence of other issues is not required. Premature closure of the metopic suture however produces a characteristic triangular (when viewed from above) deformity of the anterior skull (trigonocephaly). There is a keel-like prominence running vertically down the centre of the forehead while the supra-orbital ridges and the frontal bones above them are flattened on each side (Fig. 6.3). The anterior cranial vault is narrow with approximation of the orbits – hypotelorism – and prominent epicanthic folds.

In a large study of metopic craniosynostosis, Lajeunie et al. (1998) estimated a prevalence of 1 in 15 000 with 5.6% of cases being familial. As with sagittal synostosis there is a male preponderance of approximately 3:1. Maternal exposure to sodium valproate is also a risk factor in the development of metopic craniosynostosis (Lajeunie et al. 2001), but the affected child has (in addition to learning difficulties and other components of the syndrome) hyper- rather than hypo-telorism.

Even in the absence of an associated syndromic or chromosomal abnormality, children with metopic synostosis may grow up with learning difficulties (Bottero et al. 1998). The effect of the orbital deformity upon their ophthalmic function include a higher incidence of both refractive errors and astigmatism than would otherwise be expected – and no relationship to age at surgery (Macintosh et al. 2011).

Treatment involves, as for unicoronal synostosis, a fronto-orbital reconstruction in which the central keel is removed together with the recessed superior orbital margins and the flattened frontal bones. These pieces are reconstructed into a more regular contour and replaced. As with unicoronal synostosis some reversion is not uncommon with a return of a (usually minor) degree of lateral frontal flattening.

LAMBDOID SYNOSTOSIS

Isolated unilambdoid synostosis is rare, accounting for only 2.3% of Shillito and Matson’s series of 519 patients (Shillito and Matson 1968). Its importance lies in its differentiation from acquired positional posterior flattening (plagiocephaly).

The affected child is born with the posterior parietal/occipital area on one side of the head flattened and restricted in volume while the contralateral frontal area may be more prominent than the ipsilateral (Matushita et al. 2014). As with the other isolated single suture synostoses this deformity shows little spontaneous tendency either to progress or to worsen. Given its posterior (eventually hidden by hair) location and

Figure 6.3 CT scan showing the typical triangular deformity of the frontal region of the skull caused by metopic synostosis.
the adjacent major venous sinuses, reconstructive surgery is rarely recommended.

**Lambdoid Synostosis Versus Posterior Positional Moulding**

Posterior flattening of the skull (uni- or bilateral) can also occur as a result of skull moulding, a condition seen with greatly increased frequency since the advent of the ‘Back to sleep’ campaign to reduce the risk of cot death/sudden infant death syndrome (SIDS) (Kane et al. 1996). The risk factors for acquired positional moulding include preterm birth a head with some intra-uterine flattening at birth, a tendency to lie with the head turned preferentially in one direction (torticollis – with or without a sternomastoid ‘tumour’), a firm mattress to sleep on, no pillow and finally a being ‘good baby’ – one who sleeps through the night with little change in position. With these factors at work an infant whose head might have been perfectly round at birth can by the age of 6 weeks or so have developed marked flattening of one side of the back of the head. Viewed from above it is as if that region has been pushed forward, taking with it the ipsilateral ear (moving it closer to the eye on the affected side [Fig. 6.4]) and producing a degree of ipsilateral frontal prominence (Huang et al. 1998). For the next 6 months or so there a tendency for the deformity to become more pronounced until with the child’s greater independence of movement he or she no longer lies through-out the night in the same position and the skull has acquired sufficient rigidity to resist further pressure-inflicted change. From then on there is a tendency for further skull growth to bring with it a degree of ‘correction’ of the head shape although when marked to begin with this, this is never complete.

Posterior positional moulding can be associated with motor delay but the causal connection is due to the less active child being more liable to develop the flattening – not the other way round. Given the history and the typical head shape (Huang et al. 1998), it is usually possible to differentiate posterior positional moulding from lambdoid synostosis on clinical grounds alone; but when in doubt a skull X-ray will show whether that suture is open or not.

The mainstays of management are awareness and prevention. Once the condition has been recognised for what it is, however, treatment consists of repositioning during sleeping and feeding, physiotherapy as required for torticollis, and moulding mattresses. Head re-shaping orthoses (moulding helmets) may have a role in both limiting the degree of deformity and restoring a more regular growth pattern particularly when instituted below the age of 6 months (Collett 2014; van Wijk et al. 2014). There is as little if any place for the surgical correction of the posterior deformity that results from positional moulding as there is for that due to lambdoid synostosis.

**CRANIOSYNOSTOSIS AND CRANIOFACIAL SYNDROMES**

The craniofacial syndromes are a heterogeneous group of rare conditions in which craniosynostosis occurs alongside various manifestations of disordered craniofacial development (Rice 2008) as well as other skeletal abnormalities that can affect, in particular, the hands and feet (Britto et al. 2001a; Panthaki and Armstrong 2003).

The conditions seen most frequently are the eponymous syndromes of Crouzon, Apert, Pfeiffer, Saethre–Chotzen, Muenke (FGFR3-associated synostosis) and cranio-fronto-nasal dysplasia. Less commonly encountered are Carpenter, Antley–Bixler (Antley and Bixler 1975; Bradley et al. 2003), Jackson–Weiss (Jackson et al. 1976) and Boston-type syndromes.

The aim of management is to ensure that affected children realise their full developmental potential. Although a major component of treatment is surgical there is now recognition of the needs of the child as a whole. The centres best placed to achieve this are those that can field the multidisciplinary team that, in addition to its neuro-, plastics and maxilla-facial surgeons, includes specialists in otorhinolaryngology and audiology, genetics, paediatrics, neurology, psychology, orthodontics, respiratory medicine, speech therapy, ophthalmology and, of course, paediatrics (Hayward and Jones 2004).

**CROUZON SYNDROME**

Crouzon syndrome (Cohen and Kreiborg 1992), like the majority of craniofacial syndromes, is transmitted as an autosomal dominant condition although it occurs with near equal frequency as a new mutation. As in Apert syndrome, its occurrence is associated with increased paternal age (Glaser et al. 2000).

Typical clinical features include a retruded maxilla that leaves the lower teeth projecting anterior to the upper teeth (class III malocclusion), a ‘beaky’ nose, a recessed frontal region (brachycephaly) due to bicornal synostosis and
prominent eyes (exorbitism) due to the combined recession of the infra- and supra-orbital regions (Fig. 6.5).

Its expression is highly variable, ranging from severe exorbitism with midface retrusion and airway obstruction at one extreme to a mild prominence of the eyes at the other. A catch for the unwary is that suture fusions need not be present at birth but may develop during the first 2 years of life (Reddy et al. 1990; Connolly et al. 2004). Extracranial manifestations (Anderson 1997) seen in severe cases include vertebral fusion (most commonly cervical) (Anderson et al. 1997a, 1998a) and ankylosis affecting particularly the elbows (Anderson et al. 1998a).

A genetically distinct type of Crouzon syndrome is associated with rugated thickened skin and hyperpigmentation that affects particularly the flexure creases – acanthosis nigricans (Wilkes et al. 1996).

Intelligence may be normal in Crouzon syndrome but the more severe the phenotype the more likely the child is to have developmental and learning difficulties. Marked intellectual disability was present in 3% of Kreiborg’s series (Kreiborg 1981).

APERT SYNDROME

The child with Apert syndrome has a head that is tall and shortened from front to back (turri-brachycephaly), midfacial (maxillary) retrusion, proptosis, a downward slant to the palpebral fissures and hypertelorism (Lajeunie et al. 1999) (Fig. 6.6a). The essential clinical feature however is a complex fusion (syndactyly) of the fingers and toes (Anderson et al. 1997d, 1999; Cohen and Kreiborg 1995b) that may require multiple surgical procedures before functional effectiveness is achieved (Guero et al. 2004) (Fig. 6.6b). Visceral (Cohen and Kreiborg 1993) and cutaneous (Cohen and Kreiborg 1995a) abnormalities can also occur. Palatal abnormalities (Kreiborg and Cohen 1992) ranging in severity from frank clefts to a bifid uvula are common and occur with a frequency of up to 75% (Peterson and Pruzansky 1974; Slaney et al. 1996). Cervical vertebral fusions that may be progressive occur in over half of affected children although it is unusual for them to become clinically significant (Thompson et al. 1996).

Developmental and learning difficulties are the norm in Apert syndrome although a combination of developmental assessment tools designed for children without Apert syndrome and low societal expectations may overestimate their severity (Shipster et al. 2002). While a small percentage of children may complete secondary education (and usually only with assistance in the classroom), many drop out of mainstream education during their primary school years while a small percentage are too affected for the mainstream education system at anything above kindergarten level (Patton et al. 1988; Renier et al. 1996).

PFEIFFER SYNDROME

Although described separately for historical reasons, the genetic overlap between Pfeiffer and Crouzon syndromes is such that they are now often considered together as ‘Crouzon–Pfeiffer syndrome’.

The ‘traditional’ Pfeiffer syndrome is an autosomal dominant condition characterised by suture fusions that range from bicoronal synostosis alone to pan-synostosis (with or without the cloverleaf skull deformity – see below) (Winter 1994). Affected patients also have digital abnormalities (Panthaki and Armstrong 2003) that include curved and shortened thumbs and great toes (Anderson et al. 1998b) and, less commonly, digital fusions [although to a lesser degree than in Apert syndrome (Panthaki and Armstrong 2003)].

Cohen (1993) divided children with Pfeiffer syndrome into three types based on their clinical severity. Type 1, those least affected, may display little more than bicoronal synostosis and midface retrusion (in addition to their digital
abnormalities). Their neurocognitive development may be unaffected, particularly if early complications have been aggressively treated (Kohan et al. 2009) (Fig. 6.7).

In Types 2 and 3 Pfeiffer syndrome, the degree of midface and frontal retrusion is severe enough to obstruct the upper airway and cause eye protrusion sufficient to threaten the corneas. The shortening of the skull base and crowding of the posterior fossa due to the bi-lambdoid component of their pan-synostosis produces an increased risk of hydrocephalus. Ankylosis (bony and soft tissue) of the elbows (Anderson et al. 1998a) and knees is common as are fusions of the cervical vertebrae (Anderson et al. 1996b).

The difference between Types 2 and 3 is that Type 2 has the cloverleaf pattern of skull deformity (see below).

Neurocognitive development in Types 2 and 3 Pfeiffer syndrome is usually delayed although with active intervention aimed at improving the airway and reducing raised ICP the outlook is not as dire as was once assumed (Robin et al. 1998).

CLOVERLEAF SKULL (KLEEBLATTSCHÄDEL) DEFORMITY

The Kleeblattschädel anomaly, or cloverleaf skull, is the descriptive term given to a particularly severe form of synostosis-associated cranial deformity (Zuleta and Basauri 1984) – and one that poses a particular challenge for the craniofacial surgeon (Thompson et al. 1995b; Zuccaro et al. 1996). Although it usually occurs as a manifestation of Pfeiffer syndrome (Type 2) it can occasionally complicate Apert and Crouzon syndromes (Fig. 6.8).

Its cause is a particular combination of suture fusions and an ICP that is raised from hydrocephalus. The sagittal and squamo-parietal sutures are open but in addition to bicoronal synostosis, a bony constriction band runs posteriorly from the pterions to the lambdoids. With the addition of hydrocephalus the infant’s skull expands upwards (above) and laterally (below) this constriction band to produce the characteristic trefoil (cloverleaf) shape (Cohen 1972, 1993; Eaton et al. 1975; Kroczek et al. 1986).

SAETHRE–CHOTZEN SYNDROME

Saethre in 1931 and Chotzen in 1932 described an autosomal dominant condition that combines with great variability (Reardon and Winter 1994) coronal synostosis (uni- or bilateral) and digital abnormalities that include short digits and partial syndactylies (Anderson et al. 1996a), low frontal hairline, a prominent nose and ptosis, and more rarely fusions of the cervical spine (Anderson et al. 1997b) (Fig. 6.9). Complications such as exorbitism and airway obstruction are uncommon. Raised ICP is rarely of functional significance (de Jong et al. 2010) and the neurocognitive outcome may be only modestly affected if at all (Reardon and Winter 1994).

MUENKE SYNDROME

This condition, one of the less severe of the craniosynostosis-associated syndromes, is of interest because rather than being first described on the basis of the appearance of those affected it was ‘discovered’ during the explosion of knowledge about the genetic basis of the craniofacial syndromes that occurred during the 1990s (Muenke et al. 1997).

It has multiple manifestations (Reardon et al. 1997) but the synostosis typically affects one or both coronal sutures (Moloney et al. 1997). It is now appreciated that many patients previously diagnosed as isolated unicoronal craniosynostosis carry the FGFR3 mutation (Lajeunie et al. 1995a). Those with bicoronal synostosis typically have a broad and shallow supra-orbital region with a protruding upper forehead (Fig. 6.12a, b). Complications such as raised ICP and airway obstruction are uncommon but although a child’s development may be unaffected, a degree of learning difficulty is well described (Muenke et al. 1997).
CRANIO-FRONTO-NASAL DYSPLASIA

In this X-linked (Pulley et al. 1999) syndrome, bicoronal synostosis (usually asymmetrical in its effect) is associated with hypertelorism, wiry (‘unruly’) hair, a prominent gap between the central incisors, a bifid nose (Cohen 1979; Pruzansky et al. 1982; Saavedra et al. 1996) and sometimes abnormalities of the optic discs (Lees et al. 1998). Development is usually unaffected and treatment is indicated on predominantly cosmetic grounds (Kawamoto et al. 2007).

CARPENTER SYNDROME

This very rare condition (Carpenter 1909) is mentioned here for completeness because it has an autosomal recessive pattern of inheritance. Also known as acrocephalopolysyndactyly because of the extra digits that form part of the clinical picture, the cranial deformity is due to various combinations of craniosynostosis (Eaton et al. 1974; Gershoni-Baruch 1990).

The Molecular Genetics of Syndromic Craniosynostosis

It was hoped that when the genetic basis of many of the craniofacial syndromes was discovered in the 1990s it would allow their classification to move from the eponymous nomenclature that had been in use for so many years. Unfortunately, as the genetic ‘overlap’ between Crouzon and Pfeiffer syndromes demonstrates, the situation proved to be more complex: a single mutation capable of causing both Pfeiffer and Crouzon syndrome and mutations on either of two chromosomes responsible for Pfeiffer syndrome (Rutland et al. 1995; Schell et al. 1995; Britto et al. 2001c). It is for this reason that some specialists now prefer the designation ‘Crouzon–Pfeiffer syndrome’ to two separate entities – which, from a clinical management perspective, makes little difference to established practice.

With the exception of Carpenter syndrome (autosomal recessive [Jenkins et al. 2007]) and cranio-fronto-nasal dysplasia (X-linked [Pulley et al. 1999]) the craniosynostosis-associated syndromes have an autosomal dominant pattern of transmission. (For a summary linking the clinical features
Chapter 6 Osseous Malformations of the Skull and Craniovertebral Junction

The realisation that many of the craniofacial syndromes were monogenic (due to a single gene mutations) combined with investigation of families with several affected members led, in the 1990s, to an intense examination of the fibroblast growth factor group of tyrosine kinase receptors (FGFRs I–III) as candidate genes. These receptors are well preserved across a range of species and are involved (amongst many other activities) in cranial and limb development (Johnson and Williams 1993; Britto et al. 2001b; Robijn et al. 2011). It is now known that a particular position within each FGFR protein is strongly linked to craniosynostosis as mutations there in FGFR 1, 2 and 3 cause respectively Pfeiffer, Apert and Muenke syndromes (Bellus et al. 1996).

More recent genetic discoveries have further reduced the number of cases of craniosynostosis that were once labelled as ‘non-syndromic’. These include mutations involving the TCF12 and ERF genes.

Mutations of TCF12 have been reported in 32% and 10% of children with ‘non-syndromic’ bi- and uniconoronal synostosis respectively in whom Muenke, FGFR2 and Saethre–Chotzen mutations had been excluded. The gene is located on chromosome 15, acts synergestically with TWIST1 through ‘loss of function’ and appears to be necessary for the production of a functioning coronal suture (Sharma et al. 2013).

Mutations of ERF are less common than those of TCF12, found in only 1–2% of 402 cases of craniosynostosis operated on by the Oxford craniofacial unit (Twigg et al. 2013). They also act by loss of function to cause complex multi-suture fusions that when associated with facial abnormalities may resemble Crouzon syndrome (there is a ‘pathway-based phenotypic link with FGFR2’ [Twigg et al. 2013]). The sagittal is the most likely to be involved when only one suture is prematurely fused (Twigg et al. 2013).

Although confirmation of a particular mutation may not affect a child’s immediate management, it does allow a more informed developmental prognosis and the likely need for subsequent operations to be explained to parents (Wilkie et al. 2010). Knowledge of the responsible mutation also has important implications for genetic counselling. Parents who have already had an affected child may also wish to avail themselves of the opportunity not only for prenatal ultrasound examination of the foetus (Gorincour et al. 2005; Chitty and Lau 2011; Khalil et al. 2011; Shaw et al. 2011) but also for preimplantation diagnosis when considering further pregnancies (Abou-Sleiman et al. 2002; Harper et al. 2002).

PRINCIPLES OF MANAGEMENT OF SYNDROMIC CRANIOSYNOSTOSIS

The complexity of decision-making for children with syndromic craniosynostosis means that their management should only be undertaken in multidisciplinary units specialising in their care (McCarthy et al. 1995; de Jong et al. 2010). It is, therefore, essential that these children are referred to such a unit as early as possible so that the correct diagnosis (both genetic and clinical) can be made, the risk of complications assessed and a management plan made that is tailored to each individual child’s needs.

As the majority of craniofacial syndromes result from a particular gene mutation (either of, or connected to, the FGFR series) it should be no surprise that such mutations continue to exert their ill effects for as long as the cranial and facial skeletons are growing. The consequence of this is that the majority of children with Apert syndrome (Carr et al. 1992) and the more severe forms of Pfeiffer, Crouzon (Carr et al. 1992) and cloverleaf (Jarrah et al. 2009) syndromes may need several procedures during their early years to treat such functional issues as raised ICP, exorbitism, airway obstruction and psychological issues related to their appearance (teasing etc.) (Allam et al. 2011). This is in contrast to more mildly affected children (e.g. with Saethre–Chotzen and Muenke syndromes [Ridgeway et al. 2011]) for whom a single reconstructive procedure may be all that is required.

The problems affecting children with syndromic craniosynostosis can be divided somewhat arbitrarily into those affecting clinical function and those not.

FUNCTIONAL COMPLICATIONS OF SYNDROMIC CRANIOSYNOSTOSIS

Raised Intracranial Pressure

Raised ICP is a well recognised complication of syndromic craniosynostosis (Renier et al. 1982; Thompson et al. 1995a). Its incidence is strongly related to the severity of the phenotype making it unusual in Muenke and Saethre–Chotzen syndrome and near inevitable in Pfeiffer Type 2 (cloverleaf skull deformity).

Raised ICP can, as a consequence of unrelieved papilloedema, be responsible for a progressive deterioration in vision leading eventually to blindness (Stavrou et al. 1997; Liasis et al. 2011). Whether it can (in the absence of hydrocephalus) affect cognitive development is more assumed than proven. Renier et al. (1996) and others have proposed such a connection but it is difficult to untangle the effects of raised ICP alone from such other manifestations of the affected child’s phenotype as the direct brain effects of the disordered gene or chromosome (Wilkie et al. 2010), hydrocephalus, chronic airway obstruction, feeding difficulties and ‘failure to thrive’, the developmental consequences of impaired vision and/or hearing coupled with low societal and family expectations (including teasing) – not to mention any unintended side effects of earlier cranial surgery (Naumann et al. 2012).

THE DIAGNOSIS OF RAISED INTRACRANIAL PRESSURE

Clinical. Bulging of still open fontanelles, stretched sutures and craniectomy defects; and in the older child headache and vomiting although these are of very low sensitivity and specificity.
Radiological. A generalised copper-beaten appearance on skull radiographs in the presence of multiple suture fusions (Tuite et al. 1996b), progressive ventriculomegaly and effacement of cortical sulci on MRI and/or CT (Collmann et al. 2005).

Ophthalmological. Papilloedema (Tuite et al. 1996a) with or without abnormal electro-diagnostic studies and a fall in visual acuity (Liasis et al. 2003, 2006; Thompson et al. 2006).

Invasive ICP monitoring. Transcranial parenchymal pressure monitoring allows ICP to be measured (Renier et al. 1982; Thompson et al. 1995a). However, it is important to recognise that the figures most often used to interpret the results of ICP monitoring in childhood (normal, \(<10\)mmHg; borderline, \(11–15\)mmHg) and raised, \(>15\)mmHg) are ‘best guesses’ based on a variety of assumptions (parents of healthy children being understandably reluctant to submit them to an invasive procedure for essentially academic interest).

It is important to remember that although ICP may be normal when a child first presents, the dynamic nature of the syndromic craniosynostosis process means that surveillance (which in our unit includes regular ophthalmic assessments) should continue until a child is at least 8 years old; our experience being that it is unusual for it to develop – or recur – after that age.

Causes of raised intracranial pressure in syndromic craniosynostosis

The four principle contributors to raised ICP in children with syndromic craniosynostosis are cranio-cerebral disproportion, hydrocephalus, venous hypertension and airway obstruction.

Cranio-cerebral disproportion

Although it was once thought that a growing brain restrained by a skull restricted in its ability to expand was the principle cause of raised ICP in syndromic synostosis, it is now recognised that this situation is relatively unusual and a reduced intracranial volume (ICV) is an unreliable predictor of raised ICP (Fok et al. 1992; Gault et al. 1992). Indeed in Apert syndrome ICV, although normal at birth, may actually be greater than normal by the time raised ICP declares itself (Gosain et al. 1995; Sgouros et al. 1999). Fortunately the various forms of vault expansion surgery originally designed to increase ICV are equally effective in reducing raised ICP due to a more common cause – venous hypertension (see Raised Venous Pressure).

Airway obstruction

Impairment of the upper airway is common in the severely affected child with syndromic synostosis and is an important contributor to the vicious cycle that determines ICP in these children (Gonzalez et al. 1997). The peaks of ICP that can reduce cerebral perfusion pressure to a mean of around 30mmHg are invariably associated with episodes of airway obstruction during rapid eye movement (REM) sleep. The practical importance of this is that improvement to the airway (see Airway Obstruction) may be all that is needed to reduce the ICP (Fig. 6.10).

Hydrocephalus and the Chiari I deformity of in children with syndromic synostosis

Forty per cent may have a degree of ventricular enlargement (Collmann et al. 2005) but in many this is non-progressive. It is important therefore that the craniofacial surgeon does not proceed to treatment – e.g. a shunt insertion – unless ventriculomegaly is worsening and other indicators of raised ICP are present. Hydrocephalus occurs particularly when there is constriction of the skull base and early closure of the lambdoid sutures – which is why it occurs more frequently in Crouzon and Pfeiffer (Types 2 and 3) than in Apert syndrome (Cinalli et al. 1995). Constriction of the skull base, hydrocephalus and raised ICP and herniation of the cerebellar tonsils (the Chiari I deformity) are linked in a cycle of cause and effect (Cinalli et al. 1995; Thompson et al. 1997). The Chiari I deformity is seen particularly in children with a constricted skull base and while its progression (with additional buckling of the lower brainstem) is aided by raised ICP it is also a risk factor for the development of hydrocephalus (de Jong et al. 2012). When tonsillar herniation and brainstem compression in a child with syndromic synostosis becomes symptomatic (when respiratory studies suggest a central as well as an obstructive contribution to breathing problems (Gonzalez et al. 1998) or with the development of syringomyelia, for example) a foramen magnum decompression may be indicated.

Raised venous pressure

Intracranial venous hypertension is a major contributor to raised ICP in children with syndromic synostosis (Hayward...
Chapter 6 Osseous Malformations of the Skull and Craniovertebral Junction

2005). It is caused by narrowing or occlusion of venous channel exiting through the skull base (Rich et al. 2003) and aggravated by airway obstruction. In a digital subtraction angiography study of 23 children with the syndrome and with raised ICP, (Taylor et al. 2001) 18 had either complete or more than 50% occlusion of the sigmoid/jugular complex on one or both sides. Extensive collaterals through the retromastoid region and other trans-osseous channels can cause troublesome haemorrhage when reflecting the extensive skin flaps often required for craniofacial surgery (Thompson et al. 1995b; Anderson et al. 1997c) (Fig. 6.11). Although considered separately here, some overlap between these contributors to raised ICP in complex/syndromic craniosynostosis is common. Indeed they often interact in a vicious cycle (Fig. 6.11) in which during active/REM sleep airway obstruction and periods of apnoea cause CO₂ retention and cerebral vasodilatation to produce waves of very high pressure lasting 10–20 minutes superimposed upon a baseline that may be only moderately elevated. During these waves of pressure (most obvious on overnight recordings) mean cerebral perfusion pressures can fall as low as 32mmHg (Hayward and Gonzalez 2005).

**Airway Obstruction**

Impaired respiratory function, particularly at night when snoring is a frequent complaint, is a common problem for the more severely affected child with syndromic craniosynostosis. It is usually due to airway obstruction from narrowed nares, cramped nasal passages, a hypoplastic maxilla constricted in all planes and tracheal softening but a central component occurs when there is brainstem compression from a Chiari I deformity (Gonzalez et al. 1998). An airway clear at birth may become obstructed later from tonsillar and (in particular) adenoidal hypertrophy in the restricted pharyngeal space available to them.

In addition to contributing to raised ICP, breathing difficulties impair the ability of the infant and young child to feed and are an important contributor to their failure to thrive. In older children disturbed nights lead to sleepiness during the day and can interfere with schooling.

All children in whom breathing difficulties are suspected should undergo an overnight respiratory sleep study. Although the commonest cause is upper airway obstruction, such a study will determine whether there is a central component, which if associated with a Chiari I deformity may require a foramen magnum decompression (Gonzalez et al. 1998).

Management involves (in ascending order of magnitude) the insertion of a naso-pharyngeal airway (Ahmed et al. 2008), adenotonsillectomy (which may need to be repeated as the child grows) (Liasis et al. 2005), continuous positive airway pressure (Gonzalez et al. 1996; Massa et al. 2002), tracheostomy and, finally, operations that open the airway by advancing the maxilla – the LeFort III advance and the monobloc fronto-facial advance (Witherow et al. 2008) with or without distraction.

**Vision**

**Corneal exposure**

Recession of the maxilla below and the fronto-orbital region above can leave the corneas exposed and in danger of permanent scarring. Temporary measures to protect them include the instillation of lubricating drops (particularly useful when the eyes do not close completely at night) and tarsorrhaphies although these can raise intraocular pressure when the exorbitis is severe. Longer-term protection requires the advance of the bony orbital rim – either in part (a fronto-orbital advance [FOA]), or complete (an FOA combined with a LeFort III maxillary advance or a fronto-facial monobloc procedure which can in exceptional circumstances be performed in the very young [Britto et al. 1998]).

The vision of children with syndromic craniosynostosis can be affected also by raised ICP, astigmatism and amblyopia. In one assessment of visual acuities in children with syndromic craniosynostosis 40% had function in their better eye below a level (6/12) that would allow them to hold a driving licence in the United Kingdom (Khan et al. 2003) a proportion of which morbidity can be attributed to raised ICP.

**Failure to Thrive**

Regardless of any contribution from the disordered gene, severe breathing difficulties due to a combination of airway obstruction and any central depression of respiration can so interfere with feeding that the affected child may fail to gain weight – or even lose it. A dyspraxia of oro-pharyngeal movements may also contribute.

Adjuvent feeding of infants via a naso-gastric tube and occasionally a gastrostomy may be required but the most dramatic improvements are seen following procedures aimed at restoring a more effective airway.
Developmental Delay/Learning Difficulties

Developmental delay, learning difficulties and a wide range of cognitive issues can affect the child with craniosynostosis including those with no more than single suture involvement. While many may be related to effects of the disordered gene (and particularly any associated chromosomal abnormality), an important role of the multidisciplinary craniofacial unit is to manage any potentially remedial causes that can also contribute. These include hydrocephalus, chronic airway obstruction, feeding difficulties and ‘failure to thrive’, the developmental consequences of impaired vision and/or hearing and the effects of low societal and family expectations (including teasing). Experienced input is needed to ensure that such problems are recognised early and appropriate therapy instituted at an age when it is most likely to be of benefit.

Epilepsy is rare in craniosynostosis but has a higher than expected incidence in Muenke (Agochukwu et al. 2012) and Apert (Agochukwu et al. 2012) syndromes, in children with the fetal valproate syndrome and those with associated chromosomal abnormalities. It may also occur as a post-operative complication, a consequence of the frontal lobe retraction required during fronto-facial monobloc and bipartition procedures in children with severe frontal bone recession (Cobb et al. 2013).

Cosmesis

The cosmetic disabilities that most trouble patients with syndromic synostosis and their families include a misshapen forehead, eyes that protrude, eyes set too far apart (hypertelorism) and an upper jaw set back while the lower jaw protrudes.

When correcting for cosmesis alone it is important to remember that surgery carried out on a part of the craniofacial skeleton that is still growing may need to be repeated either wholly or in part in order to achieve a result that will prove stable over time. Our own policy, based more on clinical observation than measurement, is to assume that a forehead and supra-orbital region in a satisfactory configuration at around 10 years of age is unlikely to need further correction and essentially cosmetic reconstructions after that age can focus more on the maxilla and mandible where growth will continue until secondary dentition is complete – the mid to late adolescence.

Primary craniosynostosis whether it affects one or multiple sutures and is associated or not with a particular syndrome is rare and its management should only be undertaken by a unit with sufficient experience to ensure affected children achieve their developmental potential.

Early assessment by such a unit will enable the correct diagnosis (both genetic and clinical) to be made, the risk of complications assessed and a management plan made that is tailored to each individual child’s needs.

While in non-syndromic unisutural synostosis treatment may require no more than a single reconstructive operation, more complex cases require input from a wide range of specialists including the paediatric neurologist often until the completion of skeletal maturity.

DISORDERS OF THE CRANIOVERTEBRAL JUNCTION

Disorders of the craniovertebral junction (CVJ) in childhood occur in the context of a seemingly overwhelming array of congenital and acquired disorders, some not uncommon (e.g. Down syndrome) others exceedingly rare (e.g. metabolic bone diseases). The nosology and classification of skeletal disorders has recently been revised by the International Skeletal Dysplasia Society (Warman et al. 2011). The precise nature of the CVJ anomaly and its natural history vary according to the underlying disease. These factors are further complicated by the inevitable difficulties in neurological evaluation of the infant and young child, particularly those with co-existing musculoskeletal and cognitive impairments. Choosing the correct investigations and determining an appropriate management strategy is thus complex and a not infrequent source of confusion.

This chapter presents a simple mechanistic approach that can be applied to almost all craniovertebral anomalies. This approach serves to aid selection of particular diseases or syndromes that may require specific evaluation of the CVJ, guide appropriate investigation and determine a logical treatment pathway. Some of the more frequently encountered CVJ disorders are selected for more detailed discussion.

The clinical problems that may occur as a consequence of CVJ anomalies are a result of only three biomechanical processes namely instability, deformity or neuraxial compression. Each of the diseases or syndromes associated with CVJ anomalies has a predilection for one or more of these processes, therefore knowledge of the underlying anomaly will determine the direction of clinical evaluation and investigation. Having determined the particular biomechanical impairment, the principles of treatment then comprise reducing and immobilising instability, re-aligning deformity and decompressing the neuraxis. A range of surgical approaches and operative techniques are available to achieve these goals and these need to be modified according to patient age and the perceived natural history of the condition.

THE CRANIOVERTEBRAL REGION

The craniovertebral region comprises the bones, joints and their associated ligaments and muscles that form the articulation between the occipital bone of the skull and the cervical spine. It is a developmentally complex region and the site of a number of congenital osseous anomalies. Detailed description of
the normal and abnormal development of the craniovertebral junction can be found elsewhere (Pang and Thompson 2011).

While osseous malformations of the CVJ are found in isolation in clinical practice, they will more commonly occur in the context of a recognised syndrome or bone dysplasia. Existing classifications according to syndrome type, metabolic anomaly, genetic aberration etc. have their limitations and for the most part offer no practical guidance to the physician. A simple mechanistic approach is suggested that will alert the clinician to those particular diagnoses that are at risk of CVJ anomalies, indicate the likely clinical manifestations that might result and serve as a guide to the most appropriate initial investigations. While the final management plan and surgical intervention will be the province of the specialist it is hoped that this practically oriented approach will permit early referral where appropriate and act as a template for on going surveillance.

An understanding of the basic anatomy of the CVJ and the terms commonly used to describe its disorders is pertinent to subsequent discussion.

ANATOMY OF THE CRANIOVERTEBRAL JUNCTION

The posterior skull base is formed by the occipital bone. The occipital bone has a flattened squamosal portion that contributes to the posterior fossa and provides the large surface area for attachment of the suboccipital musculature, a ventral portion that forms the lower third of the clivus and, between these two, the occipital condyles (for articulation with C1). Together these structures form the boundaries of the foramen magnum. The first cervical vertebra (atlas), a ring shaped structure, acts as a ‘washer’ between the occipital bone and the second cervical vertebra (axis). These ‘atypical’ vertebrae are modified to permit rotation at the CVJ, which is the primary movement at C1/C2. In contrast, that between the occiput and C1 is flexion/extension (Steinmetz et al. 2010). The atlas lacks a vertebral body. Instead the odontoid peg, a rostral extension of the body of the axis, projects into the ring of the atlas vertebra. Here it articulates by means of a small synovial joint between its tip and the inner surface of the anterior ring of the axis. The odontoid is held in place, within the ring of the axis by means of the transverse ligament, a strong structure that extends from one side of the atlas to the other. Additional ligaments (apical and alar) extend from the tip of the odontoid peg to attach to the anterior margin of the foramen magnum. It is the structural integrity of these ligaments that ensure that the odontoid can act as a pivot to permit rotation while preventing backwards movement toward the spinal cord.

EXPLANATION OF TERMS USED IN DESCRIBING CRANIOVERTEBRAL JUNCTION

The nomenclature surrounding CVJ anomalies can lead to confusion. The following terms warrant clarification.

Os Odontoideum

The rostral part of the odontoid peg may become detached from its base thus resulting in a bipartite odontoid (Fig. 6.12). The separate ossicle of bone, os odontoideum, remains attached to the foramen magnum by the apical and alar ligaments. However, since the os is functionally separated from the rest of the axis, the transverse ligament is rendered incompetent leading to atlanto–axial instability. During flexion the base of the odontoid, now unchecked, can move posteriorly into the cervical canal and compress the spinal cord. Traditionally considered to be a developmental anomaly, it is now more widely accepted that os odontoideum is a result of an early, ununited fracture through the base of the odontoid (Crockard and Stevens 1995; Arvin et al. 2010). Os odontoideum is particularly well recognised in Down syndrome; in one series 10 of 12 children with Down syndrome who required surgery for symptomatic atlanto–axial subluxation had os odontoideum (Nader-Sepahi et al. 2005). The os may thus be a consequence as well as a cause of instability.

Platybasia

The term platybasia refers to the obtuse angle formed by the anterior cranial fossa with the slope of the clivus. This angle may range from 115° to 130°; however, the normal range can vary significantly depending on the measuring technique and imaging modality used (Koenigsberg et al. 2005) and so these need to be standardised when making comparisons or clinical inference. While the basal angle has important anthropological relevance it has a limited use in clinical practice.

In the past, various craniometric measures with eponymous names (Chamberlain’s line, McGregor’s line and Wackenheim’s line) were devised, usually based on plain X-rays, in an attempt to infer the effects of craniovertebral deformity on the underlying neuraxis (Smoker and Khanna 2008). The advent of MRI permitted clearer demonstration of compression or distortion of the brainstem or spinal cord thus largely obviating the need for such measurements.
Basilar Invagination and Basilar Impression

These two terms are often used interchangeably to describe situations in which the odontoid peg projects above the plane of the foramen magnum (Smith et al. 2010). More precisely, most authors use basilar invagination to describe a primary form in which there is upwards migration of the upper cervical spine into the foramen magnum in the context of congenital anomalies such as assimilation of the atlas and vertebral segmentation defects. While basilar impression, or secondary basilar invagination, is used in the presence of bone softening conditions, such as Paget disease, osteogenesis imperfecta or Hadju-Cheney syndrome resulting in an in-folding of the entire skull base (Sawin and Menezes 2009).

Basilar invagination can result in compression of the brainstem and distortion of the posterior fossa structures leading to herniation of the hindbrain through the foramen magnum (Chiari Type I) in up to half of patients (Goel et al. 1998). Conventional foramen magnum decompression alone is often insufficient treatment for Chiari Type I in this context (Greenlee et al. 1999; Kim et al. 2004).

Platyspondyly

This term refers to the flattened or bullet shaped vertebrae that typify some of the metabolic bone disorders such as spondyloepiphyseal dysplasia and Morquio disease.

BIOMECHANICAL CONSIDERATIONS

There are, in essence only three biomechanical problems at the CVJ that are of clinical relevance: these are instability, deformity and compression of the neuraxis. These can occur in isolation or in any combination. Certain conditions have a predilection for particular biomechanical problems; e.g. instability is a characteristic of Down syndrome, focal compression at the foramen magnum is seen in achondroplasia and deformity is the main issue in disorders of cervical segmentation.

Table 6.2 summarises the principle biomechanical deficiencies occurring at the CVJ in various dysplasias, syndromes or diseases.

### Instability

The stability of the CVJ is maintained by osseous, ligamentous and muscular factors. Where these are compromised by congenital or acquired disorders movement may exceed the normal physiological limits and pose a risk to the underlying neuraxis. Instability may occur at the occipito–atlantal joint, the atlanto–axial joint or in the sub–axial spine. Pure occipito–atlantal instability is rare and quite difficult to confirm radiologically, particularly in young children. (Karol et al. 1996) Occipito–atlantal instability occurs in combination with atlanto–axial instability in Down syndrome. Morquio syndrome and spondyloepiphyseal dysplasia are also particularly prone to CVJ instability.

### Investigating Instability

Atlanto–axial instability (AAI) is best assessed using a dynamic technique and the most appropriate investigation is plain lateral cervical spine X-rays performed in flexion and extension (Fig. 6.13). Instability is almost always accentuated in flexion; however, the extension view is important to assess whether any instability is reducible by restoration of the normal relationship between the odontoid peg and the anterior arch of the atlas.

The traditional measure of instability is the atlanto-dental interval (ADI), the distance between the odontoid peg and the anterior arch of the atlas measured in flexion (normal <5mm). An additional measure of AAI is the neural canal width (NCW) or posterior atlanto-dental interval (PADI).
This is the distance between the back of the odontoid peg and the anterior surface of the posterior atlantal arch. It is thus a measure of the space available for the spinal cord. White et al. (1993) measured ADI and NCW in both plain X-rays and MRI in patients with Down syndrome; they found that NCW but not ADI correlated well with subarachnoid space available for the spinal cord.

While flexion and extension CT and MRI are feasible, the range of excursion in neck movement that is achievable is less than with plain X-rays and so these tend only to be used when there is associated deformity that compromises interpretation of plain X-rays. Furthermore, dynamic studies should only be performed in awake patients therefore, in children requiring general anaesthetic for CT or MRI a dynamic study is contraindicated.

**Deformity**

If instability is defined as movement in excess of the normal physiological range, then deformity can be considered as alignment outside the normal range. Deformity at the CVJ may occur as a result of distorted normal anatomy (rotational deformity or sagittal deformity) or as a consequence of anomalous segmentation.

**Rotational deformity**

The clinical presentation is with torticollis. This is a combination of lateral head tilt and rotation resulting in the ‘Cock Robin’ deformity. The differential diagnosis of torticollis in childhood is wide including tumour, infection, trauma and vascular (Per et al. 2014); however, there are two particular conditions that are important to diagnose as they are amenable to surgical intervention.

The first, tight sternomastoid, is a condition that commonly dates back to infancy. There may be a history of birth trauma or unilateral neck swelling during the neonatal period (Cheng et al. 2000). This swelling, often called a ‘sternomastoid tumour’, is a haematoma of the muscle that resorbs, leaving a fibrotic contraction of the muscle. This results in a taut band along the line of the muscle. The treatment is division of the sternomastoid muscle and fibrotic band, a procedure that has low risk and favourable cosmetic improvement in most patients (Shim et al. 2004).

The second, atlanto–axial rotatory fixation (AARF), is an acquired condition, presenting in older children, in which there is fixed malalignment between C1 and C2 (see below).

**Sagittal deformity**

The normal lordotic curvature of the cervical spine complements the normal thoracic kyphosis and lumbar lordosis resulting in an overall balanced sagittal spinal profile. In some circumstances the cervical curve reverses, resulting in kyphosis or forward bending of the cervical spine. The craniocervical junction, instead of lying along the sagittal profile, assumes a more anterior position that compromises biomechanical stability with a tendency to progressive deformity. This is the classic appearance in Larsen syndrome (Sakaura et al. 2007). The onset of deformity is usually in infancy and may progress with myelopathy (Johnston et al. 1996). The timing of surgery can be problematic given the technical constraints associated with spinal fusion in young children.

**Segmentation anomalies**

Segmentation of the somitic mesoderm takes place in the third week of embryonic life. Segmental identity of the various vertebrae is conferred by the differential expression of Hox genes (Pang and Thompson 2011). Failure of segmentation may occur as a result of an underlying genetic mutation in a wide number of genes (Giampietro et al. 2008), though in many cases is likely to result from an early teratogenic insult (Giampietro et al. 2013). Maternal diabetes (Åberg et al. 2001), alcohol (Tredwell et al. 1982) and anticonvulsant use
(Holmes et al. 2001) are among the teratogens associated with cervical segmentation anomalies. Broadly speaking, two types of segmentation anomaly are encountered: anomalies of fusion and anomalies of form.

Anomalies of fusion (Klippel-Feil deformities)
In these there is a failure of intervertebral disc development resulting in block vertebrae (Fig. 6.14). The classic clinical description is a triad of short neck, low posterior hairline and reduced neck movements. Common sites of fusion are between the occiput and atlas (atlanto-occipital assimilation) and C2/3, although much longer segments of fusion are well recognised (Clarke et al. 1998; Samartzis et al. 2006). This is an etiologically diverse entity and dominant, recessive and X-linked modes of inheritance have been described. Anomalies of fusion frequently occur in the syndromic craniosynostoses (Thompson et al. 1996).

Anomalies of form
In contrast to anomalies of fusion, where the number of mobile segments is reduced, in anomalies of form it is the shape of the vertebrae that is abnormal. Examples include butterfly vertebrae, hemivertebrae and sometimes irregular shapes that do not fit in with conventional descriptions. In these children the neck is typically short and the range of movement reduced as with Klippel-Feil syndrome; however, torticollis is more evident. Associated features include orbital and ocular anomalies as well as abnormalities of branchial arch development including microtia, preauricular sinuses and skin tags. The clinical spectrum includes the eponymous conditions Goldenhaar and Wildervanck; however, it is now recognised that considerable overlap exists and the term oculo-auculo-vertebral spectrum (OAVS) is perhaps more clinically useful (Gorlin et al. 2001).

In both these types of deformity, neural compression resulting in radiculopathy or myelopathy is unusual in paediatric practice (Theiss et al. 1997). In fact in segmentation anomalies the spinal canal tends to be wider than normal thus sparing the spinal cord. However, patients may become unstable or ‘hypermobile’ at the junction between fused segments and this may indicate an increased risk of developing symptoms with advancing age (Nagib et al. 1984, 1985). Despite this, there is no evidence to support prophylactic fusion in childhood. In addition to cervical deformity, scoliosis in the thoracic region occurs in as many as two-thirds of cases. Children should be monitored with interval neurological assessments and radiological studies looking for symptomatic instability or progressive deformity. Split spinal cord (David et al. 1996) and mirror movements (Royal et al. 2002) are rare associations with segmentation anomalies.

**Investigating deformity**
Plain X-rays are rarely of use in the investigation of craniovertebral deformity as any rotational component makes interpretation difficult. High resolution CT is a much more appropriate tool with which to evaluate the bony anatomy. In addition to conventional axial views the data can be reformatted in sagittal and coronal planes, as well as 3D, to provide additional information regarding alignment and its effect on the spinal canal (Newton et al. 2002). CT is useful in planning elements of instrumentation surgery such as screw size and trajectory or for intra operative image guidance. Additional CT angiography (CTA) can be particularly helpful to assess the course of the vertebral arteries which may be altered by congenital or acquired deformity (Barker et al. 2009).

**Neuraxial Compression**
Stenosis at the foramen magnum, skull base malformation or narrowing of the cervical spinal canal due to anomalies of the atlas or axis can result in effacement of the normal...
CSF spaces and direct compression of the brainstem or spinal cord. The incidence of Chiari I malformation in patients with CVJ malformations is estimated to be between 33 and 38% (Menezes 2012). It should be noted that the descent of the cerebellar tonsils that characterise the Chiari I malformation is not a true malformation but rather a deformity of the neuraxis in response to the local bony anatomy. It is now widely acknowledged that the bony malformation leads to reduced posterior fossa volume and thus secondary herniation of the cerebellar tonsils (Badie et al. 1995; Sgouros et al. 2006; Trigylidas et al. 2008). Therefore, the terms cerebellar tonsillar ectopia or hindbrain hernia are perhaps more appropriate.

**INVESTIGATING NEURAXIAL COMPRESSION**

MRI is the imaging modality of choice in the evaluation of suspected neuraxial compression and the most appropriate modality for the surveillance and screening of craniovertebral anomalies in the bone dysplasias; e.g. Morquio and achondroplasia (Kao et al. 1989; Janus et al. 2003; Smoker and Khanna 2008).

**CLINICAL PRESENTATION OF CRANIOVERTEBRAL ANOMALIES IN CHILDREN**

Specific patterns of biomechanical compromise are characteristic of particular CVJ abnormalities (Table 6.2). This will aid in focusing the history and examination.

**History**

The phenotype of many bone dysplasias and metabolic bone disorders will include short stature, joint contractures or laxity, reduced muscle bulk and generalised motor delay. These features will impact on the clinical presentation and neurological examination findings; it is important therefore that symptoms and signs are interpreted in context. With this in mind a history of recent change in functional ability, loss of previously acquired motor skills, increasing tendency to fall or worsening balance may be features of emerging myelopathy.

Symptoms of bulbar dysfunction should be specifically sought. In children with CVJ or high cervical abnormalities, brainstem compression may occur both in response to direct compression of the neuraxis by the bony malformation (e.g. in the basilar invagination of osteogenesis imperfecta) or as a consequence of the associated Chiari I malformation (e.g. in cases of atlanto-occipital assimilation). Overt or subclinical respiratory dysfunction is commonly overlooked in both adults and children with cranial vertebral junction anomalies. Respiratory sleep studies may be helpful in the investigation of selected cases. Botelho et al. (2003) found that the incidence of sleep apnoea and hypopnoea syndrome were significantly higher in patients with CVJ malformation compared with controls. A history of poor sleep, snoring and morning tiredness and headache may be significant.

Pain is a common presenting feature with occipital, neck or cervical pain being present in 85% cases of CVJ abnormality. The combination of posterior headache with brainstem or cerebellar features such as ataxia, vertigo, hyperacusis or tinnitus is referred to as basilar type migraine and has been reported in 25% of children with basilar invagination (Menezes 2008).

**Examination**

Features of myelopathy are the commonest clinical findings in symptomatic craniovertebral anomalies and are present in as many as 85% of patients (Menezes 2008). Cranial nerve dysfunction is also well recognised. Menezes (2008) reported that hearing loss was the commonest cranial nerve deficit, occurring in 23% of cases. Lower cranial nerve dysfunction, sometimes in combination with brainstem compression, can produce reduced gag reflex and poor oropharyngeal co-ordination leading to dysphagia or aspiration. Video swallow studies may identify particular patients at risk. Bulbar electromyography similarly can be of help in selected cases.

Neck position and range of movement are often abnormal in CVJ anomalies. The short neck with reduced range of motion is characteristic of segmentation disorders while a fixed torticollis posture implies asymmetry as seen in cervical hemivertebrae, partial atlanto-occipital assimilation or atlanto-axial rotatory fixation.

**SPECIFIC DISEASES ASSOCIATED WITH CRANIOVERTEBRAL ANOMALIES**

Spinal involvement and neurological compromise are features of many of the skeletal dysplasias (Song and Maher 2007; McKay et al. 2012). The following conditions are among the more commonly encountered and exemplify particular aspects of craniovertebral disease.

**DOWN SYNDROME**

Atlanto–axial instability is the most prevalent craniovertebral anomaly in Down syndrome; however, there has been considerable controversy surrounding the role of routine radiological screening, the threshold for surgical intervention and the necessity to curtail physical activities (Pueschel 1998; Brockmeyer 1999). Studies in Down syndrome have cast some doubt on the utility of cervical spine radiographs in the routine evaluation of atlanto–axial instability. Firstly, there is no consensus on what ADI distance (the conventional radiological measure of instability, see Investigating Instability) constitutes a diagnosis of atlanto–axial instability nor indeed what distance constitutes a threshold for concern, with authors using from 3mm to 6mm. Secondly, the natural history of atlanto–axial instability in Down syndrome is unclear with some longitudinal studies suggesting a trend toward
decreasing ADI over time (Pueschel and Scola 1987; Morton et al. 1995), while others have reported the opposite (Burke et al. 1985). Indeed in one study, radiographs performed on the same day yielded differing results for ADI in six of 19 children leading the authors to conclude that X-rays were an unreliable means of diagnosing AAI and their use could not be supported as a screening test (Selby et al. 1991). A further factor is the prevalence of atlanto–axial instability in Down syndrome and its poor correlation with symptoms. Between 10–20% of individuals with Down syndrome will have radiological evidence of AAI, yet only 1–2% have clinical symptoms that might be attributed to this (Pueschel and Scola 1987; Pueschel et al. 1992). In one study of 84 patients with Down syndrome, 17 had radiological evidence of subluxation among whom there were five with symptoms. By contrast, in the 67 without subluxation 18 had symptoms (Ferguson et al. 1997). The available evidence therefore suggests that in Down syndrome the correlation between instability as measured by ADI and neurological symptoms is far from clear. Current UK guidelines advise against routine radiological screening for AAI in the population with Down syndrome but emphasise the importance of raised awareness of the potential for cervical spine disease in this group and the recognition of warning symptoms such as cervical pain, head tilt, limb weakness and gait disturbance. (For current UK guidelines go to www.dsmig.org.uk.)

ACHONDROPLASIA

Narrowing of the entire spinal canal is a characteristic of achondroplasia. However, it is stenosis at the foramen magnum that presents most commonly in childhood and is the most frequent reason for neurosurgical intervention in this age group, hydrocephalus being the second (King et al. 2009). The clinical presentation of foramen magnum stenosis is weakness with regression of motor milestones and hyperreflexia in the limbs. Respiratory symptoms of disordered breathing, snoring or apnoea are present in almost half of cases requiring surgery (Bagley et al. 2006) and may be both obstructive and central in origin (Aryanpur et al. 2009). Respiratory sleep studies are now recommended as part of the regular evaluation of these children (Julliand et al. 2012). Sudden unexpected death is well recognised in this population. In one study, five out of 11 children who died suddenly were found to have cervico-medullary compression (Pauli et al. 1984). Where obstructive respiratory symptoms predominate adenotonsillectomy should be considered prior to craniovertebral decompression.

Foramen magnum stenosis in achondroplasia begins in infancy and radiological evidence of stenosis is present in up to 70% of infants in some case series (Reid et al. 1987; Pauli et al. 1995), although symptoms or signs of cervicomedullary compression were present in only 15–35% of patients in these studies. It is thus important to recognise that potentially significant stenosis may develop without obvious symptoms and thus spinal MRI is recommended within the first year or so of life even for asymptomatic individuals (Keiper et al. 1999). MRI findings include narrowing in both the coronal and sagittal planes due to a combination of bone and ligamentous thickening, effacement of CSF spaces and signal change within the medulla or spinal cord (Fig. 6.15). True craniovertebral instability is rare in achondroplasia; however, due to the narrow foramen magnum even the normal range of motion may be sufficient to cause dynamic cervicomedullary compression in these children (Mukherjee et al. 2014). While dynamic MRI is not part of the routine evaluation of these children it should be considered in children who have clinical symptoms without overt compression on static MRI.

Eighty per cent of craniovertebral decompressions in achondroplasia are deemed necessary within the first 5 years of life (Aryanpur et al. 2009; King et al. 2009). Marked thickening of the bone, a deep occipital keel and unusually medial position of the vertebral arteries pose specific surgical challenges in achondroplasia, and while surgery will result in neurological and respiratory improvement in the majority of cases strict clinical and radiological criteria need to be applied to the selection of cases (Reina et al. 2014).

MORQUIO SYNDROME AND THE MUCOPOLYSACCHARIDOSES

Involvement of the CVJ and cervical spine is a feature of mucopolysaccharidoses (MPS; see Chapter 9): MPS IH (Hurler), MPS IH-S (Hurler Scheie), MPS1-S (Scheie), MPS II (Hunter) and MPS VI (Morateaux-Lamy); however, it is in Morquio syndrome (MPS-IV), the commonest of the MPS disorders, that craniovertebral involvement is particularly

![Figure 6.15](image-url) T2-weighted image showing foramen magnum stenosis with cervicomedullary signal change in a patient with achondroplasia.
prevalent and responsible for significant morbidity and mortality. Spinal abnormalities are mild or absent at birth but appear within the first 2 years of life and are progressive thereafter.

The characteristic radiological changes include odontoid hypoplasia, extradural soft tissue thickening (due to infiltration with glycosaminoglycans), platyspondyly and ligamentous laxity (Hughes et al. 1997; Solanki et al. 2013a). These changes result in CVJ instability in at least half of cases (Harmatz et al. 2013). Spinal cord damage occurs secondary to atlanto–axial instability and compression from a narrow C1 and may become severe without obvious clinical symptoms or signs. Rapidly evolving myelopathy or sudden tetraparesis are well recognised thus emphasising the need for regular radiological surveillance (spinal MRI and dynamic X-rays) from infancy (Solanki et al. 2013b). Progressive radiological changes, signal change within the spinal cord or emerging neurological symptoms are the usual indications for surgery (Fig. 6.16). As a result of the particularly high incidence of craniovertebral involvement in this disease coupled with improved surgical outcome in children prior to the development of myelopathy some authors have recommended prophylactic fusion in this group of children (Ransford et al. 1996). Surgery, therefore, tends to be required early in children with Morquio disease. The mean age at surgery was 5 years 3 months in one recent large series (Dede et al. 2013) and this would be in keeping with the authors experience. Surgery typically entails decompression (removal of the posterior arch of C1) and concomitant fusion from the occiput to C2. Successful fusion can be anticipated in the majority of patients however, there remains a risk of late deformity or junction instability, i.e., increased movement at remaining mobile segments adjacent to the fused segment (Dede et al. 2013).

While enzyme replacement therapy (see Chapter 9) has had beneficial effects on the systemic aspects of MPS I (and its subtypes), II and VI (Desnick 2004), there is currently no evidence that it halts the progression of spinal disease.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta is a disorder of Type I collagen synthesis. OMIM currently lists 13 types of osteogenesis imperfecta (OMIM 2014). The majority are due to mutations in either COL1A1 or COL1A2 genes. The CVJ anomaly associated with osteogenesis imperfecta is progressive basilar invagination and is a particular feature of osteogenesis imperfecta types III and IV. Clinically significant basilar invagination is rare in the first decade, the symptom onset tends to be in adolescence or young adult years (Ibrahim and Crockard 2007; Sawin and Menezes 2009).

Presentation is with headache and cranial nerve dysfunction which were present in 76% and 68% respectively in the series described by Sawin (Sawin and Menezes 2009). Hydrocephalus was present in 32%. Trigeminal neuralgia due to stretching of the Vth nerve is also common (Hayes et al. 1999).

Neurosurgical treatment is reserved for symptomatic cases. Because of the basilar invagination surgery will often necessitate anterior decompression as well as posterior fixation and thus surgical morbidity can be significant. Timing of surgery is important. In expert hands stabilisation or symptomatic improvement can be anticipated so long as intervention is carried out early in the evolution of symptoms (Ibrahim and Crockard 2007).

Intravenous infusions of disodium pamidronate have been shown to improve bone density and reduce the incidence of fractures in patients with osteogenesis imperfecta. There is some evidence that treatment commenced early in childhood may prevent basilar invagination (Aström et al. 2007).

SPONDYLOEPIPHYSEAL DYSPLASIA

Spondyloepiphyseal dysplasia (SED) is an autosomal dominant chondrodystrophy, characterised by dwarfism, barrel chest and limb shortening with coxa vara, though with normal sized hands and feet. It is a disorder of Type II collagen. Allied disorders include Kniest dysplasia and Strudwick dysplasia and in each there is hypoplasia of the odontoid and ligamentous laxity that predisposes to atlanto–axial instability.

Children with the early onset form of the disease (SED congenita) are more severely affected and at greater risk of myelopathy. Atlanto–axial instability tends to worsen over time (Miyoshi et al. 2004). The sagittal diameter of the spinal canal is often narrowed at the level of the atlas, even after reduction of instability due to abnormal shape of the posterior arch of the atlas; C1 laminectomy is therefore commonly required at the time of occipitocervical fixation (Nakamura et al. 1998).
Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

Part III

ATLANTO–AXIAL ROTATORY FIXATION

In contrast to the other conditions described in this chapter, atlanto–axial rotatory fixation (AARF) is an acquired abnormality; however, it is included here as it is an anomaly of the craniovertebral region that is almost exclusively seen in the paediatric population and is a common cause of missed or delayed diagnosis (Schwarz 1998). The clinical presentation is with torticollis, the ‘Cock Robin’ appearance of rotation and lateral flexion. This is initially painful though pain may settle over a period of a few days. A prior history of upper respiratory tract infection or tonsillitis (Grisel syndrome) or onset following anaesthesia (particularly for ENT procedures) is well described (Deichmueller and Welkoborsky 2010). In some cases there may have been minor trauma or some predisposition to ligamentous laxity, for example Down syndrome, though in one-quarter of cases no apparent cause can be identified. Neurological injury is exceedingly unusual, as the adjacent ligaments remain competent.

The pathophysiology of AARF relates to excessive rotation of C1 with respect to C2. The degree of rotation and the presence of any residual movement at the joint form the basis of the original classification for this disorder by Fielding and Hawkins (1977) more recently refined by Pang and Li (2005a). Establishing the diagnosis requires dynamic high resolution CT performed in the position of deformity, the neutral position and after attempted contralateral movement (Fig. 6.17). In simple muscular torticollis realignment will be demonstrated whereas in AARF the relative positions of C1 and C2 remain abnormal despite neck turning.

Some cases resolve spontaneously or with the use of regular muscle relaxants and analgesia. For cases that fail to respond to these simple measures treatment must be escalated. The majority of cases can be successfully reduced by manipulation under anaesthesia or application of halo traction. Once anatomical reduction is achieved the neck needs to be immobilised in halo-body orthosis for up to 3 months. In cases that present late chronic subluxation may develop reducing the chances of successful reduction and increasing the risk or recurrence and the need for definitive surgical fusion between C1 and C2 (Pang and Li 2005b).

TREATMENT OF CRANIOVERTEBRAL JUNCTION DISORDERS

The principles underlying the management of craniovertebral disorders in children can be summarised as follows (Table 6.3).

Restoration of Normal Alignment

This may be achieved though skeletal traction, reduction under anaesthesia or incremental traction in a halo-body jacket. This latter technique can be useful in young patients unable to tolerate conventional skeletal traction; a halo-body orthosis is applied that is then distracted at intervals until optimal alignment is achieved.

Decompression of the Neuraxis

Where the brainstem or spinal cord is compressed after restoring normal alignment then decompression is indicated. This will most commonly be performed through a posterior approach; however, where there is ventral compression a transnasal or transoral approach will be indicated in addition (Hankinson et al. 2010).

Stabilisation of Unstable Segments

When there is instability, either as a result of the underlying disease or as a consequence of surgical decompression, then internal fixation will be required. A variety of techniques are available using autologous bone or instrumented fixation. The extent of fixation (e.g. whether or not to include the occiput) will depend on the underlying pathology and age of the child, but in general terms the aim is to keep fusion segments as short as feasible in order to optimise long-term mobility.
NORMAL VARIANTS OF THE CRANIOVERTEBRAL JUNCTION

There are a number of radiological variants that occur in the craniovertebral region that are a common source of anxiety for the parent and physician but which are either within the range of normal or do not have clinical significance.

OSSICULUM TERMINALE

Also known as Bergman ossicle, this is a small bony structure sometimes seen at the apex of the odontoid process. It is considered to be a developmental remnant that would ordinarily have formed the tip of the dens. It is readily distinguishable from a dens fracture. Its margins are usually smooth and well corticated, it is smaller than an os odontoideum and in contrast to the latter it has no implications in terms of instability.

C2/3 PSUEDO SUBLUXATION

Apparent forward displacement of the body of C2 with respect to C3 is commonly seen in paediatric patients. In one study 46% of children under 8 years had evidence of ‘pseudo-sUBLUXation’ (Cartell and Filtzer 1965) on cervical X-rays. This appearance commonly raises concerns about stability particularly in cervical spine X-rays performed after trauma. The absence of bony fracture, the mechanism of trauma and absence of clinical features of neck pain or tenderness are usually sufficient to allay anxiety.

ATLAS ANOMALIES

Anterior or posterior spina bifida at C1 is a normal finding in children up to 4 years of age and represents incomplete ossification of the C1 ring and has no sinister connotations. Such abnormalities can persist beyond this age, e.g. in Down syndrome. Rarely, there is complete absence of the posterior arch of C1 which, in the absence of clinical symptoms, is not usually significant as the transverse ligament remains competent.

A wide variety of musculoskeletal syndromes commonly involve the craniocervical region. The prevalence and pattern of craniovertebral involvement can often be predicted according to the underlying genetic syndrome or skeletal dysplasia. This in turn can help to determine the appropriate level of clinical surveillance and the most relevant radiological investigations. A management strategy can then be formulated that takes into account the perceived natural history of the disorder, the skeletal maturity of the child and the protection of the neuraxis.

Hydrocephalus is one of the most important conditions in paediatric neurology because treatment can prevent, reduce or limit brain injury and disability. Although treatable, hydrocephalus is a chronic disorder, responsible for 69000 hospital admissions annually in the United States and accounting for three times as many hospital days and dollars as cystic fibrosis (Simon et al. 2009). This chapter will consider all types of hydrocephalus from fetal life to late childhood and, for convenience, will cover non-traumatic pericerebral fluid collections.

DEFINITION OF HYDROCEPHALUS

Hydrocephalus means an excess of fluid within the cranium. However, it is customary to reserve the term for the condition in which the volume of cerebrospinal fluid (CSF) is increased in all or part of the intracranial fluid spaces, and is not the result of primary atrophy or dysgenesis of the brain. The abnormal accumulation of CSF is associated with increased pressure, at least in the initial stages of the disorder.

PHYSIOLOGY OF CSF

The greater part of the CSF is secreted actively by the choroid plexus. Experiments in animals indicate that 35% or more of the CSF, depending on species, may come from extraplexic sources. In humans, it is estimated that 70–90% of the fluid originates from the choroid plexus (McComb 1983); the remainder originating in brain parenchyma as a result of exchanges with cerebral extracellular spaces.

Rate of CSF Production

The daily formation of CSF in children and adults is about 500ml. The night and day rhythm of secretion is relatively stable and amounts to 0.35ml/min in adults. The total volume of CSF in the head of an adult is about 120ml, and the average ventricular volume is around 25ml, although individual variations occur. In the neonate, CSF volume is about 50ml.

Mechanism of CSF Production

Secretion of CSF results from a two-step process. The first step is the formation, by hydrostatic pressure, of a plasma ultrafiltrate through the choroidal capillary endothelium, which is devoid of tight junctions. The second step transforms the ultrafiltrate by an active metabolic process within the choroidal epithelium. The rate of CSF formation is relatively stable and independent of pressure.

Route of CSF Flow

CSF flows from the lateral ventricles through the lateral and third ventricles and reaches the fourth ventricle through the aqueduct of Sylvius. Figure 7.1 shows the main pathways of CSF flow. Passage through the aqueduct is fast, and its pulsatile nature has been demonstrated by dynamic magnetic resonance imaging (MRI) techniques (Greitz et al. 1994). Although these pulsations probably play a significant role in CSF circulation, they have not yet been shown to play a role in the pathophysiology of hydrocephalus (Czosnyka et al. 2004). CSF then flows through the foramina of Magendie, into the posterior fossa and then the basal cisterns. CSF flow then divides, most of the CSF passing upward through the incisura and reaching the parasagittal arachnoid villi via the ambient cisterns, the sylvian fissures and the convexity cisterns. About 20% of the fluid flows downward through the foramen magnum along the spinal subarachnoid space to the arachnoid villi along the nerve root sleeves. This flow is maintained by continuous entry of newly secreted CSF into the ventricles.

CSF Resorption

Most of the CSF is resorbed passively through the subarachnoid villi (granulations of Pacchioni) along the superior sagittal sinus, into the sinus blood flow. The CSF pressure is normally greater than venous blood pressure. A pressure gradient of 20–50mm H₂O is necessary to allow resorption into the venous sinuses through the arachnoid villi. Three additional mechanisms
for CSF re-absorption have been proposed: (1) an energy-consuming pinocytotic process by which intracytoplasmic vacuoles are transported from one side of the arachnoid membrane to the other; (2) transport via olfactory nerves, cribriform plate and nasal lymphatics (Koh et al. 2005); and (3) transependymal absorption across brain tissue into blood vessels (Greitz and Hannerz 1996). The villi in the arachnoid granulations provide a greatly increased surface area available for re-absorption. However, newborn infants do not have visible arachnoid granulations nor any arachnoid villi on microscopy. The absence of such structures may mean that CSF is absorbed by other routes in the neonate or that maximum capacity for re-absorption is less than in the adult. A significant amount of CSF may be resorbed via cervical lymph vessels (McComb 1983) and via the spinal cord (Koh et al. 2005). This pathway may be of importance in hydrocephalus.

CSF Pressure
The hydrostatic pressure of the CSF (synonymous with intracranial pressure [ICP]) is determined by the CSF secretion pressure and from the resistances to its circulation and resorption. Normal intracranial (or CSF) pressure at the level of the foramen of Monro is 100–150mmH₂O in children and adolescents at rest in the lying position. In the newborn infant, CSF pressure is lower, around 40–50mmH₂O (Kaiser and Whitelaw 1986).

PATHOPHYSIOLOGY OF HYDROCEPHALUS
Except in the rare cases of CSF hypersecretion, hydrocephalus is virtually always due to an increase in the resistance of CSF circulation pathways resulting in an increase in CSF pressure. Table 7.1 lists the various sites and mechanisms by which this may occur.

Increased resistance may be located within the ventricular system, in the posterior fossa, in the cisterns or subarachnoid spaces or at the sites of resorption. CSF flow is a function of the difference between CSF and venous sinus pressures, divided by the resistance of pathways. As CSF production is stable over a relatively wide range of pressures, an increase in CSF pressure is inevitable when there is impaired absorption. The magnitude of the effects of this increase in pressure will depend largely on the yield pressure or compliance of the brain and skull.

Low versus High Compliance
When the brain and skull are highly compliant (low yield pressure), there is rapid ventricular enlargement, large final ventricular size, decline in intraventricular pressure (IVP) and relatively low final pressure after compensation. This is the situation in newborn (CSF) infants. In contrast, with low compliance (high yield pressure), ventricular enlargement is slow, final ventricular size is relatively small, IVP remains high for long periods, and final pressure after compensation remains high. This situation obtains in older children and in adolescents, and also in fetuses, in which pressure from the uterine wall limits ventricular enlargement (Oi et al. 1990). In such cases, severe hydrocephalus with high pressure can develop with deceptively little ventricular dilatation (Jones 1987).

CSF Pulse Pressure
In addition to an increase in mean ICP, CSF pulse pressure probably plays an important role in the determination of some aspects of hydrocephalus. Flow through the aqueduct is synchronous with the systolic contraction (Marks et al. 1992). CSF pulse pressure designates the systolic–diastolic
variations in CSF pressure that result from those of arterial blood pressure transmitted by arterial wall pulsations to the CSF. The amplitude of the CSF pulse pressure varies with the mean ICP and rises sharply with increasing mean CSF pressure. Pulse pressure also depends on ventricular compliance and on the rapidity with which outflow of venous blood and CSF can compensate for the instantaneous pressure rise. CSF pulse pressure has a significant role in determination of ventricular size. An experimental three-fold increase in the pulse amplitude causes hydrocephalus in animals (Avezaat et al. 1979).

Hydrocephalus and Secondary Pathological Changes

Later effects of increased ICP and dilatation of the CSF spaces include the progressive development of cerebral atrophy that predominantly affects white matter and, in turn, facilitates further ventricular dilatation. There is splitting of the ependymal lining, spongy dissociation of nerve fibres and, eventually, development of astrocytosis (Da Silva 2004). The grey matter is preserved longer. Reduction of cerebral blood flow, in particular in the anterior cerebral arteries, may play a role by inducing ischaemic injury to the cerebral hemispheres (Hill and Volpe 1982).

In addition to the physical effects of pressure, oedema and distortion, there is evidence that inflammation and free radical injury may contribute to white matter injury in posthaemorrhagic hydrocephalus. High concentrations of pro-inflammatory cytokines have been demonstrated in posthaemorrhagic CSF (Sävman 2002) as have free iron and hypoxanthine both of which can generate highly reactive radicals (Bejar et al. 1983; Sävman et al. 2001). Such periventricular damage would be likely to lead to motor deficits but cognitive and sensory functions might be injured and epileptic foci initiated if the effects were more widespread in the small immature brain.

Eventual Course of Hydrocephalus

The eventual course of hydrocephalus will depend on the achievement of a new balance between CSF production, preservation of residual absorption capacity and development of alternative resorption pathways. If, and when, resorption and secretion of CSF equalise under a stable regime of pressure, stabilisation of hydrocephalus occurs but at the expense of a variable degree of stable ventricular dilatation.

In addition, one may observe modifications in the shape of the skull, which may expand frontally with aqueductal stenosis, whereas a fourth ventricle cyst, as in Dandy–Walker malformation, may impede caudal migration of the tentorium, which inserts on the parietal bones in an abnormally high situation. Similar mechanisms may be responsible for the skull changes that are present in hydrocephalus associated with spina bifida (Britton et al. 1988).

**Epidemiology of Hydrocephalus**

Prevalence of congenital hydrocephalus, including cases with myelomeningocele, was 1.3–2.9 per 1000 births in 1961 (Myrianthopoulos and Kurland 1961). Over the last 50 years, congenital hydrocephalus has decreased because of folate supplementation and, in some jurisdictions, because of antenatal diagnosis and termination of pregnancy. Neonatal hydrocephalus was diagnosed in approximately 0.5 per 1000 live births in Sweden (Fernell et al. 1994).

Among preterm infants, hydrocephalus acquired postnatally from intraventricular haemorrhage (IVH) has increased several times as survival has increased. Posthaemorrhagic hydrocephalus is now the commonest type of hydrocephalus in infants with a prevalence of about 0.3 per 1000 live births in the United Kingdom. Reliable figures for the total prevalence of hydrocephalus at all ages are not available.

**Classification, Age and Presentation of Hydrocephalus**

The major causes of hydrocephalus vary greatly according to the age at presentation and this is shown in Table 7.2.

**Communication or Non-Communication**

Clinical manifestations and treatment decisions differ considerably according to age at onset and cause. It is conventional to classify hydrocephalus according to whether there is normal communication between the ventricular system and the subarachnoid space. In non-communicating hydrocephalus, a lumbar puncture yields only a few drops of CSF; usually less than 2ml.
In communicating hydrocephalus, a lumbar puncture produces free flow of CSF. Non-communicating hydrocephalus tends to give higher ICP and a more rapid progression. However, hydrocephalus is an evolving condition which can change from non-communicating to communicating and from chronic to acute.
of lower cranial nerves, and respiratory or swallowing difficulties that in some cases can be alleviated by treatment of the hydrocephalus alone. Chiari type I malformation is commonly associated with hydrocephalus in adults without myelomeningocele but with basilar osseous abnormalities (Levy et al. 1983). Such cases are rare in children.

Aqueductal Obstruction

Atresia or stenosis of the aqueduct can either be due to malformations, some of them genetically determined, or be acquired as a result of infection, haemorrhage or other mechanisms (Landrieu et al. 1979). The pathology is variable. It includes simple stenosis; forking characterised by division of the aqueduct into two or several channels, most of them ending blindly; glial membrane located at the intercollicular sulcus level, which seems to have a special relationship to neurofibromatosis type 1; and simple gliosis surrounding the stenosed aqueduct. In some cases there is wide dilatation of the upper part of the aqueduct. Such anomalies do not need to represent a primary abnormality but can be a consequence of acquired events either prenatally or after birth following IVH or bacterial meningitis.

Malformative stenosis may be associated with neighbouring anomalies such as ‘beaking’ of the collicular plate, suggesting that they may represent a mild form of dysraphism. With the use of MRI it has become clear that many cases of the so-called idiopathic aqueductal stenosis were in fact due to lesions encroaching on the aqueduct (Fig. 7.3), especially slow growing tumours of the quadrigeminal plate or periaqueductal and ‘pencil’ brainstem tumours. In a series of 71 patients with triventricular hydrocephalus (Valentini et al. 1995), MRI revealed such lesions in 15 of the 25 patients studied. A number of these tumours were associated with neurofibromatosis. None was progressive after 1–5 years follow-up, but regular examination is clearly indicated.

Genetics and Aqueductal Stenosis

Hydrocephalus may have a genetic cause (Table 7.3). L1 syndrome is the most common genetic cause of congenital aqueductal stenosis. It accounts for 5–10% of males with congenital hydrocephalus (Verhagen 2011). The L1 syndrome is caused by mutations in the neural cell adhesion molecule L1 (L1CAM) gene at Xq28. The abnormal cell adhesion molecules result in abnormal brainstem cell migration (Jouet et al. 1994; Jouet 1995). The phenotypic spectrum is variable and includes X-linked hydrocephalus with stenosis of the aqueduct of Sylvius (HSAS), MASA (mental retardation, aphasia, spastic paraplegia and adducted thumbs) syndrome, X-linked complicated hereditary spastic paraplegia type 1 and X-linked complicated corpus callosum agenesis (Verhagen 2011). The spectrum of conditions related to mutations in this gene has been broadened to form the so-called CRASH (corpus callosum agenesis, retardation, adducted thumbs, spastic paraplegia and hydrocephalus) syndrome (Fransen et al. 1995; Silan et al. 2005). Mutation analysis of the L1CAM gene should be performed in all males with non-syndromic aqueduct stenosis. As hydrocephalus is described in about 5% of female carriers, mutation analysis of the L1CAM gene should also be considered in (mildly) affected females, especially if there is a positive family history of congenital hydrocephalus or in the presence of aqueduct stenosis of Sylvius, corpus callosum agenesis or adducted thumbs. Other types of hydrocephalus without
Part III  Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

Dandy–Walker Malformation

Dandy–Walker malformation is an uncommon cause of hydrocephalus, accounting for less than 2% of cases. The essential features are absence of the cerebellar vermis and enlargement of the posterior fossa. Prenatal diagnosis is possible (Fig. 7.4a). In most cases, hydrocephalus is not present at birth but develops during the first year of life (Hirsch et al. 1984). The shape of the head, with a posterior bulge, may be suggestive, but the diagnosis rests on neuroimaging (Hanigan et al. 1984) (Fig. 7.4b). The condition is not usually familial although some cases are due to chromosomal aberrations, and great care should be taken not to confuse the Dandy–Walker syndrome proper with other causes of agenesis or hypogenesis of the cerebellar vermis, which often belong to genetic syndromes (Bordarier and Aicardi 1990; see Chapter 5).

Walker–Warburg Syndrome

Walker–Warburg syndrome comprises type II lissencephaly, congenital hydrocephalus, severe neurological dysfunction from the first days of life, retinal dysplasia, microphthalmia and abnormalities of the anterior chamber of the eye. The association of eye anomalies and hydrocephalus may wrongly suggest a fetal infection but the condition is familial with a 25% recurrence risk. The presence of Peters anomaly, retinal detachment or falciform fold of the retina should always raise the possibility of this syndrome, which may also include an abnormal posterior fossa reminiscent of the Dandy–Walker syndrome (Bordarier et al. 1984).

Other Malformations and Hydrocephalus

Other malformations associated with hydrocephalus include encephaloceles, which are approximately as common as the Dandy–Walker malformation, as well as a miscellany of malformation syndromes, some of which are of chromosomal origin (Chapter 5), and some are genetically determined (Waaler and Aarskog 1980; Herva and Seppäinen 1984). Agenesis of
the corpus callosum is often associated with marked ventricular dilatation and a large head (Chapter 3). Although virtually nothing is known about the hydrodynamics of such cases, experience indicates that many of these eventually stabilise, so that shunting should be resorted to only in the face of evident progression in patients with callosal agenesis. Agenesis of the granulations of Pacchioni and arachnoid villi is exceptional.

Not all malformations are genetically determined. It is important to realise that the same type of malformation can be due to either genetic or acquired factors, that this cannot often be determined for a particular case, and that no aetiological specificity exists. Therefore, no genetic classification is universally applicable. While it is believed that malformations tend to occur early, the lack of glial response to insults in the first half of gestation can make scar lesions acquired early in pregnancy indistinguishable from primary genetic errors. A significant proportion of cases of congenital hydrocephalus result from disorders or accidents incurred during fetal life, including infections usually of maternal origin such as toxoplasmosis, prenatal haemorrhage and congenital tumour (Fernell et al. 1994). Important causes of fetal IVH include allo-immune thrombocytopenia and inherited coagulation factor deficiency (Whitelaw et al. 1984; Povoa et al. 2007).

**DIAGNOSTIC METHODS FOR FETAL HYDROCEPHALUS**

**Ultrasonography**

Ultrasonography is the first imaging method used in diagnosis of fetal hydrocephalus (Fig. 7.5). Dilated ventricles may be recognised on routine scanning or during targeted scanning because of perceived risk such as a previous infant with a neural tube defect. Ventricular width at the level of the atria varies little between 20 and 40 weeks. Mean width is 6–7mm on each side. Based on analysis of 8216 fetuses, 10mm is 3 standard deviations above mean and has been defined as an upper limit of normal ventricular width (Almog et al. 2003). The shape of the ventricles or asymmetry of the ventricles may be a diagnostic clue.

**Magnetic Resonance Imaging**

MRI can better demonstrate the ventricular system as well as the rest of the CNS. MRI is not a routine technique as it requires either fetal immobilisation or rapid MRI techniques. It is thus indicated for cases with abnormalities detected by sonography and not clearly diagnosed by this sole investigation (Oi et al. 1998). Differential diagnosis includes agenesis of the corpus callosum with dilatation of the posterior horns, cysts of the choroid plexus and holoprosencephaly.

**Associated Anomalies**

The search for associated anomalies is of extreme diagnostic importance. A careful search for facial, limb, renal, cardiac and other intracranial abnormalities must be part of the examination. Associated abnormalities may be of grave prognostic significance. In the series of Nyberg et al. (1987) they were present in 85% of 61 fetuses with prenatal hydrocephalus, and the mortality rate for these was 66%. Similarly, associated malformations herald a poor prognosis in cases of apparently stable ventriculomegaly (Drugan et al. 1989).

When fetal hydrocephalus is suspected on sonographic examination, a complete investigation including karyotype, determination of alpha-fetoprotein and search for specific infectious agents by serology or by fetal blood sampling, has to be considered.

**OUTCOME OF FETAL VENTRICULOMEGALY**

The presence of ventriculomegaly cannot be equated with a diagnosis of hydrocephalus. Cases of isolated ventriculomegaly without other abnormalities (21 of 47 in the series of Hudgins et al. 1988) may resolve before birth and be compatible with normal development (Serlo et al. 1986). Goldstein et al. (2005) found that 26 of 34 infants in whom ventricular width at the level of the atrium was 10–15mm were normal at age 2 years. Gaglioti et al. (2005) followed 176 infants with mild (10–12mm), moderate (12.1–14.9mm) and severe (≥15mm) dilatation. The proportions of children with normal development in the three groups were respectively 93%, 75% and 62.5%. Parilla et al. (2006) found that mild prenatal ventricular dilatation disappeared in 41% of their cases, remained stable in 43%,
and progressed in only 16%. It thus appears that mild dilatation has an excellent prognosis in fetuses without detectable malformations and a normal karyotype, and often disappears as gestation progresses. Asymmetrical mild/moderate dilatation may have a similarly good outcome (Durfee et al. 2001).

OUTCOME AND MANAGEMENT OF FETAL HYDROCEPHALUS

The overall prognosis of fetal hydrocephalus (progressive ventricular dilatation) is poor. In many cases, spontaneous abortion or stillbirth results. The outcome of intratuteric shunting operations is not encouraging, and most centres do not use the procedure (Bruner et al. 2006). In one series (Futagi et al. 2002), only three of 58 fetuses survived and developed reasonably. Depending on the jurisdiction, parents and clinicians may opt for termination of pregnancy for hydrocephalus of very early onset or with associated malformations and/or chromosome abnormalities (Serlo et al. 1986). In cases with a relatively thick mantle and slow progression, when parents decide to go on with pregnancy, delivery will usually be by Caesarean section. Renier et al. (1988) included in their study only patients with head circumference at birth more than 2 standard deviations above the mean. The survival rate of their 108 patients was 62% at 10 years. Only 21 of the 75 survivors had an IQ ≥80, and 16 were of borderline intelligence. Kirkinen et al. (1996) found that seven of 25 infants diagnosed during pregnancy (excluding cases with associated malformations and/or lethal syndromes) were severely disabled, and six had intermediate disability. They consider that termination should be considered if there are associated anomalies or chromosomal disorder, and if rapidly increasing ventricular dilatation is found on repeated ultrasonography.

Fetal Surgery

Prenatal repair of myelomeningocele reduced hydrocephalus impressively in a randomised clinical trial (Adzick et al. 2011); 158 women pregnant with a fetus with myelomeningocele were randomised to prenatal open closure or to postnatal closure. Only 68% of the prenatally closed infants died or required shunt surgery compared to 98% of the postnatally closed infants. Only 40% of the prenatally closed infants had shunt surgery versus 82% in the postnatally closed group. Prevention of hindbrain herniation was thought to be responsible. The downside of prenatal closure was an increased risk of death and complications from preterm delivery. However, there was a significant improvement in development at 30 months in the prenatally closed group.

HYDROCEPHALUS PRESENTING IN THE FIRST POSTNATAL YEAR

All of the causes of fetal hydrocephalus may present at birth or soon afterwards, depending on the level of fetal investigation and intervention. Important causes of postnatally acquired hydrocephalus include IVH in preterm infants (now the commonest), intracranial haemorrhage from birth trauma, postnatal infection, cysts and tumours.

Posthaemorrhagic Hydrocephalus

The term, posthaemorrhagic ventricular dilatation (PHVD) is often used by neonatologists and imagers to identify the early stages of hydrocephalus before there is excessive head enlargement. Although the ventricles are enlarged when there is atrophic loss of white matter, the term PHVD is intended to apply to CSF-driven ventricular enlargement with raised pressure. A minority (around 30% depending on definitions) of cases of PHVD are transient and do not continue to expand. The initial mechanism of PHVD is thought to be multiple blood clots obstructing the channels for re-absorption of CSF (Fig. 7.6). When older infants with posthaemorrhagic hydrocephalus came to autopsy, fibrosis of the basal cisterns and meninges together with subependymal gliosis is described (Larroche 1972) (Fig. 7.7). This can be likened to scar formation or repair gone wrong. Intraventricular injection of blood in rat pups produced PHVD in the majority and showed parenchymal and perivascular deposition of extracellular matrix proteins, probably due, in part, to upregulation of transforming growth factor beta (TGFβ) (Cherian et al. 2004). Extracellular matrix proteins such as laminin, fibronectin and vitronectin act like cement between cells and, together with TGFβ, are involved in many fibrotic diseases. Releasing ‘cement’ in and around the CSF spaces over a period of weeks is thought to be the mechanism by which re-absorption of CSF is inhibited. TGFβ1 is stored in platelets and is thereby present in large amounts in grades 3 and 4 IVH. In addition, the rat model showed
neuromotor abnormalities weeks later, activation of microglia and periventricular white matter injury. Vinukonda et al. (2010) studied spontaneous IVH in preterm rabbits after intraperitoneal injection of glycerol. This model also shows periventricular white matter injury, inflammation and extracellular matrix proteins. Cyclooxygenase-2 inhibition was the most effective agent in preventing PHVD injury and the associated neuromotor abnormalities.

Although some preterm infants can expand their head and ventricles with very little elevation of ICP, some do elevate pressure to levels than can interfere with cerebral perfusion e.g. 150–200mmH₂O (Kaiser and Whitelaw 1985) and thus injure the periventricular white matter. With the breakdown of large amounts of heme, considerable amounts of non-protein-bound iron are released into CSF and this may injure white matter through free radical generation (Sävman et al. 2001). Hypoxanthine is also released into posthaemorrhagic CSF and can injure by free radical mechanisms (Bejar et al. 1983). High concentrations of pro-inflammatory cytokines in the CSF in PHVD provide further support for inflammation being another damaging process (Sävman 2002).

Blood clot within CSF is cleared very slowly and some blood is often visible on ultrasound scans 2 months later. Fibrinolysis is relatively ineffective in CSF, probably because concentrations of plasminogen are very low and there are high concentrations of plasminogen activator inhibitor (Whitelaw et al. 1995; Hansen et al. 1997).

**Postinfectious Hydrocephalus**

**Bacterial and fungal ventriculitis**

Bacterial infections are an important cause of hydrocephalus as a result of adhesive arachnoiditis or granulations that may develop following the bacteriological cure of acute meningitis or in the course of a subacute or chronic meningitis, especially tuberculous meningitis. In the latter case, ventricular dilatation is often the result of both brain atrophy and increased CSF pressure. Computed tomography (CT) or MRI can show evidence of active arachnoiditis in the form of contrast enhancement of the meninges in the posterior fossa and basal cisterns (Chapter 2). Hydrocephalus may result from chemical meningitis due to fissuration of a dermoid cyst of the posterior fossa or spinal canal. The resulting arachnoiditis may also be due in part to added infection. Fungal infections include cryptococcosis and *Candida* meningitis, and occur especially in small preterm infants or immunosuppressed patients (Ciurea et al. 2004; see also Chapter 2). It is common for septation to occur after ventriculitis (Fig. 7.8a) resulting in localised accumulation and isolated areas of hydrocephalus (Fig. 7.8b).

**Parasitic Infections**

**Toxoplasmosis**

Intrauterine toxoplasmosis produces granulomas in the brain which often calcify. Hydrocephalus may result from aqueduct obstruction (often diagnosed antenatally) or a slower communicating hydrocephalus presenting after birth (Couvreur and Desmonts 1988) (Fig. 7.9). In exceptional cases, a late flare-up of an old periaqueductal cystic lesion has produced aqueductal stenosis in adolescents.

**Neurocysticercosis**

Neurocysticercosis in its racemose type can result in obstruction of the aqueduct or the cavities of the third and fourth ventricles or basal cisterns, thus provoking acute hydrocephalus (Cavalheiro et al. 2004).

**Viral Infections**

Viral infections are only exceptionally a cause of aqueductal stenosis. A few cases following mumps infection are on record.
Part III  Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

326

(Ogata et al. 1992; Lahat et al. 1993), and cases of cerebellar swelling have been reported associated with varicella, with Epstein–Barr virus infection (Roulet Perez et al. 1993), with prenatal lymphocytic choriomeningitis, and with human T lymphotrophic virus 1 (HTLV-1) infection (Tohyama et al. 1992).

Tumours

Tumours other than those obstructing the aqueduct are not a common cause of hydrocephalus in infants, in contrast to their high frequency in older patients. They generate hydrocephalus through variable mechanisms including blockage of CSF pathways by dissemination or compression. Congenital tumours may be associated with hydrocephalus (Chapter 14), although macrocephaly in such cases may also be due to the bulk of the tumour itself. Craniopharyngiomas and optic nerve gliomas usually manifest later. Aqueductal tumours that may be difficult to distinguish from simple aqueductal stenosis (Raffel et al. 1988) have been described above. Meningeal leukaemia or gliomatosis (Civitello et al. 1988), as well as meningeal dissemination of primary brain tumours can produce hydrocephalus through basilar obstruction or blockage of arachnoid cisterns of the convexity.

Mucopolysaccharidosis

Some mucopolysaccharidoses (Chapter 9), especially Hurler syndrome, commonly cause moderate hydrocephalus associated with extreme dilatation of the Virchow–Robin spaces due to infiltration of the meninges by mucopolysaccharides.

Cysts

Cysts of the meninges and other space-occupying lesions, in contrast to tumours, are not uncommon. Posterior fossa cysts

Figure 7.8  Post-ventriculitis hydrocephalus with septation in (a) sagittal cranial ultrasound scan, (E. coli ventriculitis) and (b) T2-weighted image (Candida ventriculitis).

Figure 7.9  Hydrocephalus following intrauterine toxoplasmosis. On ultrasound the periventricular echodensities are persistent and are due to calcified granulomata.
(Di Rocco et al. 1981; Barkovich et al. 1989), paramesencephalic arachnoid cysts (Grollmus et al. 1976) and suprasellar cysts (Pierre-Kahn et al. 1990) can all produce hydrocephalus. Suprasellar cysts are often responsible, in addition, for a special endocrinological syndrome (Brauner et al. 1987). Other space-occupying lesions, (e.g. retrocerebellar subdural cyst or haematoma) can rarely cause hydrocephalus.

**Venous Mechanisms**

Obstruction within veins and sinuses or compression of these structures has long been held responsible for hydrocephalus due to deficient resorption of CSF, although experimental ligation of veins is usually well tolerated in animals. It has been postulated that an increase in sinus blood pressure can be the cause either of the syndrome of benign intracranial hypertension (or pseudotumour cerebri) or of hydrocephalus, depending on the compliance of the skull. In infants with high compliance, hydrocephalus will result, whereas pseudotumour will obtain if the brain is rigidly encased in a virtually inextensible skull. In fact, diminished compliance of the brain is essential and is probably due to increased volume of the blood compartment of the skull thus augmenting the resistance (Karahalios et al. 1996). Abnormal increases in sinus pressure may result from an anatomical obstacle or from functional factors. The former includes stenosis of the venous foramina at the base of the skull, such as occurs with achondroplasia, certain types of craniosenosis (Sainte-Rose et al. 1984), tumours compressing or invading the sinuses (Kinal 1966), and thrombosis of jugular veins or superior vena cava (Haar and Miller 1975) as a result of catheterisation (Newman et al. 1980) or surgical operations. Such cases may potentially be improved by surgically widening the basal foramina (Lundar et al. 1990).

Functional abnormalities resulting in high venous sinus pressure are mostly due to high-flow arteriovenous malformations (Chapter 15), especially of the vein of Galen, which may also act through direct compression of the aqueduct. Rarely, a more distant arteriovenous shunt, such as produced by anastomosis of the right pulmonary artery to the superior vena cava in the setting of congenital heart disease, can produce a similar increase in intracranial venous pressure (Rosman and Shands 1978). Hydrocephalus produced by high venous pressure is generally of mild to moderate severity, although shunting has been necessary in a few cases (Haar and Miller 1975). Venous bypass between intracranial and extracranial circulations can also correct the hydrocephalus (Sainte-Rose et al. 1984), as does cure of an arteriovenous malformation.

**Hypersecretion of CSF**

Hypersecretion of CSF is observed in choroid plexus papilloma or carcinoma (Pascual-Castroviejo et al. 1983). In this case, haemorrhage from the tumour and mechanical impairment of CSF circulation from the bulk of the intraventricular mass may also play a major role in the development of hydrocephalus. The diagnosis of such lesions is easy with CT or MRI, and removal of the tumour may cure the hydrocephalus, although complementary shunting is often necessary.

**DIAGNOSIS OF HYDROCEPHALUS**

Accelerated head growth is the major and most striking manifestation. After a diagnosis of IVH, significant traumatic haemorrhage or any infection of the brain, it is important to regularly measure the occipito-frontal head circumstances but ventricular enlargement can precede excessive head enlargement by 7–14 days. Between 24 and 32 weeks’ gestation, average head enlargement is about 1mm per day but from 32 to 40 weeks the growth velocity is less, being around 0.7mm per day (Fenton 2003). Excessive head enlargement can be defined as 2mm or more per day. Head circumference that crosses two centile lines is also suspicious even if not averaging 2mm per day.

The anterior fontanelle is usually large and tense or full in the sitting position. Splaying of the sutures of the cranial vault may be palpable. The scalp may appear abnormally thin and its veins dilated, strikingly so when the infant cries. This dilatation is the result of diversion of the intracranial venous drainage through emissary veins as a result of increased venous sinus pressure (Sainte-Rose et al. 1984).

Ocular manifestations are useful for the diagnosis. The ‘setting sun’ phenomenon is a downward conjugate deviation of gaze such that the iris is partially covered by the lower lid while the sclera is exposed above the upper rim of the iris. The latter is due in part to retraction of the upper eyelid. The mechanism of the setting sun phenomenon is probably compression of the mesencephalic tectum, but it is not specific for hydrocephalus as it has been observed in children with subdural haematomas (Fig. 7.10). Moreover, retraction of the upper eyelids is occasionally present in otherwise normal infants at rest and can be regularly induced in neonates by sudden change from a vertical to a supine horizontal position or by removal of a bright light that had been placed in front of the eyes (Cernerud 1975). External strabismus is common and may be related to involvement of the optic radiations or Vth nerve paralysis. Optic atrophy is found in advanced cases, but papilloedema is rare unless the hydrocephalus is evolving rapidly such as occurs with papilloma of the choroid plexus (Pascual-Castroviejo et al. 1983). Seizures were observed in almost half the cases of Noetzel and Blake (1992) but were more related to parenchymal brain pathology than raised ICP. In most infants, functional symptoms are not obvious and enlargement of the head is the major feature (49% of cases in the series of Kirkpatrick et al. 1989). That series also points to the rare occurrence of atypical features such as profuse sweating, neurogenic pulmonary oedema and stridor. An interesting presentation is the ‘bobble-head doll’ syndrome, which is caused by dilatation of the third ventricle or by suprasellar cysts and consists of 2–3Hz oscillatory movements of the head, usually in association with developmental delay. A slow tremor in patients with
hydrocephalus has been regarded as a possible equivalent of the ‘bobble-head doll’ phenomenon (Bhattacharyya et al. 2003).

NEUROIMAGING AND ANCILLARY INVESTIGATIONS FOR HYDROCEPHALUS IN INFANTS

ULTRASOUND

Ultrasonographic examination through the anterior fontanelle is safe and simple as long as the fontanelle is open. It is particularly well suited for repeated follow-up examinations. Quantitative criteria for diagnosis of PHVD have been widely used in Europe. The most commonly used measurement is the ventricular index of Levene (1981) measured in the mid-coronal view; it is the dimension from midline to the lateral border of the lateral ventricle (Fig. 7.11). In a survey of 30 European neonatal units in 17 countries, Brouwer found that 13 centres used the 97th centile of Levene to diagnose PHVD and nine used 4mm over the 97th centile (Brouwer et al. 2012). Davies et al. (2000) added the anterior horn width (to represent ballooning of the lateral ventricle), third ventricle width and thalamo-occipital distance (Fig. 7.12). In several therapeutic trials of PHVD, ventricular index (width) 4mm over the 97th centile on each side was an inclusion criterion. In the most recent trial, ventricular index over the 97th centile (Fig. 7.13) and anterior horn width 6mm on each side were used as criteria.

COMPUTED TOMOGRAPHY

CT allows for assessment of ventricular dilatation and for some rough quantification: measurement of the ventricular surface and of the ventricular surface index (ventricular surface/total surface on the same cut), and of Evan’s index (distance between the lateral walls of left and right ventricles/total width of brain). Evan’s index over 0.3 is considered excessive. CT also shows the parenchyma, and the presence of periventricular hypodensities, especially around the anterior and, to a lesser extent, the posterior horns, may indicate transependymal CSF absorption and evidence of raised CSF pressure (Fig. 7.14). Because of the significant radiation exposure involved, CT is usually only used in infants for emergency diagnosis of haemorrhage.

MAGNETIC RESONANCE IMAGING

MRI can give much more information without radiation and has supplanted CT except for emergencies. The possibility of obtaining multiplanar cuts allows for a detailed study of intracranial anatomy (Britton et al. 1988). Transependymal resorption is shown as areas of low T1 and intense T2 signal (Fig. 7.15), and the status of myelination can be assessed. MRI can permit measurement of CSF volume in the various compartments of the CNS (Condon et al. 1986; Brunelle 2004).

CSF flow can be demonstrated using specially designed sequences. Aqueductal CSF flow can be seen in the foramina of Monro, fourth ventricle and aqueduct of Sylvius (Nitz et al. 1992). In the aqueduct, downward flow can clearly be seen to be synchronous with the cardiac systole and reversed upward flow with diastole, illustrating the importance of arterial pulsations in CSF circulation. Semi-quantitative methods are being developed (Brunelle 2004). They are also used to assess the functioning of therapeutic ventriculocisternostomies.

MEASUREMENT OF CSF PRESSURE

CSF pressure cannot be measured transcutaneously with sufficient accuracy for clinical decision-making. Invasive measurement requires an intracranial catheter or needle but if there is ventriculo-spinal communication and horizontal posture, lumbar puncture pressure is equivalent. In children, normal pressure when reclining is 50–120mmH₂O at the level of the foramen of Monro. In the standing position it becomes negative (average −50mmH₂O). It fluctuates during the sleep–waking cycle, with plateau waves of about 100mmH₂O every 50–75 minutes during rapid eye movement sleep, and it appears that high plateau waves even with a normal resting pressure.
indicate that hydrocephalus is not arrested (Allen 1986). In newborn and preterm infants within the first 3 months, normal CSF pressure is about 40mmH$_2$O with an upper limit of about 8mmH$_2$O (Kaiser and Whitelaw 1986). Infants with expanding PHVD had a mean pressure of 12mmH$_2$O but with a wide range (Kaiser and Whitelaw 1985).

**Doppler cerebral blood flow velocity**

modern ultrasound equipment includes pulsed Doppler enabling velocity measurement. As ICP rises, Doppler cerebral blood flow velocity (CBFV) tends to decrease as any rise in blood pressure (Cushing response) is usually insufficient to maintain cerebral perfusion pressure (Kaiser and Whitelaw 1988). The resistance index, which is calculated...
Part III Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

from systolic velocity minus diastolic velocity divided by systolic velocity, has the great advantage over absolute velocity measurement in metre/second in that resistance index is independent of the angle at which the ultrasound beam meets the artery. Resistance index that progressively increases to over 0.85 is suggestive of rising ICP and loss of end-diastolic flow velocity indicates impaired cerebral perfusion (Fig. 7.16). Thus it is useful to record Doppler resistance index whenever a cranial ultrasound scan is being carried out to assess ventricular enlargement or raised ICP.

Electroencephalography (EEG) is increasingly used in neonatal intensive care, often as amplitude-integrated EEG (aEEG). Repeated EEG may show a deterioration with increasing discontinuity as ventricular dilatation increases in preterm infants with PHVD and this may precede other signs of raised ICP. Such changes reversed after ventricular drainage (Klebermass-Schrehof et al. 2013). Somatosensory evoked potentials show increased latency in infants with PHVD as CSF pressure increased and improved when treatment lowered pressure (de Vries et al. 1990).

Figure 7.15 T1-weighted image, frontal view, shows areas of transpendymal absorption give an intense signal.

Figure 7.16 Doppler cerebral blood flow velocity on anterior cerebral artery. Intracranial pressure was 200mmH₂O. End-diastolic velocities are absent and returned when intracranial pressure was reduced to 80mmH₂O.

Rekate (1982). These were infants not complicated by primary brain disease, haemorrhage or spina bifida. Of these 43 had aqueduct stenosis, 13 had blockage at the outlets of the fourth ventricle and 24 had communicating hydrocephalus. There was a good correlation between IQ and the thickness of the frontal cerebral mantle (determined at follow-up). Normally the cerebral mantle is 5.0–5.5cm. The children with a cerebral mantle of 3.0cm or more had an IQ distribution approaching normal. All eight patients failing to achieve a cerebral mantle of 2.0cm were not adequately shunt-operated until after 6 months of age. Six children with a final mantle of 2.0–3.0cm (IQ 63–95) were all adequately shunted after 5 months. All children adequately shunted before 5 months had a mantle measurement over 3.0cm, including nine children with initial mantle thickness of less than 1.0cm. No increase in mantle size occurred in any of the children first operated after age 18 months. The authors concluded that if infantile hydrocephalus is severe with a frontal mantle of less than 2.0cm, the opportunity for good development diminishes with time. The benefit of early shunting in severe hydrocephalus is supported by experimental work. Rat pups with inherited hydrocephalus were shunted at 4–5 days or 10–11 days. Early shunting greatly reduced neuronal injury in the visual cortex (Boillat et al. 1997).

PROGNOSIS OF HYDROCEPHALUS WITH MYELOMENINGOCELE

The relationship between frontal cerebral mantle thickness and IQ is much less predictable than in ‘pure’ hydrocephalus. These infants are identified at birth because of the myelomeningocele and hydrocephalus is expected. Very few are operated on late because of delayed diagnosis. Thus it is relatively unusual to fail to develop at least a 3cm-thick frontal mantle. The IQ distribution of the Cleveland series of hydrocephalus with spina bifida was much lower than for children.

PROGNOSIS OF UNCOMPLICATED HYDROCEPHALUS

Eighty survivors of ‘pure’ hydrocephalus operated between 1956 and 1976 in Cleveland were reviewed by Nulsen and
with ‘pure’ hydrocephalus and a 3.0cm mantle (Nulsen and Rekate 1982). Over 50% had IQ below 80 versus 15% and only 15% were above 100 (versus 51%). The frequency of CSF infections in this group may have had an adverse effect on development.

Recent cognitive outcomes are considerably better. In the randomised trial of prenatal closure of meningocele, only 33% of the postnatally closed infants had a 30 month Bayley Mental Development Index (Bayley MDI) below 85. Only 26% of the prenatally closed infants had an MDI below 85 (Adzick et al. 2011).

PROGNOSIS OF POSTHAEMORRHAGIC HYDROCEPHALUS

The Ventriculomegaly Trial (1994) and PHVD drug trial (Kennedy et al. 2001) used ventricular index 4mm above the 97th centile as entry criterion and had standardised developmental assessment. If there were no parenchymal lesions seen on ultrasound, the incidence of cerebral palsy (CP) was approximately 40% and about 25% had multiple impairments. If parenchymal echodensity or lucency was seen, in addition to PHVD, cerebral palsy was found in 80–90%. A large recent study of 998 infants with birthweight below 1000g showed that, in infants with grade 3 IVH, the subsequent need for shunt surgery greatly increased the rate of cerebral palsy and cognitive disability. In grade 4 IVH, the need for a shunt also increased disability with 48% having Bayley MDI below 50 and 80% having cerebral palsy (Adams-Chapman et al. 2008).

Recently, we have investigated quantitative imaging in PHVD. The area of a parenchymal infarction measured in the parasagittal ultrasound view has a negative linear correlation with motor developmental quotient (DQ) at 2 years corrected age (Jary et al. 2012a). Lateral ventricular area in the coronal view at the start of treatment did not correlate with development at 2 years. Infants with PHVD who subsequently required shunt surgery had larger intraventricular clot area at the start of treatment. On MRI at term in 25 infants with PHVD, total cerebral volume, thalamic volume and cerebellar volume correlated positively with motor DQ at 2 years (Jary et al. 2012b). Some of the infants showed very significant brain growth impairment with the cerebellum being less than 50% of expected size (Fig. 7.17).

TREATMENT OF HYDROCEPHALUS IN INFANTS

The decision to treat hydrocephalus depends on the answers to three questions:
1. Is ICP increased?
2. Is there active expansion of the ventricular CSF?
3. Is the infant symptomatic from raised ICP?

The method of initial treatment depends on two questions:
1. Is the ventricular enlargement permanent or might it be transient?
2. Are there technical factors that make a ventriculoperitoneal shunt operation technically difficult or at very high risk of complications?

MEDICAL TREATMENT OF POSTHAEMORRHAGIC VENTRICULAR DILATATION

In preterm infants with PHVD, immediate ventriculoperitoneal shunt surgery is contraindicated because of the very high blood and protein content of CSF and because the tiny infant is at high risk for skin breakdown, infection, and respiratory complications. Furthermore it is difficult, when ventricular dilatation starts, to know if the process will be permanent or transient. Thus a variety of temporary strategies have been used to control pressure and ventricular size.

Repeated lumbar or ventricular taps have been tested in four randomised trials without any evidence of reducing shunt surgery or disability (Whitelaw 2001a). Acetazolamide and frusemide reduce CSF production but, when tested in randomised trials, the infants in the drug group had worse outcome than the comparison group (Whitelaw et al. 2001b). Isosorbide reduces CSF production by an osmotic effect but a high incidence of side effects such as vomiting has been reported and no randomised trial has been carried out (Liptak et al. 1992).

Intraventricular injection of a fibrinolytic agent was suggested as it has improved outcome in coronary artery thrombosis and a local dose insufficient to produce a systemic effect could be given. Experience in infants with PHVD has been inconsistent and two small trials of intraventricular streptokinase showed no evidence of benefit (Whitelaw 2007a).

External ventricular drain and repeated tapping of a ventricular reservoir have their advocates but no results of
randomised trials have been published. However, a non-randomised Dutch retrospective study of 144 infants with PHVD found that those whose treatment had started with ventricular index over the 97th centile had better DQ at 2 years than those whose treatment started after ventricular index had increased above 4mm over 97th centile (de Vries et al. 2002). Third ventriculostomy and choroid plexus coagulation have had very limited use in PHVD.

In view of the poor prognosis of PHVD and the lack of a safe and effective treatment, our Bristol group developed a new approach aimed at removing as much as possible of the free iron, inflammatory cytokines and old blood as well as gently reducing pressure and distortion earlier than would occur with lumbar puncture (Whitelaw et al. 2007b). Right frontal and left occipital ventricular catheters were inserted. A small dose (0.5mg/kg) of tissue plasminogen activator was injected into the ventricles and left for 8 hours. The occipital catheter was then connected to a sterile closed system and the height of the reservoir was adjusted to ventricular drainage system and the height of the reservoir. The trial was stopped early because of an excess of secondary IVH in the DRIFT group and there was no difference in shunt surgery between the two groups (Whitelaw et al. 2007b). However, developmental assessment at 2 years corrected age showed severe cognitive disability (Bayley MDI <55) was significantly reduced with DRIFT (Whitelaw et al. 2010). Median Bayley MDI was improved by more than 18 points in the DRIFT group. Importantly, the infants in the DRIFT group who had secondary IVH did not have more disability than those who did not bleed. These children had extensive testing at age 10 years and significantly more of those who had received DRIFT have survived with normal cognition. The DRIFT trial is the only trial to demonstrate any benefit from any intervention in PHVD.

SURGICAL TREATMENT

Surgical treatment of hydrocephalus has been radically modified by the introduction of extracranial shunting procedures. A striking evolution has been the development of alternative treatments to shunts, especially endoscopic procedures that are now preferred whenever possible to shunts because of the many problems these pose. Although shunts are still the more common form of treatment they are no longer the first surgical possibility to consider in many cases. Treatment of the cause of hydrocephalus, alternative types of diversion are also to be discussed before considering shunts. There is some indication that internal diversions such as ventriculocisternostomy might be effective even for postmeningitis or posthaemorrhagic cases.

Medical treatment is rarely considered except in slowly progressive hydrocephalus and in the specific case of posthaemorrhagic hydrocephalus in preterm infants (see Posthaemorrhagic Hydrocephalus section above).

As discussed previously, the decision to operate on a patient with hydrocephalus may not be easy because ‘arrested hydrocephalus’, or ‘compensated hydrocephalus’, even though it is rare, does exist and because complications of treatment are far from negligible. It seems reasonable to defer operation in children over 3 years of age with apparently arrested hydrocephalus when intellectual performance is within normal limits and seems stable (McLone and Aronyk 1993). In younger children, the trend is to place a shunt because of the danger to normal development posed by persistent hydrocephalus.

The decision for surgical treatment may also be difficult in patients with long-standing hydrocephalus, spastic diplegia and neurodevelopmental problems. The degree of reversibility of such abnormalities is not known. On the other hand, insidious deterioration certainly occurs in many cases, and surgical treatment is indicated whenever there is doubt about the progression of the disorder.

Treatment of the Cause

This applies to hydrocephalus secondary to space-occupying processes. Removal of a brain tumour will re-establish a normal CSF circulation. However, postoperative haemorrhage and aseptic meningitis may lead to the development of adhesions that will maintain active hydrocephalus. Although some neurosurgeons advise shunting preliminary to tumour removal, the majority prefer to shunt only postoperatively when necessary. Excision or shunting of an arachnoid cyst is also a form of aetiological treatment but will be considered with shunting techniques.

Surgical treatment over the last three decades has been mainly by CSF diversion by shunts. More recently, however, major improvements in surgical techniques and the realisation that shunts were the source of multiple and often severe complications that might occur many years after surgery (see Shunting Operations section) has led to an increased use of internal diversion techniques especially ventriculocisternostomy, which tends now to be regarded as the intervention of choice whenever it is possible.

Ventriculocisternostomy

Any form of hydrocephalus that is purely obstructive in nature, with one of multiple sites of obstruction located between the third ventricle and the peripontine cistern, can be cured by endoscopic third ventriculostomy (Cinalli 2004).
The main types amenable to ventriculocisternostomy are indicated below.

Primary aqueductal stenosis due to forking, glial stenosis, membrane or other congenital anomaly is the best candidate for the operation. A satisfactory circulation of CSF can be restored by establishing a patent communication between the anterior recess of the third ventricle and the chiasmatic cistern, as the CSF pathways below the aqueduct are patent. The operation consists in perforating the floor of the third ventricle anterior to the mamillary bodies under endoscopic control.

Tumoural hydrocephalus is also amenable to ventriculocisternostomy in some tectal gliomas and in pineal tumours (Ferrer et al. 1997; Mizoguchi et al. 2000; Pople et al. 2001). It is also used as preoperative prevention of postoperative hydrocephalus in tumours of the posterior fossa (Sainte-Rose et al. 2001).

Hydrocephalus of other causes in which ventriculostomy has been used include obstructive tetraventricular hydrocephalus due to obstruction of the fourth ventricle foramina (Cinalli 2004), some cases of vein of Galen malformation, and cases of postinfectious aqueductal stenosis due to toxoplasmosis and mumps encephalomyelitis. Some investigators have used it as a first therapeutic attempt in cases of posthaemorrhagic hydrocephalus, when it is not indicated in principle because of the possibility of basal cistern blockage, and found it effective in a significant proportion of cases.

Cysts associated with hydrocephalus, especially suprasellar cysts (Pierre-Kahn et al. 1990; see Chapter 14) and incisural cysts, can be treated by ventriculocystostomy, a procedure similar in its principle to ventriculocisternostomy whereby a communication is established between the third ventricle and the cysts. In such cases, the operation may avoid a pressure dysequilibrium between the ventricular system and the cyst that can be responsible for postoperative dilatation of either cavity.

Hydrocephalus in shunt malfunction has also been treated by ventriculostomy, when feasible (Punt 2004), and was successful in 23 of 30 patients in one series (Cinalli et al. 1998) allowing control without shunt.

The success rate of ventriculostomy reported in the literature ranges widely because it essentially depends on the patient selection criteria, with a mean of 68% (Cinalli 2004). The variable results are mainly due to the heterogeneity of the operated cases. If only triventricular hydrocephalus cases are considered, the average success rate is above 60%. Ventricleocisternostomy is effective in reducing intracranial hypertension but usually leaves a persistent dilatation of the ventricles (Hirsch 1982; Cinalli 2004). The decrease in ventricular size is less than with shunting operations. Volume reduction of the order of 30–50% is expected unless there is parenchymal atrophy in long-standing cases. This less marked decrease avoids the problem sometimes seen of ventricular collapse with post-shunt pericerebral collections in patients with a large skull. Symptoms and signs of intracranial hypertension disappear promptly, and ICP should return to normal within 10 days. In case of persistence, shunting becomes necessary.

Complications of ventriculostomy include intraoperative complications such as bradycardia, asystole and haemorrhage, and also damage to the fornices that usually has minimal consequences. Hypothalamic damage may produce severe consequences (Teo 2004). Vascular damage to the basilar artery can be life threatening but is rare. Failure to control the hydrocephalus is frequent in young infants. Most of these complications should be avoided by correct technique (Navarro et al. 2006). However, the success rate decreased with increasing age to less than 50%, even when taking into account aetiology (Koch-Wiewrodt and Wagner 2006). Late failure of the ventriculostomy does occur, sometimes years after the procedure. It may result from glial scarring stenosing or obstructing the orifice but may also occur in the face of an open stoma. This is a dangerous complication that may result in acute midbrain syndrome. Therefore, patients should be informed and followed closely. Failure of the ventriculostomy seems not to occur after the 5 years following operation (Cinalli 2004).

Shunting Operations

These techniques aim at diverting the CSF that cannot reach its normal areas of resorption toward another site of drainage. This is achieved by inserting a unidirectional valve system with a specified level of opening pressure between a proximal catheter placed in the ventricular system (or other fluid-containing cavity) and a distal catheter that carries the outflow of the valve to the draining site.

Under special circumstances, for instance when there is infection of the CSF or the fluid is haemorrhagic and might obstruct the system, the distal catheter may be temporarily drained into a sterile pouch, external to the patient. External drainage is limited by the risk of infection and the consequent necessity to maintain the patient in strict aseptic conditions.

Internal shunts have become the standard treatment in the vast majority of cases of hydrocephalus. Numerous catheters and valve systems are available with different mechanisms and hydrodynamic characteristics. Residual ICP after shunting will depend on the opening pressure of the valve or the pressure within the drainage cavity and on the resistance of the shunt. Available valves are classified into low-pressure (opening pressure 20–50mmH₂O), mid-pressure (50–80mmH₂O) and high-pressure valves (80–120mmH₂O). The flow, once the valve is open, will be determined by the ratio of the differential pressure between the two extremities of the system to its resistance. Most systems have a constant resistance so that the standing position inevitably produces overdrainage. Over the years many attempts have been proposed to overcome this complication, namely ‘externally adjustable opening pressure shunts’, ‘anti-gravity devices’, ‘antisiphon devices’ and various combination of these shunt adjuncts. Variable resistance systems have been proposed (reviewed by Sainte-Rose et al. 1987) in order to avoid such problems.
Currently, drainage is generally into the peritoneal cavity (ventriculoperitoneal shunt), because this form of shunt is easier to insert and does not need lengthening with growth of the patient since a considerable length of catheter may be left within the peritoneum without serious problems (Vinchon and Dhellemmes 2004). Ventriculoperitoneal shunts are now used only when the peritoneum does not absorb enough fluid or in cases of peritoneal or intraperitoneal infection.

Most systems include an inbuilt reservoir, placed subcutaneously over the skull, which theoretically allows shunt functioning to be assessed by pumping the reservoir. In fact, the correlation between response to pumping and functioning of the shunt is poor. According to Piatt (1992) only 18–20% of blocked shunts cannot be pumped, and the ability to pump indicates shunt patency in only 65–81% of cases. There is thus no simple manoeuvre for assessing shunt functioning. For this reason, some surgeons always use a separate fluid reservoir for pressure measurement and fluid collection (Leggate et al. 1988).

Lumboperitoneal and other shunts are now only rarely used. Some surgeons employ them for the treatment of pseudotumour cerebri. The catheter is introduced into the lumbar subarachnoid space and anchored to the lumbar fascia. The tube is then fed through a subcutaneous tunnel to exit through a small incision in the loin. Then, with or without interposition of a valve, the catheter is fed into another subcutaneous tunnel to the paraumbilical area where it is introduced into the peritoneal cavity as a ventriculoperitoneal catheter.

In spite of considerable progress in the development and techniques of use of CSF shunts, numerous complications can and do occur (Hirsch and Hoppe-Hirsch 1988; Sainte-Rose et al. 1989; Di Rocco et al. 1994). They are more common in infancy and following operation for aqueductal stenosis (Di Rocco et al. 1994). Table 7.4 lists the main complications of shunts. The major complications are infection and shunt failure, and associated incidents such as fracture and migration of catheters.

Infection remains a serious complication of shunt procedures. Its incidence varies between 4% and 8% in published series (Renier et al. 1984; Ammirati and Raimondi 1987; Hirsch and Hoppe-Hirsch 1988; Di Rocco et al. 1994) but the lower figure now seems to be generally accepted. The rate is higher in infants under 6 months of age. The infecting organism is *Staphylococcus aureus* in a quarter, and Gram-negative organisms in about a fifth (Bayston 1994). Rare pathogens may colonise shunts (see Chapter 11). Infection is usually an early complication but can occur months or years after operation. Meningitis is the dominant infection (almost two-thirds of cases), while peritonitis occurs in about 20% and wound infection in over 10%. The clinical picture is often insidious, especially when *S. epidermidis* is the cause, and the diagnosis may be difficult, especially when eosinophilia is the prominent CSF anomaly (Vinchon et al. 1992). Death is possible, especially with Gram-negative meningitis. Localised peritoneal infection can lead to ulceration of the bowel with exteriorisation of the catheter through the anus. Septicaemia has become rare since ventriculoatrial shunt is now uncommon. The same applies to shunt nephritis (Wald and McLaurin 1978) and to cor pulmonale (Sleigh et al. 1993).

Prevention of infection by strict aseptic measures is essential (Hirsch and Hoppe-Hirsch 1988). Prophylactic antibiotics seem to reduce shunt infections and should be given on the day of operation and the following day. Treatment of established infection includes aggressive antibiotic therapy for 10–20 days on average after removal of the shunt. The shunt is reinserted when CSF cultures are sterile and CSF glucose back to normal. Some authors advocate initial antibiotic treatment for 5–6 days before removal, and immediate replacement of the shunt. Antibiotics are then continued for 2–3 weeks (Hirsch and Hoppe-Hirsch 1988). In an occasional case antibiotic treatment with injections into the shunt may sterilise

the CSF (Bayston 1994). Removal of the shunt seems to give the lowest mortality. On the other hand, the incidental occurrence of *Haemophilus influenzae* meningitis in a shunted child can often be successfully treated without removing the shunt (Rennels and Wald 1980). Peritonitis is usually cured by antibiotic therapy and removal of the infected catheter. Surgery is rarely necessary. Low-grade infection with formation of intraperitoneal cysts can be detected with the help of sonography.

Shunt failure can result from primary misplacement of the shunt. In such cases, parenchymal haemorrhage, traumatic puncture of the internal capsule or puncture porencephaly can be responsible for hemiplegic sequelae (Boltskhauser et al. 1980).

Most commonly, shunt failure occurs in correctly placed shunts. In the series of Sainte-Rose et al. (1989), 81% of 1620 shunts had failed by 12 years after insertion. The risk of failure was highest, at 30%, in the first postoperative year. Disappointingly, the risk was 7–14% for each subsequent year and there was no indication of a trend toward improvement with time. Blockage of the shunt was the cause of failure in half the cases, most frequently at the ventricular end. Fracture, migration and disconnection were next in frequency, being observed in 14% of cases.

Migration of catheters following rupture of connectors may be particularly difficult to diagnose as CSF often continues to flow along the subcutaneous fibrous tunnel for prolonged periods. Cortical visual impairment is a complication of shunt dysfunction. It is probably due to compression of the posterior cerebral arteries by the tentorium, when there is a sudden increase of ventricular size with resultant downward displacement of the brain. CT shows bilateral occipital infarcts (Arroyo et al. 1985).

Sainte-Rose et al. (1989) reported a mortality related to shunt failures of 1%, and the incidence of subsequent epilepsy and of recurrent shunt failure was significantly increased. The symptoms and signs of obstruction may be overt or insidious. Parents should be advised to report immediately bouts of headaches or vomiting, lethargy, or the development of diplopia or other neurological signs. In other patients, only vague symptoms and behavioural changes are present such as decreased spontaneity or poor school performance, perhaps in association with mild headaches. Still other children have intermittent shunt obstruction. Sudden death can occur (Hayden et al. 1983); hence the need for rapid hospitalisation. Non-functioning shunts need not be symptomatic. In the experience of Hayden et al., 23% of 307 patients with nonfunctional shunts remained asymptomatic for an average of 27 months.

It seems that about 85% of shunted patients will have to keep a shunt in place indefinitely if no complications supervene, and there is no simple means of determining in which patients the shunt can be removed despite various techniques having been proposed (Hayden et al. 1983). The diagnosis of blocked shunt is often difficult, and various techniques of assessment have been proposed, such as measurement of the Doppler pulsatility index (Pople et al. 1991) and MRI flow study (Frank et al. 1990). Watkins et al. (1994) showed that a normal CT does not exclude blockage; percutaneous manometry in 26 cases gave no false positives or negatives but the results were equivocal in five children. In fact, all shunts are bound to stop functioning with time, as the annual rate of failure remains constant over the years (Sainte-Rose et al. 1991). This is due mostly to fibrous changes and calcification around the catheters. However, the diagnosis of non-functioning shunt is quite difficult and no method of recognition is consistently successful. This gives rise to discussions about removal of uncomplicated but probably nonfunctional shunts. There is no reason to remove a shunt in asymptomatic patients, even if it is thought to be nonfunctional, as this can result in intracranial hypertension.

It is hoped that the development of new material can lead to prevention of the formation of biofilms and may reduce inflammatory or other tissue reactions, thus avoiding the two most common shunt complications, failure and calcification.

Overdrainage is a frequent complication of ventriculoperitoneal shunts because of the ‘siphon’ effect that occurs in the upright position, due to the height of the hydrostatic column between the inlet and the outlet of the shunt. In standing patients, the draining capacity of the shunt exceeds the ventricular CSF secretion rate and overdrainage is constant. Overdrainage is more important with low-resistance valves (spring-ball type or silicone rubber diaphragm type) than with high-resistance valves (silicone rubber slit types).

Complications of overdrainage classically include subdural effusions, slit ventricle syndrome, orthostatic CSF hypotension, craniosynostosis (Serlo et al. 1985; Epstein et al. 1988). Overdrainage is also an important factor in the mechanism of trapped ventricles. A trapped fourth ventricle can behave as any space-occupying posterior fossa lesion and requires placement of an additional shunt within the cavity. The diagnosis by neuroimaging is straightforward. But above all chronic overdrainage is the major cause of ‘late’ shunt proximal obstruction as it will favour the migration into the drainage system of various tissue or debris (choroid plexus, ependymal or glial tissue).

Intracranial hypotension occurs especially after lumoperitoneal shunts (Rando and Fishman 1992) and can be responsible for headaches, vertigo and vomiting. MRI may show striking dural enhancement with gadolinium (Fishman and Dillon 1993; Pannullo et al. 1993; Mokri et al. 1995).

The same phenomenon has also been reported following lumbar puncture (Krause et al. 1997). In rare cases, prolonged hypotension may result in spinal canal stenosis (Kobayashi and Hashi 1983). Overdrainage is also one of the causal factors of isolated ventricles (Matsumoto and Oi 1985) and may be associated with an increased incidence of epilepsy.

Slit-like ventricles are seen in about 20% of cases but most remain asymptomatic. The ‘slit ventricle syndrome’ is characterised by recurrent signs of increased ICP due to intermittent obstruction of the shunt by the walls of the ventricle. It may also manifest as chronic headache. CT shows only slightly larger ventricles in the presence of shunt obstruction than
with a functioning shunt. This is because the slit ventricles are also usually stiff ventricles, in part because of the loss of CSF volumetric buffering reserve, necessary for instance in the case of vasodilatation, and in part because of periventricular gliosis as a result of previous infections and gliosis impairing re-expansion of previously collapsed ventricles. Prevention of the slit ventricle syndrome is difficult (Rekate 2004). Various techniques have been proposed such as antisiphon valves or constant flow valves (Sainte-Rose et al. 1987).

Post-shunt pericerebral collections occur in about 3% of shunted patients but are symptomatic in only half the cases (Hoppe-Hirsch et al. 1987). A simple treatment is insertion of a valveless shunt into the subdural cavity draining it to the peritoneum in order to establish a temporary lower pressure in the subdural space than in the ventricle.

Orthostatic CSF hypotension and shunt dependency are often associated with the presence of slit ventricles. They can be associated with headaches or behavioural changes but are more commonly asymptomatic.

Post-shunt craniosynostosis is in most cases limited to the premature fusion of the sagittal suture with resulting scaphocephaly. Only exceptionally do post-shunt synostoses represent more than a purely cosmetic problem, requiring surgical correction.

Epilepsy has been reported to be more common in shunted patients than in unoperated ones. The reported occurrence varies enormously in different series that are extremely heterogeneous and impossible to compare. Ines and Markand (1977) found the frequency of seizures to be 18.2% before operation and 65.4% after. In a study of 171 patients, Di Rocco et al. (1985) found that 34 (19.9%) had seizures, 25 of these having had seizures before surgery. Saukkonen et al. (1990) reported that 48% of their 168 shunt-treated patients had seizures, regardless of the aetiology of hydrocephalus. They were of the opinion that the mere presence of a shunt device in the brain parenchyma is of relatively little importance. Infections and parenchymal damage due to the cause of hydrocephalus were associated with an increased seizure rate as were multiple surgical procedures. High ICP may be a factor favouring the emergence of epilepsy (Faillace and Canady 1990). Bourgeois et al. (2004) followed 802 children treated with shunts for hydrocephalus of multiple causes for an average of 7.6 years (range 1–26 years). Seizures occurred in 255 of them (32%) and were recurrent and unprovoked in 27%. Seizures began before shunting in 29% and after shunting in 71%. All types of seizures were observed, with a predominance of focal seizures. The latter type was more frequent following shunting, while generalised seizures, often occasional, predominated before shunting. Hydrocephalus is one possible cause of continuous electrical status of slow sleep (Battaglia et al. 2005; see also Chapter 16). The incidence of seizures was higher in children who had shunt dysfunction and/or infection. A young age at operation and a higher incidence of shunt complications were associated with seizure frequency. In all cases the presence of epilepsy was a predictor of poor cognitive outcome.

Complications unrelated to shunt procedures

These are rarely observed now as virtually all cases of definitely progressive hydrocephalus are effectively treated with shunts or other methods. However, some complications can develop insidiously before treatment, including hemiplegia. There is an established relationship between hydrocephalus and the hemiplegic type of CP. In 28 cases of CP secondary to hydrocephalus investigated by O’Reilly and Walenty nowicz (1981), 11 were of the hemiplegic type. In rare cases a puncture porencephaly can develop along the track of a ventricular needle or of a non-functioning catheter. In other children, hemiplegia may result from ependymal rupture with CSF dissection into the centrum semi-ovale or from the development of a diverticulum of the lateral ventricle, located in most cases at the level of the trigone on the internal aspect of the hemisphere, that may enter the posterior fossa (Naidich et al. 1982). Such diverticula may rupture into cisternal spaces and realise a spontaneous ventriculocisternostomy with stabilisation of the hydrocephalus. Occasional complications of unoperated hydrocephalus include IVH in the case of rapidly evolving hydrocephalus, and hydroxyringomyelia as a consequence of stabilised hydrocephalus (Olson and Milstein 1988). The latter may be associated with marked scoliosis that may improve with treatment of the hydrocephalus.

Overall outcome of hydrocephalus

Before the introduction of shunt treatment, fewer than 50% of live born term infants with hydrocephalus survived, whereas currently the mortality rate is between 10% and 15% (Fernell et al. 1986, 1994). At the same time, there has been a major decrease in the frequency of the characteristic major sequelae of chronic untreated hydrocephalus (Fernell et al. 1988). That study found frequencies of 8% and 18% respectively for ataxic and other forms of CP and of 21% and 16% respectively for mild and severe intellectual disability; epilepsy was present in 25% of survivors and visual difficulties with optic atrophy in 11%. Bourgeois et al. (1999) reviewed 802 children with operated hydrocephalus with a mean follow-up of 8 years. Thirty-two per cent developed epilepsy, usually severe. Epilepsy was more frequent in children with shunt complications. The presence of the shunt might be a factor, although this remains dubious. The incidence of the ‘cocktail party syndrome’ (children who talk a lot without listening while the content is superficial and without understanding) (Hagberg 1962) was only 3% as compared with 27% in the preshunting era. It seems likely that CP other than the ataxic form, intellectual disability, epilepsy and precocious puberty, none of which has decreased significantly since shunting was introduced, are attributable mainly to the brain pathology associated with hydrocephalus. In contrast, ataxia, strabismus and the cocktail party syndrome seem more directly related to unchecked long-standing intracranial hypertension and ventricular distension. Despite the improved outlook, recent work on unselected children with hydrocephalus showed that 47% had specific learning
At this stage, most surgeons believe that avoidance of the correlation between ventricular size and intellectual function adversely affects the cognitive outcome, and there may be little operational delay and associated atrophy, which can also tors can be responsible. Ventricular dilatation augments with in view of the less marked decrease in ventricular size with results on performance scales of IQ tests are lower than those of clumsiness and poor motor coordination. In most cases, the who develop relatively normally, there is an overrepresentation before shunt.

Results of ventriculostomy appear to be satisfactory. A long-term outcome study of 975 consecutive children followed for a mean of 11 years included 280 treated with endoscopic third ventriculostomy and 695 treated with shunt insertions. (Beuriat et al. 2011). Those of shunting operations are still far from fully satisfactory. Kokkonen et al. (1994) had seven deaths among 42 children, and five of the survivors were institutionalised for severe cognitive impairment. Only one-third of these patients had vocational training, while a quarter stayed at home without meaningful activity. In the series of Mori et al. (1995), 22% of 1450 patients had intellectual disability. Poor results were correlated with age and cause of hydrocephalus, with the presence of epilepsy, with shunt complications and delay in their treatment, and with the degree of ventricular dilatation before shunt.

Even in children with effectively treated hydrocephalus who develop relatively normally, there is an overrepresentation of clumsiness and poor motor coordination. In most cases, the results on performance scales of IQ tests are lower than those on the verbal items (Billard et al. 1987; Fernell et al. 1988).

It is still uncertain whether treatment should aim at achieving a normal ventricular size; an important issue in view of the less marked decrease in ventricular size with ventriculostomy. Although children with moderate or severe ventricular dilatation do less well than those with normal-sized ventricles (Fernell et al. 1988), a number of associated factors can be responsible. Ventricular dilatation augments with operational delay and associated atrophy, which can also adversely affect the cognitive outcome, and there may be little correlation between ventricular size and intellectual function. At this stage, most surgeons believe that avoidance of the frequent and serious complications of shunts outweigh the undemonstrated effect of ventricular dilatation. Some patients who have a very large head and a thin cerebral mantle may be quite normal. Multivariate analysis of prognostic factors indicates that ventricular dilatation in itself explains from a statistical point of view only 20% of the ultimate variance of the results. Children with large ventricular size after shunting seem to do less well on nonverbal and visuospatial function tests, but the rest of their functions seem normal when aetiology and age at operation are taken into account (Billard et al. 1987).

The cause of hydrocephalus and the age of presentation are major prognostic factors. Fetal hydrocephalus has a particularly poor outcome (Mori et al. 1995). Preterm infants with ventricular haemorrhage currently represent a large group with a rather poor prognosis. Hislop et al. (1988) found that of 19 infants shunted for PHVD, 14 developed shunt complications and several had severe sequelae such as hypsarrhythmia and infantile spasms. Seventy-three per cent of the very preterm infants studied by Fernell et al. (1994) developed CP; 55% had intellectual disability, 52% epilepsy and 22% severe visual impairment. The prognosis is largely determined by the presence of other lesions associated with IVH such as periventricular leucomalacia (Ventriculomegaly Trial Group 1994). These are much more difficult to detect by ultrasonography than are haemorrhages so that the outcome may be difficult to predict.

Patients with postmeningitic or toxoplastic hydrocephalus also do rather poorly because of the usual occurrence in such cases of diffuse brain damage. It is difficult in many cases to assess the role of high pressure itself irrespective of the cause.

A significant number of the sequelae are no doubt due to repeated episodes of shunt dysfunction, which favours the use of endoscopic surgery. When a shunt is necessary, improvement of the material and methods of shunting is a high priority. Prevention of hydrocephalus can be achieved by measures such as earlier and better treatment of bacterial meningitis and prevention of haemorrhage. Prevention of preterm birth is a major target, as the majority and the most severe cases of hydrocephalus occur among small preterm infants.

**NON-TRAUMATIC PERICEREBRAL COLLECTIONS**

Pericerebral fluid collections represent one of the most common causes of large head size in infants and children. Since the widespread use of modern neuroimaging they have been recognised both in symptomatic and asymptomatic patients and can be divided into two broad groups: symptomatic cases that are associated with brain damage or genetic syndromes, and cryptogenetic cases that have been variously designated as benign subdural collections, benign external hydrocephalus (Alvarez et al. 1986), and benign extracerebral or extra-axial collections (Hamza et al. 1987). Most cases in the asymptomatic group can be considered as a variant of normal development and represent simple enlargement of the subarachnoid space. Reported frequencies for these groups vary. Symptomatic cases accounted for 13 of 94 patients (14%) in the series of Hamza et al. (1987) and for 36 of 63 patients (57%) in that of Alvarez et al. (1986).

The exact location of fluid is controversial (Aoki 1994). It is probably initially subarachnoid, but possible effraction into the subarachnoid space is sometimes demonstrated and may be spontaneous or due to additional minimal trauma as occurs also in cases of large subarachnoid cysts associated with subdural collections. The reasons for the anterior predominance and delayed effacement of the collections remain unclear.
Imperfection of CSF resorption into the venous system as a result of increased venous pressure or increased resistance of the arachnoid villi has been speculated. The presence of fluid in the subdural space may be explained by a subarachnoid–subdural fistula with a one-way valve effect or by other, undefined mechanisms. Baraton et al. (1989) have shown that contrast injected into the lumbar space in 26 patients did not contaminate the peri-cerebral collections but remained limited to the anterior part of the pericerebral space underneath the pericerebral collection, therefore suggesting a subdural location.

The fluid is usually clear and the protein level normal or only slightly elevated. Ventricular dilatation of variable, but usually mild, degree may be associated.

PERICEREBRAL COLLECTIONS OF KNOWN CAUSE

These are usually associated with ICP and at times with some degree of internal hydrocephalus.

Abnormal Venous Return

This produces an increased volume of the intracranial venous blood compartment with consequent increase in intracranial contents and ICP. This in turn results in turgescence of the brain, which prevents or limits ventricular dilatation. Abnormal constriction and/or aberrant venous pathways rarely exist in isolation, but they may be associated with certain types of craniosynostosis (Sainte-Rose et al. 1984; Tanaka et al. 1985). Thrombosis of the superior vena cava, of jugular veins or of intracranial sinuses may also be a cause. Vena cava thrombosis is most often caused by indwelling central catheters used for drug infusion or parenteral feeding. Hydrocephalus from such causes is virtually always mixed internal and external. The external part, however, may communicate with the subdural space. Increase in pressure from large arteriovenous malformations, especially aneurysms of the vein of Galen, also produces external as well as internal hydrocephalus.

Achondroplasia

This disease is regularly associated with external hydrocephalus as well as ventricular dilatation (Pierre-Kahn et al. 1980). Increase in venous pressure is due to narrowing of the basal venous foramina. Such narrowing may also prevent dampening of CSF pulse pressure waves by immediate outflow of blood from the cranium. Treatment of external hydrocephalus of venous origin is based on reduction of venous pressure by cure of its cause or by bypass operation (Sainte-Rose et al. 1984).

Other Causes

These include venous hypertension due to thrombosis of the superior vena cava and various genetic syndromes such as the Sotos, Beckwith–Wiedemann, Goldenhar and Weaver syndromes (Alvarez et al. 1986) and organic acidurias, especially glutaric aciduria.

PERICEREBRAL COLLECTIONS OF UNKNOWN CAUSE

Cryptogenic or Benign Pericerebral Collections

Cryptogenic pericerebral collections are manifested clinically by a large head. Affected children often have head circumference above the 95th centile by 1 year of age, and tension of the fontanelle may be observed (Kumar 2006). Eventually, velocity of head growth decreases and the head growth curve becomes parallel to the normal growth pattern or tends toward normal. This phenomenon may be particularly striking in preterm infants. In 12 such patients followed by Al-Saedi et al. (1996), the head circumference stabilised between 15 and 18 months at the 95th centile.

Most infants have no abnormal neurological signs, but motor and sometimes language development may be delayed (Alvarez et al. 1986). The radiological signs include moderate enlargement of the pericerebral spaces, especially in the frontal or frontoparietal regions bilaterally and symmetrically, with interhemispheric sulcus dilatation extending posteriorly to the middle third of the brain.

There is often a mild dilatation of the ventricles. Differentiating benign enlargement of the subarachnoid space from subdural collections may be difficult. Colour Doppler ultrasonography show the veins crossing the pericerebral spaces in benign collections but not in subdural effusions (Aoki 1994; Chen et al. 1996). MRI shows a higher density of fluid and the presence of a dense external membrane (Wilms et al. 1993) in subdural fluid.

Although the causes of cryptogenic effusion are, by definition, unknown, a relationship to simple macrocephaly (Lorber and Priestley 1981; Gooskens et al. 1988) has been suggested. Alvarez et al. (1986) found a family history of large head in 32 of their 36 cases and suggested the existence of a continuum between collections and the familial megalencephaly. The occurrence of ‘external hydrocephalus’ in twins has been reported (Cundall et al. 1989).

The diagnosis of cryptogenic pericerebral effusion should exclude all known causes, particularly chronic traumatic subdural haematoma.

The course of pericerebral collections is regularly benign. The rare patients left with mild or, rarely, moderate intellectual disability (Hamza et al. 1987) may have been misclassified. Although surgical treatment has sometimes been performed (Tolias et al. 2000), spontaneous resorption is the rule and no treatment is justified.

Ingeborg Krägeloh-Mann

Cerebral palsy (CP) is currently defined as a group of disorders of motor function, movement and posture; it is permanent but not unchanging; it is due to a nonprogressive lesion or abnormality in the developing/immature brain (SCPE 2000). The motor disorders of CP are often accompanied by disturbances of sensation, perception, cognition, communication and behaviour, and by epileptic seizures as well as secondary musculoskeletal problems (Bax et al. 2005; Rosenbaum et al. 2007).

This definition is based on clinical phenomenology and clinical history. Additional features such as imaging or laboratory results are not primary inclusion criteria, but are important to further describe CP subgroups with respect to aetiology or at least pathogenesis. However, these investigative modalities are not available in all countries to the same extent and while their use has enhanced knowledge and understanding of CP pathogenesis, the findings and features do not form part of the CP definition. As CP epidemiology relies on standard inclusion and exclusion criteria, comparison between countries and time periods would be difficult if these features were part of the CP definition. Progressive conditions resulting in loss of acquired skills, spinal diseases and, in most countries, cases where hypotonia is the sole neurological finding are excluded. Neurological criteria define the subtypes (e.g. spastic, dyskinetic and ataxic; Hagberg and Hagberg 1993).

From a clinical viewpoint, the symptoms and signs of CP are not unchanging. The typical neurological signs take time to develop – (see Diagnosis and Differential Diagnosis of Cerebral Palsy section) – and it is generally agreed that the child should be at least 3 years of age before the CP diagnosis is established: CP registers accept children only at the age of 5 years (SCPE 2000; Stanley et al. 2000). Some slowly progressive conditions with early onset, such as hypomyelinating disorders, may still appear as a static condition clinically at the age of 5 years, which leaves a certain ‘grey zone’ when defining CP using clinical phenomenology only (Krägeloh-Mann et al. 1995).

The concept of CP is to some extent artificial, not only because the causes, mechanisms and consequences of the underlying brain pathology are multiple, but also because the age limit of brain immaturity is difficult to define. Usually there is a distinction between CP of postnatal onset and CP due to pre-, peri and neonatal events, the latter being the basis for reported trends on CP prevalence, when not otherwise specified. Postnatal CP should be distinctly addressed as causes are usually clearly defined. The age limit is somewhat arbitrary being dependent on what is understood as immaturity with regard to the brain. There are recommendations for using the term ‘postneonatal cerebral palsy’ such as onset being between 5 weeks postnatal and 2 years (SCPE 2000) or 2–3 years (Rosenbaum et al. 2007). Some countries do not include postneonatal CP but prefer to describe the clinical condition specifically, for example, hemiparesis due to stroke at a certain age.

PATHOLOGY, AETIOLOGY, PATHOGENESIS

Only elements that are operative in CP in general are discussed in this section. More detailed information is given in sections on the individual subtypes of CP.

Pathology is not specified in the definition of CP. Conventional neuropathology used to be the main informational source to describe pathological changes in CP. This has changed with the advent of neuroimaging, especially magnetic resonance imaging (MRI), which has a good potential to detect lesions or maldevelopments of the brain. Because the human brain undergoes complex organisational changes during intra- and extruterine development, the pathological patterns of abnormalities/lesions found will depend on the stage of brain development at the time of insult (Krägeloh-Mann 2004). The brain pathology of CP is to a large extent dependent on the time of occurrence of noxious events that interfered with the development of the brain or actually damaged it (see Chapters 1–3).
Pathology and Timing

Cortical neurogenesis takes place predominantly during the first and second trimesters, characterised by proliferation, migration and organisation of neuronal precursor cells, then neuronal cells. Disorders of this process result in specific pathological patterns, that is, malformations of cortical development, such as lissencephaly, pachygyria or polymicrogyria. Some of these disorders may be of genetic origin, especially when symmetrical in extent (Kato and Dobyns 2003; Barkovich et al. 2012).

During the third trimester, when the ‘gross architecture’ of the brain (neuronal cyto- and histogenesis) is largely established, growth and differentiation events are predominant and persist into postnatal life (axon, dendrite and synapse formation, myelinisation). Disturbances of brain development during this period mainly result in cistic lesions. Their causes are multiple and key factors are inflammation with excessive cytokine production, oxidative stress and excess release of glutamate, triggering the excitotoxic cascade, factors that are induced by hypoxic–ischaemic and/or infectious mechanisms, whereby a potentiation of single effects can be assumed (Duggan et al. 2001; Johnston et al. 2001; Hagberg and Mallard 2005; Edwards and Tan 2006). Early in the third trimester, white matter is especially affected. The major neuropathology, that is often reported to result in CP includes periventricular leukomalacia (PVL) or complications of intraventricular haemorrhage (de Vries 1996; Olsén et al. 1998; Krägeloh-Mann et al. 1999; Stewart et al. 1999; Volpe 2009).

In the late third trimester the cortical grey matter, basal ganglia and thalamus appear to bear the brunt of damage (Keeney et al. 1991; Baenziger et al. 1993; Rutherford et al. 1995; Volpe 2001). Infarcts of the MCA are reported mainly in children born at or near to term with unilateral spastic CP (Hagberg et al. 1996; Govaert et al. 2000). They may also occur in the very preterm child, then involving more the lenticulostriate arteries (de Vries et al. 1997; Benders et al. 2009).

The different patterns of first, second and third trimester origin are indicated in Table 8.1 and Figure. 8.1.

Systematic reviews on MRI findings in children with CP (Krägeloh-Mann and Horber 2007; Korzeniewski et al.)
2008; Reid et al. 2014) find a clear pathology indicating a specific pathogenesis in around 80% of cases, with a predominance of white matter lesions (around 50%), followed by predominantly grey matter lesions (around 20%) and maldevelopments of the brain (around 10%). Thus, the major pathology in CP is lesional, in the sense of clastic, affecting a primarily normal brain. The same lesional patterns tend to occur at the same gestational ages regardless of the time of birth. Thus, for example, PVL can occur in utero (in a term-born child) or peri- and neonatally.

Genetic origin, in contrast, plays a minor role. As indicated earlier maldevelopments of the brain resulting in CP may have a genetic or acquired background. For example, a child with bilateral spastic CP may have lissencephaly-pachgyria due to Miller Dieker syndrome, a 17p13.3 deletion syndrome (Spalice et al. 2009), or due to prenatal cytomegalovirus infection (Manara et al. 2011). The proportion of maldevelopments causing CP due to genetic changes is, however, not clearly known. In addition to monogenetic aetiologies of CP, there is a discussion that multiple genetic factors may cause the disorder, or may contribute to its underlying pathology (Moreno-De-Luca et al. 2012). A certain increased familial risk, after excluding preterm birth as an important risk factor for CP, has been reported not only for twins, but also for siblings and when the father or mother is affected (Tollanes et al. 2014).

The main findings in CP subtypes will be summarised here briefly (see also Table 8.2) with more detail given in the following paragraphs. Lesions (e.g. patterns of early or late third trimester origin), whether of pre- or peri-, neonatal timing, are found in bilateral spastic CP in more than 80%, in spastic hemiplegia in about 70–80%, in dyskinetic CP probably in more than 50%. Genetic and acquired CP of first or second trimester origin is found in around 10% of cases. Ataxic CP seems to form an exception within CP subtypes as morphological abnormalities are found in probably less than 50% of cases and are probably heterogeneous with some predominance of maldevelopments. This, together with a higher occurrence of familiarity suggests a mainly genetic origin. Taken together, CP, when phenomenologically defined, is mainly, but not exclusively, a lesional condition, and ataxic CP is clearly an exception.
Part III  Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

Prevalence of Cerebral Palsy

Incidence looks at the occurrence of new cases of a condition within a period of time, prevalence looks at those who currently have the condition during a particular period or at a particular date. In CP, it is typically prevalence that is measured and compared, the reference basis being mainly birth periods and place of residence at birth. This relates to the fact that the CP diagnosis is only possible with some delay between brain compromise and its obvious clinical signs, and some children may have died within this period (e.g. before CP diagnosis could be established). Data on prevalence of CP vary with the series studied and the period over which they are collected. Overall, CP prevalence is between 2 and 2.5 per 1000 live births, indicating that CP is the commonest cause of physical disability in early childhood (SCPE 2002; Stanley et al. 2000).

Studies of CP in relation to birthweight estimate that infants of very low birthweight (VLBW) (<1500g), are between 40 and 100 times more likely to have CP than normal birthweight infants (≥2500g). A combination of factors including decreased neonatal mortality and increased survival rates in VLBW infants, due to improved care of the preterm infant, lower accepted viability limits and an increase in multiple births, has resulted in a rise in the absolute number of VLBW infants at risk of CP.

Evidence from CP registers suggests that the prevalence of CP among VLBW infants rose over the 1980s (Pharoah et al. 1990; Hagberg et al. 1993; Stanley et al. 2000). This rise was probably due to the survival of very preterm infants of less than 1000g birthweight (Hagberg et al. 1989b). This was reported also for the 1990s (Doyle et al. 2000). Other studies, however, indicate that the rates of CP in VLBW infants are now decreasing (Krägeloh-Mann et al. 1994; Topp et al. 2001; Surman et al. 2003; Himmelmann et al. 2005).

As data from different registers and studies are difficult to compare, the Surveillance of Cerebral Palsy in Europe (SCPE) network was founded in 1998 to build up a common database among CP registers in Europe in order to describe trends in CP prevalence for different birthweight and gestational age groups on the basis of criteria cohorts with common inclusion and exclusion criteria. Results from the European database confirm this decrease: the decline in rate was seen in infants of 1000–1499g birthweight from 60 to 40 per 1000 livebirths from 1980 to 1996 or from 90 to 44 per 1000 neonatal survivors (NNS) (Platt et al. 2007) (Fig. 8.2).
The trends in the rate of CP by gestational age mirrored that of birthweight. The moderately preterm group also showed a clear decrease from 10 to 6 per 1000 livebirths from 1980 to 1998 (Andersen et al. 2011). Interestingly, CP rates in the 1990s in this European cohort did not differ much in children of birthweight less than 1000g from those in children with birthweight 1000–1500g. Recent data from the SCPE, analysing birth years until 2003, indicate that this decline continued for children of LBW and VLBW and resulted for the first time in a significant decrease of total CP prevalence from 1.90 to 1.77 per 1000 livebirths (1980 to 2003) (Sellier et al. 2016). A recent report of the Australian CP network based on children born 1993–2006 showed trends per birthweight very similar to the European study (ACPR 2013).

This indicates that while the survival of infants of low birthweight or gestational age continues to improve, this continued improvement is not at the expense of increased morbidity, but results since the late 1990s in a decrease of neurological morbidity. Also for the first time, this also resulted in a decrease of overall CP prevalence. So, the usual conclusion in reviews on CP, that its prevalence remains constant (Oskoui et al. 2013), can now be updated. Cerebral palsy prevalence data from population-based studies, thus, provide a more global view of the impact of the neonatal intensive care on survival and quality of survival in the last two decades.

### Classification of Cerebral Palsy

Attempts at classification of CP have been multiple (Ingram 1966) and no system is fully satisfactory. Even with the broader availability of neuroimaging, especially MRI, an aetiological classification is not useful, first because of a different availability of MRI in different countries and second because of the fact that universally accepted standards such as a neuroimaging classification for CP are not yet available. In addition, similar aetiological factors, for example PVL, can lead to a different clinical picture dependent on the lesion extent and topography. And different aetiological factors, for example a stroke in the domain of the MCA or focal cortical dysplasia in the motor area can lead to a similar clinical picture, spastic hemiplegia, or unilateral spastic cerebral palsy (US-CP). A clinical, phenomenological classification, therefore, is more useful than aetiological or pathological ones. It makes comparison between different countries with different standards of medical care more feasible and, what is more important, allows grouping of children with similar neurological involvement necessitating similar therapeutic interventions and leading to similar outcome. In the clinical routine, it is recommended, however, to add, if possible, aetiology or pathology to the clinical CP diagnosis; for example, spastic hemiplegia/US-CP due to an infarct of the MCA (see Diagnosis and Differential Diagnosis of Cerebral Palsy section).

Cerebral palsy is usually classified into neurologically defined subtypes, for example, spastic, dyskinetic and ataxic (Hagberg and Hagberg 1993). There is a variety of subdivisions within spastic CP:

- hemiplegia, hemiparesis, describing unilateral involvement with the addition of ‘arm-’ or ‘leg-dominated’ to describe topographical involvement;
- diplegia, diparesis or tetraplegia and quadriplegia, describing bilateral involvement; the first two meaning that legs are more involved than arms, the latter that arms are as much or more involved than legs.

Usually, mild, moderate or severe are gradings which are added to describe functional severity. However, these terms are not easily applied in a standardised way and attribution to the clinical situation is subjective. Thus, for example, rates of diplegia versus tetraplegia between different centres may vary from 20 versus 80, to 80 versus 20 (Colver and Sethumadhavan 2003). Therefore SCPE recommended to use the terms uni- or bilateral spastic CP and describe functional severity in legs and arms according to standardised scores (SCPE 2002) such as the Gross Motor Function Classification System (GMFCS; Palisano et al. 1997) and the Bimanual Fine Motor Function System (BFMF; Beckung and Hagberg 1992) or the Manual Ability Classification System (MACS; Eliasson et al. 2005). The combination of functional scores for arms and legs could give a clinical picture for the clinician, for example, higher scores in the legs describe diplegia or leg-dominated bilateral cerebral palsy (BS-CP) (Krägeloh-Mann et al. 1993), the prerequisite would be that scores are equivalent for legs and arms which is, however, not unchallenged.

When the neurological features are not purely attributable to one of the neurological categories, the predominant type should determine the classification. This can be especially difficult, when spasticity and dystonia occur together, so that a spastic-dystonic subgroup has been recognised (Hagberg and Hagberg 1993; Krägeloh-Mann et al. 1993). In such a situation, dystonia usually affects face and arms, whereas spasticity is predominant in the legs, with some involvement of the arms also. Thus, with respect to predominance, these children can be usually classified as having predominantly spastic CP.

The clinical picture of CP is often not only characterised by motor function problems but also by additional disturbances of sensation, cognition, communication, perception and/or behaviour and/or by a seizure disorder, which determine prognosis and treatment and have to be taken into account in the individual assessment of the patient and the multidisciplinary therapeutic approach (SCPE 2002; Rosenbaum et al. 2007).

In the clinical context, classification – and diagnosis – of a child with CP is recommended to respect to following domains:

1. Neurological subtype, spastic unilateral or bilateral, dyskinetic or ataxic;
Part III  Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

2. Severity of motor dysfunction according to GMFCS BFMM, or MACs;
3. Additional impairments of vision, cognition, seizure disorder;
4. Child being born term or preterm and indication of possible complications; and
5. Aetiology or pathology according to imaging results.

THE VARIOUS TYPES OF CEREBRAL PALSY

In the following section the subtypes of CP are described with respect to their prevalence, their motor dysfunction and the presence of additional impairments and with respect to neuroimaging findings. Spastic forms account for the majority (a little less than 90%) of cases, around one-third being unilateral and around two-thirds bilateral; dyskinetic forms occur in around 7% and ataxic in around 4% (Hagberg and Hagberg 1993; SCPE 2000, 2002; Sellier et al. 2016). As it is difficult to verbally describe movements disorders, the European network SCPE within the process of consensus building and harmonising CP definition and classification has established a reference and training anual which illustrates the neurological subtypes of CP with video examples and also gives typical case descriptions; this manual is accessible for health professionals: www.scpenetwork.eu.

SPASTIC CEREBRAL PALSY

The neurological symptoms in spastic CP are as follows (Platt et al. 2009; SCPE 2000):

- increased tone characterised by increased resistance to passive movement which is velocity dependent (Sanger et al. 2003);
- pathological reflexes; for example, increased reflexes or hyperreflexia and pyramidal signs, for example, Babinski response;
- abnormal pattern of movement and posture, in lower limbs characterised by equinus foot, crouch gait, internal rotation and hip adduction, in upper limbs by arms in flexion, hands fisted with thumb adducted or stiff and poorly directed movements of fingers.

BILATERAL SPASTIC CEREBRAL PALSY

BS-CP is especially prevalent in preterm born children. The overall prevalence is 1.2 per 1000 livebirths – around 0.5 per 1000 livebirths in children with normal birthweight, 6–10 per 1000 livebirths in children with moderately reduced birthweight and around 40–60 per 1000 livebirths in very low birthweight children (Platt et al. 2007; Andersen et al. 2011). Interestingly, the decrease in prevalence reported above in preterm born children with CP was especially due to a decrease in BS-CP.

Clinical Findings

As studies on clinical findings used different nomenclature, the terms diplegia, diparesis and leg-dominated are summarised in the following as milder forms and tetra- or quadriplegia as severe forms and data are specified when functional scores were applied. The milder forms, (GMFCS scores I–III), are most common. In most studies they account for around 60% of BS-CP cases and are typical for the preterm born child (Fig. 8.3). The severe forms often have some additional impairment and occur more often in the term-born child (Krägeloh-Mann et al. 1993; Horber et al. 2016). In the severe forms, additional dystonic features, which affect hands, face and even trunk, are common so that the delineation towards dystonic CP is not always clear cut.

Motor deficit is severe in more than two-thirds of children in the sense that they cannot walk without aid at the age of 5 years (Krägeloh-Mann et al. 1993). Contractures develop frequently, especially in children who do not learn to walk, in equinus position, hip adduction knee flexion, and so forth.

Additional impairments occur clearly more often, when gross motor dysfunction is more severe, which indicates that the more severe the brain lesion, the more severe are not only the motor, but also additional deficits (Surman et al. 2009; Horber et al. 2016). Cognitive problems in the sense of learning difficulties (corresponding to an IQ between 85 and 70) or intellectual disability (corresponding to an IQ<70) are encountered especially in the children with severe forms (e.g. 20% and 70%), whereas 40% of children with leg-dominated BS-CP have normal intelligence, 20% have learning difficulties and 40% intellectual disability (Krägeloh-Mann et al. 1993). Severe cerebral visual problems are encountered...
especially in the children with severe forms, around half of these children are blind or nearly blind; this is found in less than 10% in children with milder forms. Hearing problems (deaf or near deaf) are, however, not frequent, occurring in around 3% (Krägeloh-Mann et al. 1993). Epilepsy is encountered in around one-third of children with BS-CP and West syndrome in about 10%. Epilepsy is probably mainly symptomatic, as it is related to the severity of functional disability and to the extent and topography of causative lesions – children with BS-CP and epilepsy have a severe motor disability in 85% and a learning difficulty or intellectual disability in 90%; 100% of children with West syndrome have intellectual disability (Krägeloh-Mann et al. 1993).

**Aetiology and Pathogenesis of Bilateral Spastic Cerebral Palsy**

BS-CP is especially frequent in preterm born children, around 60–70% of children with CP in the different low birthweight groups have BS-CP (Sellier et al. 2016), often referred to as diplegia (Ingram 1964; Bennett et al. 1981). Systematic reviews of MRI in CP and population-based studies (Krägeloh-Mann et al. 1995; Krägeloh-Mann and Horber 2007; Korzeniewski et al. 2008; Himmelmann and Uvebrant 2011; Reid et al. 2014) show that genetic, first and second trimester abnormalities are rare, whereas white matter lesions are predominant and account for around 90% of findings, mainly the MRI PVL (Figs 8.4 and 8.5). As discussed in the Pathology, Aetiology, Pathogenesis section, the origin of white matter lesions are multiple and key factors are inflammatory. There is evidence that PVL is frequently accompanied by neuronal/axonal disease, affecting not only the cerebral white matter, but also thalamus, basal ganglia, cerebral cortex, brainstem and cerebellum. This constellation of PVL and neuronal/axonal disease has been termed ‘encephalopathy of prematurity’ and is supposed to be a complex amalgam of primary destructive disease and secondary maturational and trophic disturbances (Volpe 2009). The timing of this lesion is also a topic of controversy. A prenatal origin has been reported (Sinha et al. 1990; Iida et al. 1993). From hospital-based studies, however, there is evidence for a decrease in PVL (Hamrick et al. 2004). Also, van Haastert et al. (2011) described a decrease in cystic PVL of more than 50% between birth periods 1990–1993 and 2002–2005, whereby the severe form, cystic PVL III, showed the most significant decrease (ten-fold). The decreasing prevalence of BS-CP in the low birthweight children on a population basis is in accordance with the hospital-based observation that PVL is decreasing. PVL is typically bilateral, thus, when it affects the motor tracts, it usually gives rise to BS-CP (Fig. 8.5). These data of decreasing PVL and BS-CP argue against a primarily prenatal origin.

In term-born children with BS-CP, the systematic reviews of magnetic resonance findings show somewhat more heterogeneous results (see Table 8.2): maldevelopments of the brain with a genetic origin or originating in the first and second trimester account for around 15% of cases, examples are schizencephaly, lissencephaly and polymicrogyria. About 40% show predominantly white matter lesions, thus, patterns of early third trimester origin, most often magnetic resonance correlates of PVL a prenatal origin, thus, can be assumed. Around a third of the term-born children with BS-CP show lesional patterns characteristic of the more mature child indicating late third trimester or peri- and neonatal compromise (parasagittal

**Figure 8.4 Periventricular leukomalacia** of three severity patterns (all axial T2-weighted images). (a) Mild very asymmetrical periventricular leukomalacia affecting the motor tracts only on one side (thick arrow), thus giving rise to unilateral spastic cerebral palsy, the frontal gliosis (thin arrow) supports the periventricular leukomalacia diagnosis; (b) mild symmetrical periventricular leukomalacia with bilateral gliosis but no white matter reduction giving rise to bilateral spastic cerebral palsy; (c) severe periventricular leukomalacia with irregular enlargement of lateral ventricles due to white matter reduction and periventricular gliosis giving rise to severe bilateral spastic cerebral palsy.
Part III  Neurological Consequences of Prenatal, Perinatal and Early Postnatal Interference with Brain Development

injury, multicystic encephalomalacia, basal ganglia and thalamus lesions with involvement of the central sulcus) (Figs 8.6 and 8.7). Often a history of hypoxic–ischaemic encephalopathy or shock confirms the peri- or neonatal origin.

### CORRELATION BETWEEN MORPHOLOGY AND FUNCTION AND PREDICTION OF OUTCOME

Severe motor disability (defined as inability to walk at the age of 5 years) is found in about 80–100% of children who have brain maldevelopments or predominantly grey matter lesions but also in about 70% of cases in severe PVL (PVL with global extensive reduction of white matter as indicated in Figs. 8.4 and 8.5) (Krägeloh-Mann et al. 1995; Reid et al. 2014). Children with mild PVL (periventricular gliosis without white matter reduction as indicated in Figs. 8.4 and 8.5) or PVL with only focal extensive reduction of white matter (moderate PVL) have severe motor disability in only one-third of cases. The degree of motor deficit in children with PVL is clearly related to the lesion extent within the pyramidal tracts (Staudt et al. 2000). Studies using diffusion tensor imaging have shown that PVL, which is usually more extensive when it reaches the parieto-occipital area, also involves thalamocortical pathways, which seems to be related to sensory changes (Hoon et al. 2009).

Cognitive impairment is again especially found in the children with brain maldevelopments and children with predominantly grey matter lesions (in up to 100%), but also in 90% of children with severe PVL; whereas normal cognitive outcome...
Severe visual impairment (visual acuity <0.3) is associated either with bilateral involvement of the optic cortex or with severe involvement of the optic radiation, which means bilateral widespread occipital cortical damage or extensive occipital white matter reduction in severe PVL. Mild PVL is usually not associated with visual impairment, especially not to severe visual impairment, but there is evidence for secondary visual problems, for example, in the domain of visual perception (for a review see Pavlova and Krägeloh-Mann 2013).

Neonatal imaging is important for the prediction of BS-CP and its severity. It has a good potential to identify lesions, especially when they are severe and after the first evolution of these lesions. For example, Figure 8.8 illustrates severe, cystic PVL and parasagittal injury as seen late in the neonatal period. Figure 8.9 shows the development of a basal ganglia and thalamus lesion involving also the central sulcus and is discussed in detail below in the section on dyskinetic CP.

See also neonatal imaging findings in the Diagnosis and Differential Diagnosis of Cerebral Palsy section.

UNILATERAL SPASTIC CEREBRAL PALSY OR HEMIPLEGIA

The prevalence of US-CP, or hemiplegia, hemiparesis, is reported in the European survey to be about 0.6 per 1000 live births (SCPE 2000). It typically occurs in the term-born child. About one-third of cases are preterm born (Horber et al. 2016) and in contrast to BS-CP, the prevalence of US-CP in preterm cases, is not decreasing (Platt et al. 2007; Andersen et al. 2011).
forms in preterm born children (Uvebrant 1988; Bouza et al. 1994a) (Fig. 8.10). Facial palsy is not seen in US-CP in contrast to acquired forms of postneonatal origin where it is often seen (Brown et al. 1987).

Motor deficit is rarely severe; fewer than 2% of children in the population-based series of Uvebrant (1988) did not walk at the age of 5 years; more than half could walk without much restriction, 30% had a moderate limp and 10% a severe limp. In around a half, hand function was described as quite good with single finger movements possible; only 20% did not have more than holding function. Sensory problems were reported in around 20%, they add to the functional deficit and should be carefully sought, for example, by discrimination tests such as 2-point discrimination, younger children can be asked to recognise objects when given in the normal or the paretic hand. Secondary motor problems with contractures are mainly seen in the paretic foot with equinus position; hip subluxation is not a frequent problem. Hypotrophy of the affected limbs is often seen, but correction of leg length is seldom necessary.

Cognitive problems in the sense of learning difficulties or intellectual disability are less often found in children with US-CP than in other CP forms. Uvebrant (1988) found mild intellectual disability in 12% of his preterm children with US-CP; 6% of the term-born children had
severe intellectual disability and 13% had a mild intellectual disability. In the SCPE database (until birth years 2003), around 70% had normal cognitive development, around 20% had a learning difficulty or mild intellectual disability and less than 10% had more severe cognitive problems (Horber et al. 2016). This means that around 85–90% of children with US-CP do not have intellectual disability and more than two-thirds have a normal cognitive development.

Severe cerebral visual problems are rare, reported mainly in term-born children, at a prevalence of around 5%. Hemianopsia is probably often overlooked as it is well compensated for by the children and only recognised when specifically looked for. The neuroimaging may give a hint when the optic radiation or visual cortex is clearly affected on one side due to, for example, a porencephalic lesion or an extensive infarct.

Epilepsy is a major comorbidity in US-CP, it is found in around a third of the children; 25% of them have severe epilepsy (Uvebrant 1988). Epilepsy is mainly symptomatic and more often encountered in US-CP due to cortical malformations or due to cortical lesions.

**Aetiology and Pathogenesis of US-CP**

MRI studies in children with US-CP (Krägeloh-Mann and Horber 2007; Reid et al. 2014) show abnormal results in a high percentage (around 90%) (Table 8.2). Brain maldevelopments account for around 15–20% of cases, mainly cortical dysplasias, but also unilateral schizencephaly and other forms of focal cortical dysgenesis. White matter lesions are seen in more than one-third, such as focal periventricular gliosis or focal periventricular tissue loss with or without gliosis. The latter typically are sequelae of intraventricular haemorrhages grades III and IV (haemorrhagic infarction) (de Vries et al. 1999). To a minor degree, very asymmetrical PVL may be responsible affecting the motor tract only in one hemisphere (Figs 8.4 and 8.5). Another third have infarcts of the MCA (Fig. 8.11). Again, as in BS-CP, there is a clear difference between preterm and term US-CP. White matter lesions occur significantly more often in preterm US-CP than in term (around 90% versus 20%). Whereas infarcts are reported less often in preterm children with US-CP in population-based studies. From a neonatologist point of view, however, where children are recognised with infarcts, when they are symptomatic in the neonatal period, up to 40% are reported with a gestational age below 37 weeks. Benders et al. (2009) reported infarcts of the main branch of the MCA to be characteristic for the moderately preterm child (>33 weeks) and involvement of the lenticulostriate branches for the more immature child. Taken together, also in US-CP, patterns of third trimester origin (e.g. clearly acquired patterns), are predominant and found in about two-thirds of patients.

In contrast to the observed decrease of PVL, there is no clear evidence for a decrease of severe IVH in the preterm infant during the same time period (Fanaroff et al. 2007; Riegger et al. 2012), which is likely to explain that prevalence of preterm US-CP is not decreasing.

**Figure 8.11** Infarct of the middle cerebral artery with cortico-subcortical damage and of the basal ganglia and thalamus explaining a unilateral spastic cerebral palsy (T2-weighted axial image).

**Correlation Between Morphology and Function and Prediction of Outcome**

A good correlation between extent of lesion and deficits has been found. In periventricular lesions, motor deficit for the arm and leg respectively was described as clearly related to the extent of the lesion within the pyramidal tract (Staudt et al. 2000). Cognitive impairment (learning disability or intellectual disability corresponding to an IQ<70) is most frequent in brain maldevelopments (60%), it occurs in about 40% in children with an infarction of the MCA and also in the group with considerable ventricular enlargement (it is noteworthy, that this ventricular enlargement is not purely unilateral in most of the children). In children with focal periventricular gliosis, normal cognitive functioning is found in more than 80%.

When periventricular haemorrhagic infarction is seen in neonatal imaging, asymmetrical myelination of the posterior limb of the internal capsule is an early predictor of US-CP (de Vries et al. 2005).

**Unilateral Spastic Cerebral Palsy: a Model to Study Neuroplasticity Motor Function**

The compensatory potential of the young nervous system following brain injury is considered to be superior to that of the adult brain (Kennard principle; Kennard 1936). The malformations and lesions, which characterise pathogenic events at different times during early brain development, offer a good model to study compensatory mechanisms of the developing brain. The healthy hemisphere plays an important role in compensating for the damage on the opposite side.
role after unilateral lesions within the central motor system. In smaller lesions, not disrupting the motor tracts, an enlarged motor network involves also the healthy hemisphere (Staudt et al. 2002a). However, this is also described in adult patients following stroke (Weiller et al. 1993). In larger lesions, disrupting the motor tracts, abnormal fast conducting corticospinal projections from the healthy hemisphere exert the primary motor control. Such ipsilateral projections are physiological in the neonate; they do not mature and can no longer be elicited in later normal development (Eyre et al. 2001). They can apparently be maintained under pathological conditions, (e.g. when the contralateral projections are severed) (Farmer et al. 1991; Carr et al. 1993). However, their functional role seems to decrease already during late gestation, as Staudt et al. (2004) found evidence that hand function in patients with ipsilateral projections correlated with the timing period of the underlying brain lesions. In contrast to the motor system, there is no evidence that function can be reorganised interhemispherically (Wilke et al. 2009; Juenger et al. 2012).

Language in Unilateral Spastic Cerebral Palsy

In US-CP due to lesions acquired until the neonatal period, there is no gross difference in language with the hemisphere affected (Rankin et al. 1981; Aram et al. 1985; Carlsson et al. 1994) and there is good evidence that language in such a situation can be reorganised to the right hemisphere (Staudt et al. 2002b; Liegeois et al. 2004; Lidzba and Krägeloh-Mann 2005; Lidzba et al. 2013). However, this may be at the expense of originally right hemispheric functions, as visuospatial functions can be shown to be mildly deficient and there is evidence that this is correlated to the degree of right hemispheric language reorganisation and not to the overall lesion size (Lidzba et al. 2006). This supports the concept of ‘crowding’ initially proposed by Teuber (Teuber 1974; Lidzba and Krägeloh-Mann 2005). Children with left hemispheric lesions are reported to be slower in language development (Chilosi et al. 2001), which may indicate that the right hemisphere is not equally able to process language as the left hemisphere. And the evidence that complex linguistic processing is not as good when language is organised in the right hemisphere supports the concept that the left hemisphere has a genetic predisposition for language processing (Schwilling et al. 2012; Lidzba et al. 2013). Although there is no gross difference in language with the hemisphere affected, impairment of both verbal and nonverbal IQ is greater in children with left hemisphere lesions, while visuospatial functions are equally affected with lesions of either side (Vargha-Khadem et al. 1985; Carlsson et al. 1994). Speech and language defects are, of course, also related to the severity of intellectual disability. Taken together, language reorganisation to the healthy right hemisphere is a unique example of superior plasticity of the young brain, although there is evidence that the right hemisphere is not equally competent for language processing. The question still to be answered is up to what age can language be taken over by the right hemisphere without overt dysfunction occurring?

DYSKINETIC CEREBRAL PALSY

Prevalence of dyskinetic CP was reported to be 0.1 per 1000 livebirths in the European series (SCPE 2002; Himmelmann et al. 2009). It is reported especially in term-born children, who account for around 70% of children with dyskinetic CP. A significant increase in prevalence, from 0.05 to 0.12 per 1000 livebirths, occurred between 1976 and 1996 in children with a birthweight ≥2500g, whereas in the children with BS-CP and normal birthweight prevalence did not change during this period, which was also characterised by a significant decrease of mortality in the normal birthweight group.

Clinical Findings in Dyskinetic Cerebral Palsy

Dyskinetic CP (Fig. 8.12) is characterised by involuntary, uncontrolled, recurring, occasionally stereotyped movements, primitive reflex patterns predominate, muscle tone is varying (SCPE 2000). The European CP network recommends to sub-classify, if possible, into dystonic and choreoathetotic CP.

Dystonic CP is dominated by abnormal posturing and may give the impression of hypokinesia; fluctuating tone is characterised by easily elicitable tone increase; involuntary movements or distorted voluntary movements are typical and abnormal postures are due to sustained muscle contractions leading to slow rotation, extension or flexion of body parts.

Choreoathetotic CP is dominated by hyperkinesias and tone is fluctuating but mainly decreased; ‘chorea’ means rapid
involutary, jerky, often fragmented movements, ‘athetosis’ means slow, constantly changing, writhing or contorting movements.

Pure dyskinetic movement disorders do not show hyper-reflexia with clonus or pyramidal signs. But in dyskinetic CP, these spastic signs may be present indicating some involvement also of the pyramidal system. As reported above, severe BS-CP is very often characterised by additional dyskinetic more specifically dystonic features. So allocation to spastic or dyskinetic CP may be difficult. It is recommended that subtype classification be determined according to the dominating features. Dystonic CP is very similar to severe BS-CP with respect to its functional problems and severity, as described above. Children with choreoathetotic CP may be less severely affected and may learn to walk without aids. Children with dyskinetic CP in general are characterised by global movement disorders that also involve facial expression and because they have great problems in expressing themselves, they are often misjudged with respect to their cognitive capabilities. Kernicterus, now a rare aetiology of CP (see Aetiology and Pathogenesis section) is typically characterised also by hearing loss.

### Aetiology and Pathogenesis of Dyskinetic Cerebral Palsy

Epidemiological studies show that perinatal adverse events in dyskinetic CP of normal birthweight are more frequent than in BS-CP of normal birthweight; for example, convulsions before day 3 occurred in 76% versus 25% and an Apgar less than 5 at 5 minutes in 43% versus 9% (data from the European series in the birth years 1991–1996; Himmelmann et al. 2009). Together with the data on increasing prevalence of dyskinetic CP paralleled by decreasing mortality in normal birthweight children (see Prevalence section), it can be assumed that a higher survival of perinatal adverse events has lead to a higher morbidity.

In accordance with these epidemiological data, systematic studies of imaging findings in dyskinetic CP (Yokochi et al. 1991; Himmelmann et al. 2007) show in term-born children mainly lesions which are typical sequelae of severe asphyxia or shock with consequent hypoxic–ischaemicencephalopathy (lesions of late third trimester origin): bilateral involvement of the medio lateral thalamus and posterior putamen and pallidum (Fig. 8.7, Table 8.2), often associated with cortical-subcortical lesions, around the sulcus centralis; the diencephalic lesions may be subtle and thus missed when not looked for or when imaging quality is not very good. Because of monitoring and treatment of hyperbilirubinemia in the neonatal period, a typical pathology leading to dyskinetic CP, kernicterus, has become very rare. MRI typically shows hyperintensity of the globus pallidus on both sides (Govaert et al. 2000) and is, thus, distinct from the typical hypoxic–ischaemic pattern involving the putamen and the thalamus.

Preterm born children with dyskinetic CP are rarely reported and imaging findings in these children are even less systematically discussed. Kernicterus is also reported in preterm born children (Govaert et al. 2000); and basal ganglia and thalamus lesions can occur in the more mature preterm child (Bax et al. 2006).

### Morphology–Function Relationship and Prediction of Outcome

Functional deficit can be relatively well predicted in these basal ganglia and thalamus lesions (Krägeloh-Mann et al. 2002). Children with a pure involvement of the diencephalic structures with subtle putaminal and thalamic lesions may learn to walk independently, although they always develop a general, mainly choreoathetotic movement disorder and have a high chance for normal or only mildly impaired cognitive functioning. This observation seems very important as cognitive development is often misjudged in these children who cannot express themselves because of their general dyskinetic movement disorder, which may impact on speech considerably. When diencephalic lesions get more extensive, usually also accompanied by cortico-subcortical lesions in the central region, children develop more severe motor problems (e.g. no independent walking (GMFCS levels III and IV), often not even trunk control (GMFCS V)) and also cognitive problems (e.g. severe intellectual disability), bulbar signs are then frequent leading to swallowing and severe speech problems. But even in these situations it is recommended to evaluate carefully what the child can understand, as it is often underestimated. Neonatal MRI in this lesion type is helpful for the prediction of outcome. Lesions here are best seen on T1 weighted images (4–7 days after the acute event; Rutherford et al. 2005) (Fig. 8.9). This is important to know, as in contrast later images, for example, after the first year of life, show lesion best on T2-weighted images (Fig. 8.7). Very early imaging during the first week after the acute event, usually the first week of life, needs diffusion-weighted images to reveal the lesion (Rutherford et al. 2005). A myelin signal in the posterior limb of the inner capsule predicts the ability to walk at the age of 2 years, whereas severe diencephalic lesions together with cortico-subcortical lesions predict CP with severe motor impairment with high accuracy (Martinez-Biarge et al. 2012).

### Ataxic Cerebral Palsy

Ataxic CP, called by some authors nonprogressive congenital ataxia (Esscher et al. 1996; Steinlin et al. 1998), occurred in 0.09 per 1000 live births in the European series (SCPE 2002), which means that 4.3% of all individuals with CP had this specific subtype.

### Clinical Findings of Ataxic Cerebral Palsy

Ataxic CP is characterised by loss of orderly muscular coordination, so that movements are performed with abnormal amplitude, rhythm and accuracy (SCPE 2002). Typical features include trunk ataxia that leads to disturbed balance. In the upper limbs a characteristic feature is past
pointing, that is, over- or undershooting of goal-directed movements; tremor is another common sign, mainly a slow intention tremor. Low tone is also a prominent feature. Motor development is usually clearly impaired and 10–25% are reported not to learn to walk independently (Steinlin et al. 1998; Horber et al. 2016). In the above mentioned studies, cognitive function was in the range of intellectual disability in two-thirds of cases, which was severe in half of these; visual problems were described in over 50% and 20–30% developed epilepsy. The clinical features vary from case to case. Most cases of nonprogressive cerebellar ataxia are congenital even though the clinical manifestations often do not become suggestive before 1 or 2 years of age, at the time when children normally begin to walk.

**Aetiology and Pathogenesis of Ataxic Cerebral Palsy**

Nonprogressive ataxia is an obviously heterogeneous condition (Table 8.2). Its pathogenetic mechanisms are poorly known and its nosological interpretation is controversial. The results described here, rely mainly on two studies (Steinlin et al. 1993, 1998; Esscher et al. 1996), which describe imaging findings in children with nonprogressive cerebellar ataxia. In contrast to the other CP types, a lesional pattern in ataxic CP is exceptional. In more than 50% of cases, Computed tomography (CT) or MRI may show a normal result; in about 30–40% cerebellar hypoplasia of variable degree is found, which is not related to the degree of the motor involvement. Cerebellar lesions are increasingly recognised in the very preterm born child (Limperopoulos et al. 2007). Cerebral palsy in these children is often spastic (BS-CP) due to additional supratentorial white matter lesions (Krägeloh-Mann et al. 1999; Messerschmidt et al. 2008). When the latter do not affect to motor tracts, or when there are exclusively cerebellar lesions, the children are characterised rather by intellectual disability than by ataxia (Krägeloh-Mann et al. 1999; Limperopoulos et al. 2007). Thus, ataxic CP due to cerebellar lesions seems not a frequent finding in the very preterm born child. The familiarity in both term and preterm cases is high, thus, a probably main genetic origin of ataxic CP has to be assumed.

Prenatal factors play a dominant role in the aetiology of nonprogressive cerebellar ataxia (Hagberg et al. 1975b; Sanner 1979; Clement et al. 1984; Kvistad et al. 1985; Wichman et al. 1985; Tomiwa et al. 1987) which is supported by the predominant imaging findings discussed above. Obvious prenatal factors were present in 25% of the cases of Hagberg et al. (1975b) and, in 41% of patients, no cause was obvious but a prenatal origin was probable. Genetic factors were found in many series (Hagberg et al. 1972; Sanner 1973; Sanner and Hagberg 1974; Clement et al. 1984; Kvistad et al. 1985; Wichman et al. 1985; Tomiwa et al. 1987). Familial congenital nonprogressive ataxia has been reported from many parts of the world and autosomal recessive (Mathews et al. 1989; Pascual-Castroviejo et al. 1994), autosomal dominant (Furman et al. 1985; Tomiwa et al. 1987) and X-linked dominant (Fenichel and Phillips 1989) or recessive (Young et al. 1987) cases are on record. The correspondence between pathology (atrophy or dysplastic) and mode of inheritance is poorly documented (Guzzetta et al. 1993). Sporadic cases are common.

On the basis of these findings, which illustrate that ataxic CP stands out from the other CP subtypes insofar as it is rarely lesional, probably often genetic and imaging findings do not predict functional deficits, the question arises, whether ataxic CP should rather be excluded from CP and described as nonprogressive cerebellar ataxia. Inclusion of ataxic CP within the CP concept relies on the fact, that the latter is still based on phenomenological criteria which constitute a useful sociomedical framework for certain children with motor disability with special needs, as stated at the beginning. And a classification based on aetiology or pathogenesis is not, yet, agreed on.

### DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS OF CEREBRAL PALSY

#### POSITIVE DIAGNOSIS

The diagnosis of CP is essentially clinical. The practice parameter jointly developed by the American Academy of Neurology and the Child Neurology Society (Ashwal et al. 2004) suggests the following diagnostic steps: (1) history taking; (2) neurological and developmental examination for the assessment not only of motor but also of cognitive and language development and of behaviour; and (3) neuroimaging.

Neuroimaging, especially MRI, is increasingly playing a decisive role. Cerebral palsy is mainly characterised by brain lesions, which can be identified by MRI in 70–80% of patients and to a lesser extent by brain maldevelopments, which occur in around 10% (see Pathology, Aetiology, Pathogenesis section). The question addressed to neuroimaging is to find evidence for such a lesion or malformation and whether the topography and extent explains the neurological symptoms and the severity of the clinical picture. These questions are addressed above in the Various Types of Cerebral Palsy section.

Electromyography (EMG) which may shed some light on the mechanisms (Harrison 1988; Kanda et al. 1988), has no place in practical diagnosis except for the exclusion of other conditions that share with CP some weakness or hypotonia.

#### DIFFERENTIAL DIAGNOSIS OF CEREBRAL PALSY

An essential diagnostic consideration is the differentiation of progressive versus static neurological disorders, especially
treatable ones, from CP. Spinal cord tumour in the cervical region and slow growing brain tumours should always be excluded (Haslam 1975).

Many metabolic or heredodegenerative diseases run a slow course and their clinical manifestations can mimic all types of CP. Again here, neuroimaging plays a decisive role, as only cases where lesional or maldevelopmental patterns cannot be identified, must give rise to differential diagnostics.

Hypomyelinating disorders may be difficult to differentiate clinically from CP, as development is often primarily disturbed and neurological signs, whether ataxic, dyskinetic or spastic, are usually present. This again stresses the importance of doing MRI early in the diagnostic work-up of a child with developmental delay and neurological signs suggestive of CP. The finding of hypomyelination indicates the need for molecular genetic testing. It is of importance here to note that the diagnosis of hypomyelination relies on white matter signal hyperintensities on T2 weighted images without changes in two MRIs of at least 6 months distance and in a child 2 years of age or more (Schiffmann and van der Knaap 2009).

Hypotonia is a feature common to most early cases of CP but also to different diseases that are not infrequently misdiagnosed as CP. Prader–Willi syndrome is especially likely to be confused with hyperekplexia (see Chapter 5) and may simulate BS-CP, but there is progressive improvement and touch stimuli frequently produce a considerable hypertonic response with apnoea. The same applies to congenital myotonic dystrophy (Chapter 26), which indeed may coexist with actual hypoxic encephalopathia due to early asphyxia resulting from respiratory muscle involvement (Rutherford et al. 1989).

Hypertonia, which is a common early feature of several forms of CP, may also occur in infants with other problems or in otherwise typical infants (PeBenito et al. 1989). Neck extensor hypertonia in particular is often a precursor of CP (Amiel-Tison et al. 1977; Ellenberg and Nelson 1981). Touwen and Hadders-Algra (1983) found this to apply only when other abnormalities were associated with hypertension of the neck and trunk. In this respect, it has to be stressed that hypertonia or opisthotonic posturing as an early sign of severe CP is associated with marked developmental delay. Thus, hypertonia in a child with normal early developmental milestones is usually not indicating CP.

Differential Diagnosis of Bilateral Spastic Cerebral Palsy

Dopa-responsive dystonia usually differs in its age at onset, initial normal development, normal imaging and fluctuating course. But it may resemble mild BS-CP in its movement pattern when the onset is early, as diurnal fluctuation may be absent yet. Because atypical cases occur (Nygaard et al. 1994), a trial of L-dopa at the least suspicion and especially when the MRI is normal, is indicated.

The other important differential diagnosis in a child with leg-dominated spasticity are the hereditary spastic paraplegias there are forms which start early and progress slowly. Some forms with early onset are associated with abnormal cognitive development such subtypes caused by SPG (spastic paraplegia genes), 11 or 21. MRI may be abnormal in some forms (hypomyelination in SPG2 or hypoplasia of the corpus callosum in SPB 11) (Gasser et al. 2010). Molecular genetics, thus, seems indicated in a child with leg-dominated spasticity which does not respond to L-dopa and has a normal or ‘not CP typical’ MRI.

Older patients with severe intellectual disability and hypotonia may be given a diagnosis of severe BS-CP because the child may be very hypokinetic and contractures may have developed which makes it difficult to positively diagnose hyperactive tendon reflexes and hypertonia. Again, neuroimaging may help to differentiate, as a severe BS-CP usually has a severe lesion or maldevelopment, whereas in severe intellectual disability, MRI may be unspecific.

Differential Diagnosis of Unilateral Spastic Cerebral Palsy

The differential diagnosis of US-CP or congenital hemiplegia is not difficult. In the first months of life, the main differential diagnoses include temporary neonatal hemis syndromes and obstetric brachial palsy. The latter can be differentiated by the absence of deep tendon reflexes and of any involvement of the lower limb just by careful clinical examination. Later, pure hemidystonia or athetosis can raise difficult problems. Indeed, a mixture of dystonic and spastic signs is more common than either alone.

Acquired Hemiplegia

Acquired hemiplegia can result from multiple causes. Cases of acute onset can result from inflammatory disorders, demyelinating diseases, migraine, trauma and, especially, vascular disease and the so-called hemiconvulsion-hemiplegia-epilepsy or HH syndrome (Gastaut et al. 1960; Auvin et al. 2012) or acute postconvulsive hemiplegia (Okuno 1994). Cases of progressive onset mainly suggest neoplastic disease, especially gliomas of the brainstem, basal ganglia or thalamus and degenerative disorders (Chapters 10 and 14).

Although acquired hemiplegia can occur at any age, the vast majority of cases start during the first 3 years of life. The onset is often acute and dominated by the features of the causative illness such as convulsions and coma. The hemiplegia is generally maximal from onset and flaccid with marked facial involvement. Spasticity develops later in most cases. Aphasia is present in left-sided cases, in contrast with congenital hemiplegia (Rapin 1995). The degree and rate of recovery are quite variable, some patients being left with severe, persistent weakness, while others make an almost complete recovery. The cause of hemiplegia largely determines the prognosis. Post-epileptic hemiplegia has a bleak outcome, with 75%
of patients developing residual epilepsy and more than 80% having some degree of cognitive impairment (Aicardi et al. 1969; Aicardi and Chevrie 1983). Children with post-epileptic hemiplegia exhibit a characteristic sequence of predominantly unilateral hemispheric oedema, followed by global atrophy of the affected hemisphere, which is a virtually specific finding (Kataoka et al. 1988; Aicardi 1994). Vascular hemiplegia has a more favourable prognosis dependent on the extent of the underlying infarct.

Acquired hemiplegia may be difficult to distinguish from US-CP when it occurs in infants, especially as seizures may reveal a previously unrecognised deficit. Flaccidity and facial involvement are strong arguments in favour of an acquired hemiplegia.

Acquired hemiplegia resulting from vascular disease, especially arterial thrombosis or embolism, is dealt with in Chapter 15.

**DIFFERENTIAL DIAGNOSIS OF DYSKINETIC CEREBRAL PALSY**

The differential diagnosis of dyskinetic CP includes degenerative and metabolic conditions. Genetic dystonias of early onset may be difficult to differentiate and a normal MRI in a dyskinetic movement disorder should give rise to molecular genetic diagnostics. Glutaric aciduria type I usually has a sudden onset following an infectious episode but can also evolve in a slow, progressive way, but usually after a primary normal development (Gascon et al. 1994). Rarer metabolic conditions (e.g. molybdenum cofactor deficiency), may be a cause. Complicated forms of spastic paraplegia with dystonia may raise difficult problems (Fletcher and Marsden 1996). Dopa-responsive dystonia when starting early rather mimics mild BS-CP as described above. Transient dystonia may occur in apparently normal infants during the first year of life (Willems et al. 1986; Deonna et al. 1991). It usually affects one or more limbs, does not involve the trunk or neck, presents after 4 months of age and interferes relatively little with the child’s activities. The limb posturing may be intermittent or permanent and disappears in weeks or months. A form involving the trunk has been tentatively attributed to maternal cocaine use (Beltran and Coker 1995). A paroxysmal form has been described (Angelini et al. 1988). Transient dystonic attitude limited to the foot may simulate dystonia (Newman et al. 2006).

**DIFFERENTIAL DIAGNOSIS OF ATAXIC CEREBRAL PALSY**

Ataxic CP should not be confused with physiological incoordination of young infants or of children with global delay of milestones. Simple clumsiness may be responsible for diagnostic errors (Gubbay 1985). The most difficult differential diagnosis is with the progressive ataxias and this problem may take a long time to clarify as some of the progressive cerebellar ataxias may start early and have a very slow course (Gasser et al. 2010). A neuromuscular disease with still normal tendon reflexes may give rise to a misdiagnosis of ataxic CP. Thus, it seems important to stress that low tone is not the qualifying symptom for ataxic CP; other signs such as, for example, disturbed balance beyond of what could be explained by weakness, or over- or undershooting of goal-directed movements are necessary to give the diagnosis.

**DIAGNOSTIC DIFFICULTIES AND EARLY DIAGNOSIS**

As discussed above, the diagnosis of CP is a clinical one. Consequently, because the typical clinical picture becomes clear only over time, early diagnosis may be difficult. The correct diagnosis of CP is highly dependent on knowledge of normal development and its variants. It is relatively easy to exclude the diagnosis of CP early if the developmental pattern of a suspected infant is normal.

Prechtl et al. (1997) developed an early diagnostic system for the diagnosis of CP that evaluates video-documents of spontaneous neonatal and early infantile movements. A repeatedly documented occurrence of writhing movements and the lack of development of fidgety movements during the first 3 months were reported to be a sensitive and specific sign for the development of neurological abnormalities, which were in the majority CP, but also the development of intellectual disability or minor neurological signs.

Abnormal neurological signs may be transient, so asymmetries of posture and tone, hyperexcitability and hyper- or hypotonia may be found in infants with normally acquired developmental milestones in whom no brain abnormality can be demonstrated. Such features are transitory in over 90% of patients (Michaels et al, 1993). Transient dystonia occurs in some apparently normal infants during the first year of life (Willems et al. 1986; Deonna et al. 1991). It usually affects one or more limbs, does not involve the trunk or neck, presents after 4 months of age and interferes relatively little with the child’s activities. The limb posturing may be intermittent or permanent and disappears after weeks or months. Such transient anomalies may be the cause of overdiagnosis of CP and be responsible for the description of children who ‘outgrow cerebral palsy’ (Nelson and Ellenberg 1982; Taudorf and others 1984). However, we are not aware of any positively documented case in which clear neurological signs and MRI findings as described above were associated with normal outcome. Children who start walking on tiptoes when they acquire ambulation may be misdiagnosed as having mild
‘diplegia’. The clinical experience shows that when independent walking is acquired within the normal range, BS-CP is highly unlikely as even mild forms of BS-CP are delayed in learning to walk independently. It is also useful to ask whether the child has used a baby walker, as to some extent these induce tiptoe walking.

Such figures indicate how much the diagnosis can err if infants are not followed up and how one should be careful in evaluating the ‘effect’ of early intervention. For this reason, it is generally agreed that the diagnosis of CP should be tentative before the age of 3 years and that CP registers should definitively accept children when the diagnosis is confirmed at the age of 5 years. Of course, there are clear individual situations, especially when the aetiology is known, where the diagnosis can be established earlier.

The changing clinical picture or features of CP can also be a source of diagnostic problems, especially in choreoathetotic and ataxic CP, in which hypotonia is often an early sign. Dyskinetic CP may be wrongly diagnosed in children who are hypotonic and have stereotyped movements. Infants who later prove to have intellectual disability without CP, and who have early neurological signs such as truncal hypotonia, hyperexcitability and decreased variability of motor patterns, can be misdiagnosed with spastic CP. In most infants with US-CP or hemiplegia, asymmetry of movement usually becomes evident only after 4–6 months, even when the lesion is known.

Neonatal neuroimaging findings play an important role in the early diagnosis and prediction of CP. As indicated in The Various Types of Cerebral Palsy section the correlation between morphology and function, topography of a lesion or malformation is related to neurological signs and functional deficit. Thus, the early identification of a lesion or malformation and its topography helps to predict outcome with respect to CP.

- In a preterm born child at term equivalent age, normal MRI is highly predictive of normal motor development, thus the development of CP is highly unlikely (Sie et al. 2005).
- Normal myelination of the posterior limb of the internal capsule (PLIC) seen on MRI in the neonatal period indicates normal motor development. For example, in a child with haemorrhagic infarction, symmetrical myelination of the PLIC argues against the development of US-CP (de Vries et al. 1999) or after asphyxia with HIE and imaging abnormalities of the deep grey nuclei, a normal PLIC bilaterally predicts normal motor development (Martinez-Biarge et al. 2012) (Fig. 8.13).
- Neonatal cranial US-CP has been extensively studied with respect to outcome: 60–100% of preterm born neonates with cystic PVL are at risk of developing spastic CP; when the cysts are located in the domain of the motor tracts there is a risk of nearly 100% (de Vries et al. 2004; Ancel et al. 2006). The same studies give a risk of 47% and 66% for ICH grade IV (haemorrhagic infarction) and of 28% for ICH grade III; whereas ICH grades I and II are only rarely followed by CP. In a preterm born child, US-CP without abnormal periventricular echogenicity and peri- and intraventricular haemorrhage is predictive of a favourable outcome (van Wezel-Meijler et al. 2011).
TREATMENT AND MANAGEMENT

Cerebral palsy is not exclusively a motor syndrome as associated or even dominant other signs and symptoms may occur in individual cases. Thus, issues of management concern a very wide range of functions including vision, hearing, speech and language development and intellectual status. All these are the subjects of other chapters in this book and here we largely restrict ourselves to some general principles and a look at current developments in the management of CP.

PREDICTION OF MOTOR FUNCTION AND EARLY INTERVENTION

The development of reliable testing instruments for gross motor function, the Gross Motor Function Measure (GMFM; Russell et al. 2002) has led to the development of prediction bands with which levels of gross motor function in children with CP can be predicted very accurately from the age of 2–3 years (Palisano et al. 1997; Rosenbaum et al. 2002). These prediction bands have an important implication: that treatment or management is not in fact going to substantially change the overall outcome for movement in the child with CP beyond the motor function which can be identified or predicted around the age of 2–3 years. This does not mean that treatment is not helpful. First, neglect of any management of the motor system in the child with CP may lead to undesirable secondary effects such as contractures. Second, effective management of a condition has also to do with support in everyday life situations, with acceptance of a dysfunction and with integration despite that dysfunction. The prediction bands also play a role when it concerns parental hopes/expectations that early intervention will improve the long-term prognosis for their child.

There is a continuing debate about how much early ‘treatment’ can affect the outcome. Blauw-Hospers and Hadders-Algra (2005) in a systematic review of the effects of early intervention on motor development evaluated 32 studies with interventions starting between birth and a corrected age of 18 months in infants at high risk of developmental disorders and concluded that there was no clear beneficial effect on long-term motor outcome. Another concept is ‘enriched environment’ for promoting optimal brain injury recovery, which has been put forward following animal studies. Systematic reviews show that environmental enrichment improves cognitive outcomes and to a certain extent also motor outcome in infants at high risk of CP (Morgan et al. 2013). This is supported by the idea that learning in infancy is implicit.

MANAGEMENT OF CEREBRAL PALSY AND QUALITY OF LIFE

Discussion on management in CP needs to address a specific aspect related to quality of life. Although children with CP report similar quality of life as their peers, severity of impairment and especially pain is associated with lower quality of life (Dickinson et al. 2007; children were aged 8–12 years). Furthermore, problems with physical health such as bodily pain, not necessarily psychological health, are reported to be clearly related to the severity of gross motor deficits and additional impairments (Beckung et al. 2008). Restricted participation of children with CP was also found to a high degree to be explained by pain and higher impairment (more severely impaired walking, fine motor skills, communication and intellectual abilities) (Fauconnier et al. 2009). Thus, management of a child with CP needs to take into account that pain may be a problem and require special treatment. This underlines that adequate treatment of orthopaedic problems (see Treatment and Management section) is not only of functional relevance but also important with respect to pain. Treatment of pain in childhood and adolescence is also important for the prevention of chronic pain syndromes in adulthood, this concerns all motor severity levels in CP.

MEETING THE NEEDS OF THE DISABLED CHILD

The child needs: (1) diagnosis, (2) assessment, (3) treatment, (4) management, (5) care, (6) counselling and (7) periodic diagnostic review and reassessment. In most developed countries, assessments will be carried out in an assessment centre, maybe within a hospital setting although sometimes in separate facilities. Because early diagnosis may be difficult, and diagnosis should be tentative before 3 years of age, this will often mean that there is a painful pause for the parents while it is being confirmed. Blood tests may need to be carried out to exclude progressive diseases such as some metabolic disorders. Genetic testing may also be important at this time. But often brain damage has been clearly identified by imaging and a diagnosis has to be conveyed to the parents. Disclosure of a diagnosis of chronic illness in their child is obviously deeply disturbing to the family and the process needs to be carried out sensitively. Good guidelines about disclosure are contained in a booklet provided by the UK charity Scope (Leonard 1999).

Assessment on follow-up relies on four domains: physical, neurological, developmental and sociomedical.
PHYSICAL ASSESSMENT

Any child with CP needs regular assessment of his or her general health status. Upper respiratory tract infections are just as common, or may be more common, in children with CP as in the typical population. In a child with severe motor disability, a lack of mobility may enhance an upper respiratory infection and poor swallowing; a weakened cough reflex may contribute to the development of pneumonia. It is important to counsel with respect to vaccination; CP is not a condition associated with reduced immune competence, and vaccination is of high importance as infections may easily become severe in a child with severe motor disability and lack of mobility.

Anthropometry is important in any child, but especially important in a child who may develop CP. Head circumference indicates normal or abnormal brain growth, which is important where there is a history of brain lesion. In a child with neonatal intracranial haemorrhage, head circumference is important to monitor as hydrocephalus may develop. Children with CP often experience disturbances in growth; many have feeding difficulties and every care has to be taken to maintain adequate nutrition bearing in mind that their basal metabolic rates may be different to those of children without disabilities (Sullivan and Rosenbloom 1996). Many children with CP and severe disability have difficulties with feeding and insufficient intake. Feeding may take a longer time which reduces time for other activities. Forced feeding in a child with swallowing difficulties risks aspiration which can be the cause for repeated pneumonias. In such situations treatment options include a percutaneous gastrostomy.

Contractures and reduced joint mobility are frequent in children with CP, especially those who are non-ambulatory. The ankles (contractures in fixed equines position), the hips (subluxation or luxation) and the spine (scoliosis) have to be regularly monitored (see also hip surveillance in the Orthopaedic Management section). Children with US-CP may develop shortening of both upper and lower limb but predominantly the lower.

Osteoporosis is a frequent problem in immobile patients with CP (GMFCS IV and V), in these the surveillance of osteodensity and prevention of osteoporosis is important (see also Feeding).

DEVELOPMENTAL ASSESSMENT

Development, especially motor, is often delayed and milestones may (e.g. walking) or may not be achieved; the planning of a management programme relies on knowing what exactly the child is able to do. Thus, assessment of the child involves comparing function in all aspects of development with the expected norms for the age (Bax et al. 1990; Michaelis et al. 2013). By the age of 2–3 years future ambulatory ability can be predicted as stated above with around a 90% accuracy.

SOCIOMEDICAL ASSESSMENT

The diagnosis of CP carries the message of a lifelong impairment, often not only with respect to motor, but also to other functions. Thus, good management requires that families receive counselling very early on with respect to support systems that are available. These vary from country to country; while in one country special kindergartens and schools are established others try to integrate children with disabilities into regular institutions. Sociomedical assessment has to take into account the welfare of the entire family, for example, siblings may experience a certain ‘neglect’ as most attention is given to the disabled child.

TREATMENT AND CARE ISSUES

When a health professional talks about treatment, the patient and their family may assume that the health professional is talking about a cure. In the early years parents may believe that the child will become ‘normal’. While as indicated below some aspects of the child’s condition can be effectively managed, there are many others where problems will persist. It is important, therefore, to discuss with the family and also, when possible, with the child, that what can be offered is a management programme that can ameliorate the condition and allow the child to develop the best possible function and participation.

As CP is mainly of lesional origin, it is logical to look for prevention or restoration of lesions. Research in neonatology and neurology on neuroprotection has been very active for decades, besides basic research numerous clinical trials have been performed. The only concept which could clearly show improved outcome and which has, thus, been introduced into routine care in neonatology intensive care is hypothermia in the term-born child following asphyxia and hypoxic–ischaemic encephalopathy (HIE). Three positive randomised controlled trials of moderate hypothermia for term infants with hypoxic–ischaemic encephalopathy HIE showed that moderate hypothermia within 6 hours of asphyxia improved survival without CP or other disability by about 40% and reduced death or neurological disability by nearly 30% (Gluckman et al. 2005; Shankaran et al. 2005; Azzopardi et al. 2009).
MANAGEMENT OF MOTOR DISORDERS

The following sections centre on physiotherapy, surgical (largely orthopaedic) management, and drug treatments. In general, most of the treatments relate to the spastic form of the disorder; dyskinetic problems are mentioned separately.

Physiotherapy

Many therapists use particular systems of therapy to treat (or manage) the child with CP. The best known (and probably the best thought out) are the techniques developed by the Bobaths (Semens 1967; Bobath 1980; Bobath and Bobath 1984) but there are many other systems of therapy including those of Vojta (1984) and the Petö School (Hári and Akos 1971). A danger with some of these systems of therapy (such as those advocated by Doman and Delacato – see Cummins 1988) is the great strains they place on the family, disrupting the normal pattern of family life (McConachie et al. 1997). In recent years the American Academy of Cerebral Palsy and Development Medicine has had working parties reviewing many of these systems and published reports on them. In general, these have failed to find that these systems of therapy are effective, and despite the enthusiasm their use is diminishing with the emphasis being on evidence-based methods being used. Thus the Butler and Darrah (2001) report on the neurodevelopmental treatment (NDT; based on the Bobath method) cast doubt on the value of this method of treatment. However, it should be noted that while orthodox medicine has in recent years been largely converted to the importance of evidence-based medicine, many physical therapy approaches are still widely promoted and parents may still embrace claims that the child can be ‘cured’. The emphasis now is on the prevention of contractures and deformities and on efforts to see that practical functions such as standing, walking and feeding are developed and that participation becomes possible. The therapist will therefore look at the child together with the parents and other members of the team and produce a programme aimed at preventing abnormal patterns of behaviour developing and providing a management programme that will help the child to achieve their optimal development.

A certain feature of management of the child with CP that has changed in recent years and that is the emphasis on the value and importance of helping the child’s mobility and access to the environment and participation. An initial study in this regard was that of Butler (1986) emphasising the importance of stimulating the child whose movement capacity limits his or her ability to explore the environment. All the data herald a long overdue positive approach to the strengthening of the child’s motor system in CP and the abandonment of older theories of therapies attempting to change the basic neurological pattern (Damiano 2004).

The levels of evidence for physiotherapy interventions, particularly strengthening and to a lesser extent functional training, in school-aged children with CP has improved in recent years. A systematic review focusing on the common conventional physiotherapy interventions used with children with CP, aged 4–18 years, included strength and functional training, weight-supported treadmill training and neurodevelopmental treatment (Martin et al. 2010). Strength training was the most studied intervention with significant improvements found in the strength of selected muscle groups using dynamometry, some studies also showed significant improvement in function. Functional training showed improvements in gross motor function, endurance and temperospatial measures, such as gait speed and stride length. Nonsignificant trends of improvement on the GMFM and gait velocity were found for treadmill training by a few studies with low levels of evidence (case series). Of three studies that evaluated neurodevelopmental treatment, one high-level evidence study, that is, randomised controlled trial, found significant improvements on the GMFM. All studies reviewing treatment dosage, yet found no significant differences for different intensities of treatment.

Constraint-Induced Movement Therapy

Constraint-induced movement therapy (CIMT) has been developed in adult stroke patients where the unaffected limb is constrained, requiring the patient to attempt to use their partially inactive limb. It has proved effective for these patients and its use has been extended to children, particularly those with US-CP. A recent systematic review and meta-analysis (Tinderholt Myrhaug et al. 2014) summarised the effects of CIMT on hand function and functional skills and supported the existing evidence that CIMT improves unilateral hand function and functional skills. However, in a majority of the included studies, equal improvements were identified between intensive intervention and conventional therapy or between two different intensive interventions. The authors concluded that different types of training, different intensities may have contributed to the observed variations in the effectiveness of CIMT.

Another factor may contribute to these variations: many children with US-CP due to early unilateral brain lesions control their paretic hands via ipsilateral corticospinal projections from the contra-lesional hemisphere (see The Various Types of Cerebral Palsy section). They can be identified by the fact that they show mirror movements of either hand when moving their hand. These patients respond less well to CIMT especially with respect to motor speed than patients with preserved contralateral corticospinal projections (Kuhnke et al. 2008). These differences have also been shown concerning the neuromodulative effects of therapy, as demonstrated by magnetoencephalography, transcranial magnetic stimulation and functional magnetic resonance imaging (Juenger et al. 2007; Walther et al. 2009).

In conclusion, physiotherapy in CP is considered necessary either continuously or in regular, more intensive settings. It is important to note that no system is more effective than another. In the individual patient, choice of a specific system and its intensity will depend on the goal which the treatment wants to achieve and this goal achievement has to be adapted continuously to every day life situations.
Drug Therapy

The two most commonly used drugs in CP are botulinum toxin and baclofen.

The background to the use of botulinum toxin goes back to the work of Tardieu et al. (1972) who reported that alcohol or phenol injections into spastic muscles decreased spasticity by blocking the release of acetylcholine at the neuromuscular junction. Long-term results were, however, debatable. With the introduction of botulinum toxin there has been a great increase in attempts to reduce spasticity by this means. Early papers of Cosgrove et al. (1994) and Corry et al. (1997) with reasonable trials in both upper and lower limbs have lent quite powerful support to its use as an adjunct to other forms of management of the motor disorder. Botulinum neurotoxin type-A (BoNT-A) has been used in association with other interventions in the management of spasticity in children with CP now for almost two decades. A consensus statement based on an extensive review of the literature (Love et al. 2010) concluded that injection of BoNT-A in children with CP is generally safe although systemic adverse events may occur, especially in children with more physical limitations (GMFCS V). The committee further concluded that injection of BoNT-A is effective in the management of lower limb spasticity in children with CP and when combined with physiotherapy and the use of orthoses, these interventions may improve gait and goal attainment. But it was also stressed that assessment of children with CP and evaluation of outcomes following injection of BoNT-A are complex and therefore, a range of measures and the involvement of a multidisciplinary team is recommended.

Baclofen orally has been used in CP for a long time and it can be an effective muscle relaxant. It often has to be used in relatively high doses and the consequent side effects, particularly of sleepiness, urinary retention and gastrointestinal problems, may be significant. In these situations, the use of baclofen intrathecally, giving the drug by continuous infusion or in boluses (Armstrong et al. 1997) can be helpful. It is recommended especially in severe BS-CP, where stiffness may make it difficult for the child to be nursed and managed, and may be very effective also in reducing pain. There is evidence from non-randomised, controlled trials to support the effectiveness of intrathecal baclofen infusion for the short-term reduction of severe spasticity in patients who are unresponsive or cannot tolerate oral baclofen, and evidence from observational studies with controls, for the long-term reduction of severe spasticity (Health Quality Ontario 2005).

Orthopaedic Management

It has already been mentioned that many contractures and the abnormal growth of muscles and hence joints may be prevented by early postural management, helped by splinting to maintain joints in their neutral position. The management of this will be the responsibility of both the orthopaedic surgeon and a physical therapist.

- With respect to hip(sub)luxation, a prospective study of hip surveillance programme in Sweden did impressively show that, by systematic monitoring and soft tissue surgery, luxation can be successfully prevented in near to 100% of participants (Robb and Hägglund 2013). This programme has now been introduced in several other countries in Europe.

- Probably the commonest orthopaedic procedures are carried out around the ankle to address problems of equines position and tightening of the Achilles tendon. In a first step the feet are supported by an orthosis for the correction of dysfunctional posture; predominant hypertonicity of the extensor muscles may be modulated by botulinum toxin injection; in the case of fixed contractures operative correction may become necessary.

Scoliosis management is usually done in a combination of physiotherapy and adapted support for the sitting position. Surgical treatment may become necessary in single cases and requires an interdisciplinary approach: the paediatric pulmologist to assess lung function, the paediatric neurologist to evaluate the global situation and functioning and the orthopaedic surgeon with specific expertise in scoliosis surgery.

Specific Surgical Approaches

Dorsal rhizotomies were considered in the 1970s but were not performed for many years until Peacock and Arens (1982) initiated the use of this form of therapy again. In selective dorsal rhizotomy (SDR) a partial sectioning of the dorsal roots from L2 to S1 is performed. SDR can be performed where the nerve root exits the intervertebral foramina via multi-level laminotomies, or at the level of the conus via a single-level laminotomy; outcome is reported similar (Ou et al. 2010). Functional improvement and good levels of satisfaction with life habits has been demonstrated as much as 17–26 years later (Langerak et al. 2011). In a meta-analysis of three randomised controlled trials of patients treated with SDR combined with physical therapy or with physical therapy alone, McLaughlin et al. (2002) found that 9 months to 2 years after SDR, there was a significantly greater improvement in the gross motor function abilities in the group treated with SDR and physiotherapy. A recent systematic review of 52 studies found that selection criteria for SDR vary considerably (Grun et al. 2014). A certain consensus concerns two indications: children with BS-CP, who can walk and have spasticity mainly in the legs, for example, the typical diplegia of the preterm. As discussed in the Prevalence section, this form of CP is decreasing, which also explains that dorsal rhizotomy is less often performed. A second indication is severe spasticity in the legs with pain and difficulties in every day handling which does not adequately respond to drug treatment.
Other Aspects of the Motor Disorder

The above discussion about management of the motor disorder largely relates to the spastic forms of CP. In patients with dyskinetic CP, contractures and fixed deformities are not usually a problem (although they do occur). The main difficulties relate to the involuntary movements and dystonic posturing. Sometimes this can be very powerful and extremely difficult to interrupt, making all purposeful movement impossible. The following drugs may be used, but success is difficult to predict and individual trials are recommended.

- **Dopamine** may be effective, it is important to introduce the drug slowly because of the risk of side effects.
- **Trihexyphenidyl** may be used together with dopamine, then in a low dose, or alone.
- **Tetrabenazine** is another possibility, although in off-label use.
- **Baclofen** - severe dystonic CP may also respond well to a baclofen pump.

A particular problem in CP is **drooling**, which may occur in as many as 50% of patients. It is an unpleasant problem and difficult to treat. Various drugs have been tried, of which scopolamine patches are probably the most easy to use as effect and tolerability can be judged immediately (Lewis et al. 1994). Benztropine and glycopyrrolate are orally administered drugs. BoNT-A can be used injected into salivary glands, either into the parotis which is responsible for the pulsatile excretion of saliva during meals or rather into the submanibular glands, which also excrete between meals and thus, are probably mainly responsible for the drooling. Redirection of the salivary ducts and removal of the salivary glands is another possibility that is reported to have good rates of success in experienced hands (Burton 1991). A Cochrane database review (Walshe et al. 2012) evaluated the effectiveness and safety of interventions aimed at reducing or eliminating drooling in children with CP. The authors found six trials, meeting their quality criteria, four using BoNT-A and two were trials on the pharmacological interventions, benztropine and glycopyrrolate. No randomised controlled or controlled clinical trials were retrieved on other forms of intervention. All studies showed some statistically significant change for treatment groups up to 1 month post intervention. However, methodological flaws did not allow conclusion on the effectiveness and safety of either intervention.

Speech/Communication

Communication is highly dependent on the ability to speak. Children with CP often have speech difficulties. This is because, on the one hand, they have severe intellectual disability and do not learn to understand language and to develop a speech concept. On the other hand, the neurological features in CP may be so extensive as to also affect the articulatory motor domains, which can result in dysarthria or even anarthria, so that speech production is incomprehensible or not possible although the affected children do understand language. This is especially seen in children with dyskinetic CP and in the severe forms of BS-CP. As it seems important to have a tool to describe the speech performance of children with CP in a reliable way which is easy to use by doctors, therapists and also care givers, the SCPE network has compared different tools and suggests the Viking Speech Scale as a reliable, easy to use tool which can be applied through direct observation of children or through case note review (Pennington et al. 2013).

FEEDING

It is curious that older textbooks on CP (Ingram 1964) make no mention of feeding problems in the child. In fact a very large proportion of children with CP have feeding difficulties. These often persist through into adult life. In moderate to severe CP something like 15% of young adults may have a gastrostomy (Eltumi and Sullivan 1997). Difficulties occur early and need to be recognised so that the child does not suffer from inadequate nutrition, which may have an effect on the developing brain. A child with CP may never develop beyond the suck–swallow pattern of feeding and never be able to chew. Cerebral palsy clinics and child development centres now have specialist feeding clinics with dieticians, speech therapists and physicians as part of a team trying to maintain adequate nutrition and a satisfactory feeding pattern. Better feeding together with putting weight on skeletal structures is important for the prevention of osteoporosis and bone fractures. It is important to remember that apart from a nutritional role, mealtimes are significant social occasions in most societies and it is desirable that the child should not be isolated by being fed away from the rest of the family (Sullivan and Rosenbloom 1996).

ADOLESCENCE AND ADULT LIFE

It is beyond the scope of this book to discuss the issues that arise as the child with a disability gets older. Briefly, it is important to know that severity of motor and additional impairment is the main factor determining long-term survival of children with CP and after the first years the expectation of life for people with CP is not substantially lower than that for the normal population; for example, around 90% of those who were alive at 2 years become 20 years and older (Hemming et al. 2005).

Often services that have been provided by paediatricians or paediatric neurologists fall away and young people find themselves in the community without a dedicated health service (Thomas et al. 1989). The tasks for the adolescent include the achievement of independence, self-image and identity, the expression of sexuality and vocation. The word vocation rather than work is used deliberately because for many of these young people open employment may be difficult to find. The
situation may have to be faced that the young person is not going to have a job but nevertheless needs to have a purposeful life plan. For the family this is often a difficult period. The parents/carers are becoming older and if their child is severely disabled they may begin to realise that the care that they have formerly lavished on the child may not be possible in the future. Provision for where a young person with severe disabilities can spend adult life vary considerably from country to country and is often unsatisfactory.

The number of inborn errors of metabolism is extensive, and more than 600 entities have been recognised. Most of these diseases are rare. As a consequence, it is difficult for physicians taking care of adults or children to have a readily available knowledge of all clinical syndromes and their biochemical and genetic basis as well as their treatment possibilities. It is useful to describe screening procedures that can help in the initial identification of patients with inborn errors of metabolism.

Many symptoms prominent in patients with inborn errors of metabolism are often nonspecific and can be caused by more common conditions, such as infections or asphyxia. These conditions are usually easier to diagnose; therefore, their differential diagnoses should always be considered first.

It is necessary that each physician assessing a child with unexplained symptoms and signs thinks of the possibility of a metabolic disease and further investigates the case. This will be done initially with the indicated screening methods and further with a specific diagnostic work-up, in collaboration with a specialist who has a broad knowledge of available laboratory tests and who can help select the ones that lead to an exact diagnosis.

Progress in the molecular understanding of these disorders has revealed the clinical heterogeneity of some metabolic diseases. This important variability in the clinical syndrome caused by a specific metabolic abnormality can be apparent even among affected members within the same family. It is important to be aware of this complicating aspect, as the family history is used as one criterion for the identification of an inborn error of metabolism. To further complicate matters, affected family members sometimes develop symptoms later in life such as in adolescence or adulthood.

Most inborn errors of metabolism affect the nervous system. For many of these diseases little is known about the exact pathogenic mechanism by which the metabolic deficit generates the central nervous system (CNS) anomalies, including the dysmorphogenesis that is often present. Energy deficiency or toxic effects from the storage of certain metabolites leading to neuronal death are possible explanations, but exactly which processes are involved is often far from clear.

Several diseases can now be diagnosed using specific biochemical assays performed on specific tissues to reveal the enzymatic deficit. With the advances in molecular biology, corresponding gene mutations often can be identified and eventually can be used for further family testing and prenatal counselling. Sometimes, one is restricted to a biochemical assay when the gene involved is not yet fully characterised or it is too cumbersome to analyse, as can be the case for very large genes. In other cases, the opposite is true, and it is easier to document a specific mutation than to do the biochemical assay. More and more, use of gene panels in specific groups of metabolic diseases and next generation sequencing is used early in the diagnostic evaluation leading to a number of new diseases over recent years. However, clinical phenotyping is necessary in order to make the right interpretation of genetic data.

Most inborn errors of metabolism are inherited in an autosomal recessive mode. In most of these cases, the disease can only manifest itself fully in homozygotes for the mutation. This is generally a rare occurrence, except in consanguineous families. However, some inborn errors of metabolism are caused by mutations in genes located on the X chromosome, and the disease is then called ‘X-linked’. The effect is two-fold: first, the disease becomes dominant in male offspring inheriting the mutation; second, because of variable random X chromosome inactivation in various tissues, the expression of the disease can be highly variable from one tissue to another and from one girl to another. Few inborn errors of metabolism are autosomal dominant or arise de novo. Finally, subsets of the respiratory chain genes that are encoded within the mitochondrial DNA are only maternally inherited. Treatment possibilities include special diets, enzyme replacement therapy, stem cell transplantation, specific cofactors or other substances. Early diagnosis can be life saving in some conditions.

### DISORDERS OF SUBCELLULAR ORGANELLES

#### LYSOSOMAL DISEASES

The function of the lysosome is to hydrolyse a large number of complex molecules. When this function fails, storage within the lysosomes in different organs is the result. Most lysosomal diseases are due to a genetic defect of one of the lysosomal enzymes involved in the degradation of a specific substance. However, some diseases, including mucolipidoses II and III,
result from post-traductional abnormalities affecting normally synthesised proenzymes. Others (e.g. Salla disease and cystinosis) are due to defective transport of substrates across lysosomal membranes.

All lysosomal diseases are inherited as recessive – mostly autosomal recessive traits.

The clinical presentation and phenotypic manifestations of the same defective enzyme are variable, reflecting the possible existence of multiple different abnormalities of the same gene and/or occurrence of joint effects of other genes, alternative messenger RNA splicing, or post-traductional modifications.

**SPHINGOLIPIDOSES**

The sphingolipidoses are lysosomal diseases with absent or imperfect degradation of the sphingolipids, which are essential components of CNS membranes. The major steps of sphingolipid catabolism and the corresponding enzymes and enzymatic blocks are represented in Figure 9.1.

**GANGLIOSIDOSES**

These are important diseases that result from enzymatic blocks involving the removal of N-acetylgalactosamine from the complex ganglioside molecules. Gangliosides are found mainly in nuclear areas of grey matter and less in the white matter. Although many gangliosides have been isolated from the brain, four major components, GM1 to GM4, account for over 90% of the total ganglioside fraction.

**GM1 Gangliosidosis**

This group of disorders is caused by deficiency of acid beta-galactosidase, the gene is located on 3pter–3p21. In addition to lipid storage closely similar to that in the GM2 gangliosidoses,
the stored material also includes vacuolar inclusions with accumulation of numerous mannose-containing oligosaccharides, resulting from defective terminal beta-galactose residue removal during glycoprotein catabolism. Several beta-galactosidase isoenzymes are recognised. GM1 deficiency can also present as a nonimmune fetal hydrops. The severity of the phenotype is proportional to the degree of residual enzyme activity (Brunetti-Pierri and Scaglia 2008).

The three isoenzymes (A1, A2, A3) are defective in all forms of GM1 gangliosidosis, and the various phenotypes are probably explained by mutations resulting in proteins with different residual substrate specificities (Suzuki et al. 1991, Lyon et al. 2006). Beta-galactosidase is involved not only in the degradation of GM1 but also in other galactose-containing oligosaccharides and keratan sulphates. Deficiency of beta-galactosidase can therefore also result in Morquio B (MPS type IV B) or can be involved in galactosialidosis.

**GM1 gangliosidosis type 1** (pseudo-Hurler disease) is a rare autosomal recessive disease, clinically present at birth or even prenatally (Tasso et al. 1996). Affected infants are markedly hypotonic, suck poorly, fail to thrive and do not make any psychomotor progress. They have frontal bossing, coarse facial features, oedema, gum hypertrophy, macroglossia and hirsutism. Half of them have a retinal cherry-red spot, and hepatosplenomegaly is usually evident. The skeletal deformities are similar to those of Hurler syndrome. The course is severe. Blindness and deafness, quadriplegia and epileptic seizures appear, and death usually supervenes before 2 years of age.

**GM1 gangliosidosis type 2** has a later onset: between 6 months and 3 years of age. No marked skeletal abnormalities are present, although the first or second lumbar vertebrae are abnormally shaped, so that the presentation is one with developmental delay, then regression with pyramidal, cerebellar and extrapyramidal signs (Sandhoff and Harzer 2013). Optic atrophy and a cherry-red spot may be present, and acoustic startles occur in half of the cases although usually late in the course. The gene is the same as for type 1 but there is heterozygosity for two separate mutations.

**GM1 gangliosidosis type 3** (so-called adult type) is rare. Onset may be in childhood or adolescence with abnormal gait and worsening speech. The presentation is variable; dystonia and parkinsonism are frequent (Rozet et al. 2005). A picture of spinocerebellar degeneration is possible. Variants include a dystonic form (Tanaka et al. 1995) and atypical cases, for example with myopathy and cardiomyopathy. Intellectual deterioration may be late or absent in such forms. Low T1 signal from the pallidum and putamen has been reported (Tanaka et al. 1995), and a leukoencephalopathy is present (van der Voorn et al. 2004).

The diagnosis of GM1 gangliosidosis is characterised by absence or presence of small amounts of urinary excretion of keratan sulphates and increase of oligosaccharides; the presence of bony abnormalities, especially of the lumbar vertebrae, and the presence of foamy cells in the bone marrow. Vacuolated lymphocytes may be found in the peripheral blood and foamy histiocytes in the bone marrow.

It is confirmed by the absence or marked reduction of beta-galactosidase activity in leukocytes or fibroblasts. In the late (type 3) forms, beta-galactosidase deficiency is partial (5–20% normal). Prenatal diagnosis can be made on cultured amniotic cells or trophoblasts.

**TREATMENT IN GM1 gangliosidosis**

The use of iminosugar inhibitors of glycosylceramide transferase that are effective in Gaucher disease has been tried in other glycosphingolipid disorders (Aerts et al. 2006). Other chaperone therapies might be promising such as NOEV (N-octyl-4ep-B-valienamine) acting as a competitive inhibitor of beta-galactosidase and a chemical chaperone to restore enzymatic activities in somatic cells from patients with GM1-gangliosidosis (Suzuki 2013). So far, there is no definite cure for this disease.

**GM2 Gangliosidoses**

GM2 gangliosidoses are the commonest diseases of this group. Several varieties are known depending on the nature of the enzyme. Three isoenzymes of hexosaminidase have been recognised.

Hexosaminidase A is composed of one alpha and two beta subunits (A1, B2). hexosaminidase B solely of B units (B2, B2) and hexosaminidase S only of A units (A2). In classic Tay–Sachs disease or B variant, hexosaminidase A (Hex A) and S are inactive as a result of a mutation at the alpha locus on chromosome 15 (15q22–q25.1). Hexosaminidase B is normal but unable to hydrolyse gangliosides in vivo. Different mutations at the alpha locus are known. GM2 gangliosidosis in French Canadians (Palomaki et al. 1995) may be due to a different DNA defect (deletion of intron 1 and promoter region) to that in Ashkenazi Jews which in 73% of cases comprises a four-base insertion in exon 11. However, some French Canadians have the same mutation as Ashkenazi Jews and, within a single population, different mutations can be observed.

The B1 mutation results in an altered substrate specificity of Hex A. In this variant, the mutated enzyme displays essentially normal activity when tested with conventional methyl-umbelliferyl substrates but is unable to hydrolyse GM2 or sulphated methyl-umbelliferyl synthetic substrate. The O variant (Sandhoff disease) is characterised by deficiency of both beta-hexosaminidase isoenzymes A and B due to a mutation at the beta locus on chromosome 5q13. Variant AB is caused by the deficiency of an activator protein (saponin) required for the interaction of HEXA-A with its natural substrate (Cordeiro et al. 2000). There is, thus, a considerable clinical and biochemical heterogeneity among the GM2 gangliosidoses (Lyon et al. 2006).

The pathological changes in the CNS are common to all forms of gangliosidosis, with some variations related to the length of the course and undefined factors. The main finding is the presence in neurons of lipid-soluble material within the cytoplasm, with later disappearance of many neurons and the development of extensive gliosis. Purkinje cells and neurons
in brainstem nuclei, and neurons in visceral plexuses, are also affected.

**Tay–Sachs disease** is by far the most frequent form of gangliosidosis, affecting 1 in 2,000 persons among the Ashkenazi Jewish populations of eastern European background. The gene frequency is estimated to be 1 in 27 among Ashkenazi Jews and 1 in 380 in non-Jews.

The onset is between 3 and 9 months, with loss of acquired milestones and of muscle tone following an essentially normal initial development. Acoustic startles may precede all other symptoms and persist for several months. Neurological symptoms rapidly progress. Initial hypotonia is replaced by spastic tetraparesis, and epileptic seizures may appear late in the course. After the first year of life, the infants are blind and unresponsive and often develop a progressive macrocephaly. Magnetic resonance imaging (MRI) in the early stages of the disease shows increased T2 signal from the basal ganglia. The caudate nuclei often protrude into the lateral ventricles. Later, T2 signal is increased throughout the white matter (Grosso et al. 2003).

Death usually occurs before 3 years of age. From early in the course, a cherry-red spot is present in both macular areas, surrounded by a zone of whitish retina. The whitish zone is due to lipid storage in the retinal ganglion cells that are especially dense in the posterior pole, whereas the red spot represents the normal macula, which is devoid of ganglion cells and appears abnormally red by contrast with the surrounding retina. Although characteristic of Tay–Sachs disease, the cherry-red spot may also be seen in other types of gangliosidosis, in sialidosis, in Niemann–Pick disease, in infantile Gaucher disease and in rare cases of metachromatic leukodystrophy and of Krabbe disease (Chen et al. 2014).

**Sandhoff disease** (type O gangliosidosis) is clinically indistinguishable from classic Tay–Sachs but represents only 7% of cases of GM2 gangliosidosis.

The diagnosis of Tay–Sachs disease is easily confirmed by the absence of Hex A or of both Hex A and Hex B in serum or leukocytes. Patients with a B1 mutation have intermediate levels of Hex A activity when tested with a nonsulphated umbelliferyl substrate. For them the use of sulphated 4-Mu-gal-N-Ac-6-sulphate (4-MUG) substrate is necessary for diagnosis (Matsuzawa et al. 2003). Prenatal diagnosis by Hex A assay is possible in the second trimester of gestation.

Carrier detection using blood is possible and has been automated for mass screening surveys (Leib et al. 2005). Pseudodeficiency of Hex A occurs in compound heterozygotes who carry one common disease-causing mutation on one allele and one of two benign mutations on the second allele. Such individuals are clinically normal although they cannot hydrolyse synthetic 4-MUG substrates. These benign mutations have significant implications for heterozygote screening programmes and for prenatal diagnosis. Their frequency was found to be respectively 3% and 38% in Ashkenazi Jewish and non-Jewish enzyme-defined carriers (Cao et al. 1993).

**Juvenile GM2 gangliosidosis** is rare. Onset is between 2 and 6 years with gait instability and often speech disturbances, followed by ataxia and pyramidal tract signs. Intellectual deterioration is present at end-stage. Ataxia and dysarthria may be the first manifestation. Seizures may occur and dystonia and choreoathetotic movements have been reported. There is no racial predilection.

**Late-onset GM2 gangliosidosis** (Neudorfer et al. 2005) is also termed chronic GM2 gangliosidosis or ‘adult form’, although the onset is before 10 years in 35% of cases. Onset is with a special form of dysarthria followed by gait difficulties, pyramidal tract signs, ataxia and lower motor neuron involvement. Psychiatric disturbances occur later in half the patients. Dystonia is present in some patients, and supranuclear ophthalmoplegia has been reported (Rucker et al. 2004).

Atypical forms may present as anterior horn cell disease of juvenile onset (Drory et al. 2003), as isolated dystonia, or as atypical spinocerebellar degeneration. An unusual presentation mimicking a brainstem tumour has been reported (Nassogne et al. 2003).

A clinical picture of Tay–Sachs disease may be seen in patients with normal amounts of Hex A and B (AB variant) (Cordeiro et al. 2000; Lyon et al. 2006) and is difficult to diagnose as it requires direct study of labelled natural gangliosides catabolism.

The B1 variants usually present as infantile disease but may also be found in patients with juvenile and chronic forms (Grosso et al. 2003), although in the latter type an AB variant may be less rare.

No effective therapy for the GM2 gangliosidoses is yet available. Substrate reduction therapy with the ceramide synthesis inhibitor miglustat has been shown in animals to be partially effective (Andersson et al. 2004; Cox 2005) (see below). However, the process of ganglioside accumulation and consequent brain degeneration is already well established by the mid-trimester of fetal life, so the prospects for enzyme replacement therapy are not favourable.

**Deficiency in lysosomal alpha-N-acetylgalactosaminidase** – Schindler disease – may resemble infantile neuroaxonal dystrophy.

**Gaucher Disease**

Gaucher disease is a relatively frequent recessive disease affecting 1 in 50,000 to 1 in 200,000 persons and 1 in 800 in Ashkenazi Jews (Grabowski 2008). It is due to deficiency of beta-glucocerebrosidase (see Fig. 9.1). Its deficiency results in the accumulation of glucosylceramide in the lysosomes of macrophages. The gene coding for beta-glucocerebrosidase is located on chromosome 1q21–q31. The different types may correspond to allelic mutations at this locus, although other factors are operative as shown by phenotypic differences even for the same mutations. Over 150 mutations are currently known, some with neurological manifestations. It has been proposed that phenotypic variations may be due to compound heterozygosity, which is frequent, or to post-transcriptional abnormalities. Three main phenotypes are encountered:
neuropathic type (Sidransky 2012).

**Type 1 Gaucher Disease**

Type 1 Gaucher disease or non-neuronopathic type is the most common type and can start in childhood. It is mainly marked by hepatosplenomegaly, bone abnormalities, and sometimes hypersplenism with anaemia and pulmonary manifestations. There is no involvement of the CNS except in rare cases (Filocamo et al. 2004). However, there is some evidence that subclinical neurological involvement may be detected; for example, by study of saccadic eye movements (Accardo et al. 2005). Glucocerebrosides accumulate throughout the reticuloendothelial system. The major marker is the presence of the Gaucher cell in the bone marrow, spleen, liver and lymph nodes.

**Type 2 Gaucher Disease**

Type 2 Gaucher disease (acute infantile Gaucher disease or neuronopathic type) is also due to glucosylceramide beta-glucosidase deficiency. The clinical onset is at 3–5 months of age with muscle hypotonia, axial hypertonia and loss of interest in surroundings. Spasticity gradually sets in, with neck retraction and bulbar signs becoming prominent and resulting in feeding difficulties. There can be a vertical ophthalmoplegia. Splenomegaly is usually pronounced. Cherry-red spots are sometimes present. Convulsions may occur at age 6–12 months. Death usually occurs before 2 years of age.

**Type 3 Gaucher Disease**

Type 3 Gaucher disease (juvenile Gaucher disease) becomes apparent during the first decade of life, the major features at this period being slowly progressive hepatosplenomegaly, rapidly associated with intellectual disability. Cerebellar ataxia and extrapyramidal signs frequently develop. The most suggestive features include supranuclear horizontal ophthalmoplegia that may be the initial feature, and in some myoclonic epilepsy (Verghese et al. 2000; Frei and Schiffmann 2002). Audiometric studies show that involvement of the auditory pathways is frequent (Bamiou et al. 2001). Moderate bony changes such as widening of humeral and femoral diaphyses may be present. Neurological features are quite variable. Some patients have early features such as ophthalmoplegia starting in the first few years and may keep a normal intellect to adulthood with only extrapyramidal signs without epilepsy or deterioration, and many intermediate forms exist (Lyon et al. 2006).

A phenotypic variant of type 3, known as the Norrbottnian type, is frequently encountered in northern Sweden. The onset is early, around 1 year of age, with progressive hepatosplenomegaly and hypersplenism. Cognitive deterioration, ataxia and spastic tetraplegia evolve slowly after age 3 years. Splenectomy often precipitates appearance or aggravation of neurological signs. This type is regularly associated with a homozygous L444P mutation.

**Diagnosis of Gaucher Disease**

Bone marrow can show Gaucher cells; in serum, elevated levels of chitotriosidase and angiotensin-converting enzyme and increase of acid phosphatase are found.

Defective beta-glucocerebrosidase can be measured in lymphocytes, leukocytes and also on dry blood spots. Further confirmation can be by molecular analysis.

Saposin C deficiency due to mutations in the PSAP gene encoding the precursor of saposin A, B, C can have a similar picture (Tylki-Szymańska 2007). In saposin C deficiency glucocerebrosidase activity, however, is normal but the finding of Gaucher cells on bone marrow and striking elevation of chitotriosidase should lead to the molecular analysis of the PSAP gene.

**Treatment in Gaucher Diseases**

Enzyme replacement therapy (Grabowski 2005) is highly effective for Gaucher type 1 and for the systemic manifestations in Gaucher type 3. It does not improve neurological signs because the enzyme does not cross the blood–brain barrier, although some improvement might occur in the long term.

Enzyme replacement by imiglucerase, is currently infused every 2 weeks with doses varying between 15 and 60U/kg per infusion. Recently velaglucerase-alfa and taliglucerase were also approved (Zimran and Elstein 2014).

With this treatment the volume of liver and spleen decreases quickly and stabilises; anaemia and thrombocytopenia disappear, painful crises are less and general status improves. Biological markers such as chitotriosidase, acid phosphatase and angiotensin-converting enzyme are useful in the follow-up. There is no evidence that enzyme replacement therapy has influenced the neurological progression even when used in high doses (120 U/kg/2 weeks [Kaplan et al. 2013]).

Substrate reduction therapy with imino sugar inhibitors of glycosyl ceramide glucosyl transferase, especially N-butyl deoxygalactonojirimycin (miglustat), the key enzyme in synthesis of glycosyl sphingolipids, has been shown to be effective against the visceral manifestations of the disease, resulting in decrease in size of the spleen and correction of haematological abnormalities (Pastores et al. 2005). It is used as a daily oral therapy (100mg/1.73m² of body surface) three times daily. Its effect is probably less complete than with enzyme replacement. In addition to its substrate reduction effect (Cox 2005), it may also produce a chaperone-mediated stabilisation of mutant beta-galactosidase enzyme. Adverse reactions include weight loss, tremor, and more rarely a peripheral neuropathy, requiring electromyography (EMG) monitoring.
Niemann–Pick Disease A and B

Niemann–Pick disease comprises a heterogeneous group of disorders linked by an accumulation of sphingomyelin in the reticuloendothelial system. Of the three main types A, B and C, types A and B are due to a deficiency of acid sphingomyelinase and constitute a neuronopathic form A and non-neuronopathic form B. Type C will be discussed with disorders of cholesterol metabolism.

Niemann–Pick disease A and B is transmitted as an autosomal recessive character and type A occurs especially in Ashkenazi Jews.

Clinical features of Niemann–Pick disease type A

The clinical onset is during the first year of life, with hepatosplenomegaly and poor physical and cognitive development. Jaundice, diarrhoea and pulmonary infiltrates are common. Myoclonic seizures, spasticity and blindness are the major manifestations. One-quarter of the patients have retinal cherry-red spots. A peripheral neuropathy occurs in 10% of cases, with slowing of conduction velocities. Death occurs before age 5 years.

The diagnosis is suggested by the presence of vacuolated cells in the bone marrow. Sphingomyelinase deficiency can be found in leukocytes or fibroblasts. The diagnosis can be confirmed by molecular analysis.

The gene maps to 11p15, and multiple mutations are known. Some correlation is found between certain mutations and the phenotype. Three mutations account for 92% of cases in Ashkenazi Jews (Schuchman and Wasserstein 2016).

The pathological hallmark of the condition is the presence in the reticuloendothelial system of large vacuolated cells. Foam cells and ballooned ganglion cells are found in the CNS. Biochemically, there is a marked storage of sphingomyelin, a major component of normal myelin, in association with cholesterol in the spleen, liver and kidney. Storage is also present in the brain, although usually at a moderate level.

Clinical features of Niemann–Pick disease type B

Clinical features of Niemann–Pick disease type B (visceral type) is characterised by visceral involvement without neurological features and occurs mainly in older children and adults. An occasional patient may develop neurological signs.

In fact, the distinction between types A and B is not always clear-cut. Protracted neurovisceral forms with a course extending over periods of years are recognised and intermediate forms were the most common type in a large series, being observed in 12 of 25 patients (Pavlou-Pereira et al. 2005).

Treatment trials with enzyme replacement therapy (ERT) are in process.

Fabry Disease

Fabry disease is a rare, X-linked disorder is due to a deficiency of the A isoform of alpha-galactosidase (ceramide trihexosidase) caused by several mutations of the GLA gene, mapping at Xq22. As a result, large amounts of trihexoside accumulate in various organs, especially the kidneys. Foam cells with vacuolated cytoplasm are found in smooth and striated muscle, in marrow and renal glomeruli. In the CNS, storage is confined to walls of the blood vessels and, to a lesser extent, to the autonomic nervous system. MRI may show peri-ventricular high signal and discrete lesions suggestive of demyelination.

Clinical manifestations usually begin in childhood in boys. Skin abnormalities may be the presenting feature, in the form of punctate angiectatic lesions (angiokeratoma corporis diffusum) that are commonly found on the genitalia or umbilicus or about the hips, but may rarely involve the face. Episodes of pain or dysesthesiae in the limbs and sometimes in the abdomen are often the first symptoms. Pain is deep, of a burning character and occurs in episodes lasting from hours to weeks. These episodes are often associated with unexplained fever (Schiffmann and Ries 2016). Cornea verticillata is seen by slit lamp examination and is often present in heterozygotes (Watts and Gibbs 1986). Peripheral neuropathy involving small fibres has been reported and anhidrosis is frequent. Cochleovestibular and autonomic nervous system involvement is frequent. Approximately 30% of patients have cardiac defects including mitral valve prolapse and cardiomyopathy, and transient ischaemic episodes commonly occur (Ries et al. 2005).

The disease runs a progressive course, and CNS and visceral vascular accidents often occur with focal neurological signs, hypertension or myocardial infarcts. Renal involvement is the usual cause of death. Female carriers usually display late and milder symptoms.

Diagnosis is confirmed early by determination of alpha-galactosidase in plasma, leukocytes or fibroblasts in males. In females, genetic analysis is necessary.

Symptomatic treatment includes prevention of painful episodes, which can usually be achieved with carbamazepine, gabapentin or phenytoin, and therapy for renal insufficiency. Renal transplants have little effect on the CNS lesions, although sensory symptoms and renal function may improve.

Enzyme replacement therapy has changed the evolution of the disease. Large controlled studies in affected males have shown the safety and efficacy of recombinant enzyme preparations, which decrease pain and stabilise renal function (Clarke and Iwanochko 2005; Schaefer et al. 2005). Enzyme replacement therapy can be given under the form of agalsidase alfa (0.2mg/kg every 2 weeks) or agalsidase beta (1mg/kg every 2 weeks).

The quality of life of patients is significantly improved, especially the pain-related symptoms (El Dib et al. 2016). Preventive treatment for non-symptomatic female carriers is not generally advised. Antibodies against the enzyme have been found to develop (Linthorst et al. 2004) but their clinical significance is not yet clear.

Ceramidosis

(Lipogranulomatosis, Farber Disease)

This rare disease is due to deficient activity of lysosomal ceramidase and is transmitted as an autosomal recessive character.
The onset is during the first weeks of life, with irritability, a hoarse cry and the appearance of nodular erythematous swellings around the wrists and other joints (Sands 2013). Severe motor and intellectual disability is frequent and convulsions are common. Cardiac valvular lesions may be present. Death occurs before 2–3 years of age although a mild form may allow survival for several years.

The basic lesion is a granuloma that forms around mesenchymal cells containing large amounts of ceramide. Neurons and glial cells are swollen by storage material.

**Mucosulfatidosis (Multiple Sulphatase Deficiency, Austin Disease)**

This is a rare disease characterised by absence of arylsulphatase A, B and C and of mucopolysaccharide sulphatase activity due to mutations in the formylglycine generating enzyme (Cosma et al. 2004; Lyon et al. 2006) and mutations in the SUMF1 gene. As a result, patients accumulate sulphatides, mucopolysaccharides and cholesterol sulphate in CNS and viscera and there is increased excretion of heparan sulphate in urine. Ichthyosis is a suggestive manifestation.

A recent review (Sabourdy et al. 2015) included 10 cases with mutations in SUMFG1 and showed that in the severe cases the symptoms of non-neurological as well as the psychomotor regression occur before 2 years of age.

**Mucopolysaccharidoses**

The mucopolysaccharidoses (MPS) are a group of diseases caused by a deficiency of a lysosomal hydrolase that degrades glycosaminoglycans (GAGs).

Table 9.1 indicates the main characteristics, associating progressive accumulation of different GAGS within cells of different organs, resulting in somatic changes and neurological symptoms. Because of the involvement of different organs and tissues, a multidisciplinary follow-up is necessary after correct diagnosis, using GAGs in urine and then confirmation by biochemical assays in leukocytes and identification of the mutations. A full clinical evaluation is necessary including skeletal X-ray, echocardiography, eye examination, audiometry, MRI, electrocardiography etc.

Treatment options require early diagnosis. Haematopoietic stem cell transplantation in MPS I severe neurological type is an indication if the neurological condition is still good, preferably under the age of 2 years (de Ru et al. 2011).

For a number of MPS types, ERT has been developed, especially for those in the spectrum who have no severe neurological involvement. ERT is now currently used in MPS I and II attenuated cases, MPS IV and MPS VI. ERT has good results on the somatic involvement, but ERT does not pass the blood–brain barrier. Intrathecal therapies are also being developed for MPSII severe form, and in MPSIII (Sanfilippo). Other therapies such as substrate reduction or gene therapy are still under study.

Supportive therapy and careful follow-up remain necessary in all patients.
MPS IH (Hurler type)
The severe form, Hurler type, starts with symptoms within the first year of life. It is an autosomal recessive disorder (Fig. 9.2).

Clinical features of MPS IH
Characteristically within the first 6 months of life, frequent ear infections leading to hearing loss, umbilical and inguinal hernias can be alarm signs. Diarrhoea and failure to thrive occur often. After 6 months to 2 years, joints become stiff in elbows, wrists and knees. Hepatosplenomegaly, coarsening of the face, development of a lumbar kyphosis in the sitting position are the next signs together with a slowing in development. Corneal clouding develops and the head may become macrocephalic and somatic growth may slow down. MRI will show increased Virchow–Robin spaces and accumulation of storage material. Cardiac involvement, especially valve insufficiency and thickening, can occur early.

Diagnosis of MPS IH
The diagnosis is based on demonstration of an increase of urinary GAGs, mostly heparin sulphate and dermatan sulphate on electrophoresis, leucocyte analysis for L-iduronidase and mutation analysis. Some specific mutations can predict outcome (Kingma et al. 2013) which might be important in case of future neonatal screening for some of the MPS disorders.

Treatment of MPS IH
The general treatment is now haematopoietic stem cell transplantation. While awaiting a donor, ERT should be started and continued until full engraftment with transplantation.

MPS IH (Scheie type)
The milder forms of MPSI called Scheie disease have similar somatic features without neurological involvement, except the possibility to develop hydrocephalus (due to meningeal storage) and carpal tunnel entrapment. The diagnosis of the milder patients, is usually made later, around 3–4 years.

Treatment consists of lifelong ERT (laronidase Aldurazyme\textsuperscript{R} 100U/kg) with good results on somatic features except skeletal abnormalities and cardiac involvement. Most patients develop antibodies against laronidase, which might influence treatment outcome.

MPS II (Hunter Disease)
The deficit lies in iduronate-2-sulphatase (Kato et al. 2005) which is an X-linked trait. The incidence is estimated as 1 in 80,000 to 1 in 130,000 male births. Depending on the presence or absence of neurological regression, a mild and a severe form can be recognised.
Clinical features of MPS II
In the severe form of the disease symptoms are similar to those in MPS I except presentation can be somewhat later. It starts also with a number of somatic features and then there is a cognitive decline, often with very difficult behaviour. As in MPS I, there is a spectrum with a more attenuated disease not affecting the brain in half of the patients. The neurological abnormalities in the attenuated type may include sensorineural deafness, retinitis pigmentosa, moderate hydrocephalus (Froissart et al. 2002) and carpal tunnel syndrome. For complete clinical presentations and treatments there are some excellent reviews, such as Scarpa et al. (2011).

Diagnosis of MPS II
An increase of GAGS (dermatan and heparan sulphate) is found in the urine of affected boys. Enzyme assay permits antenatal and postnatal diagnosis. The gene is located on Xq28 and a deletion is found in 30% of cases.

Treatment of MPS II
Haematopoietic stem cell transplantation is not a therapeutic option (Wraith 2008). ERT iduronate-2-sulphatase can be injected weekly at a dose 0.5mg/kg with good result on the somatic features especially when started early, but with no result on the intellectual decline (Rosella Tomanin et al. 2014). Intrathecal therapy is being studied and trials are ongoing.

MPS III (Sanfilippo Disease)
Sanfilippo disease is a genetically heterogeneous disorder of which four types resulting from four biochemical defects are known (Table 9.1).

Clinical features of MPS III
Infants can present with learning disabilities or with profound behavioural disturbance and sleeping problems (Wijburg et al. 2013). The clinical presentation is that of a progressive neurological and intellectual disability beginning between 2 and 6 years of age. Although corneal opacities are absent, abnormally coarse features and thick hair and eyebrows, present early and are superseded by the neurological disturbances. Epilepsy is frequent.

Diagnosis of MPS III
The diagnosis is often difficult initially because of the predominantly neurological and behavioural manifestations. Urine screening for GAGS should be done routinely in patients with unexplained regression. Increase of heparan sulphate but not dermatan sulphate is typically seen in MPS III. Enzyme assay and molecular analysis of the different genes permits differentiation of four types that are phenotypically indistinguishable. Antenatal diagnosis is feasible.

Treatment of MPS III
Attempts have been made with bone marrow and stem cell transplantation but seem to be not conclusive, resulting in further neurological deterioration. Intrathecal ERT and gene therapy are being now developed.

MPS IV (Morquio Disease)
Morquio disease has two types due to different genetic and enzymatic defects (Table 9.1).

Clinical features of MPS IV
The clinical manifestations are predominantly bone abnormalities and corneal opacities without intellectual disability. In type A, cognitive function is normal, but patients are severely affected by spondyloepiphyseal dysplasia, leading to extremely short stature, marked shortening and instability of the neck, deformity of chest and marked joint hyperlaxity. In the B form, symptoms are much milder.

Diagnosis of MPS IV
The diagnosis is usually clinical except in the milder types. Increase of urinary GAGs can be absent. The enzymatic analysis can be done for type A alpha-acetylglucosamine-6-sulphatase and in type B beta-galactosidase. Further molecular analysis is possible.

Treatment of MPS IV
Orthopaedic and neurological surveillance and treatment are essential. ERT has started with good tolerance and seeming improvement of the quality of life of the patients. Early treatment could probably further increase this positive effect.

MPS VI (Maroteaux-Lamy Disease)
Maroteaux-Lamy disease (MPS-VI) has diverse degrees of severity.

Clinical features of MPS VI
Short stature and visceral involvement are the main symptoms. Children may present in the first 2 years of life with frequent ENT infections and facial changes. Intellectual disability is absent (Vairo et al. 2015).

The main neurological complication is spinal compression, usually at cervical level, that may produce quadriplegia. This complication results from thickening of the meninges due to deposition of MPS and is difficult to treat surgically.

Diagnosis of MPS VI
In urine, there is an increase of GAGS mainly dermatan sulphate. Biochemical analysis of N-acetyl galactosamine-4 sulphatase on leukocytes and molecular confirmation of the gene mutation are diagnostic.
TREATMENT OF MPS VI
Enzyme replacement therapy Naglazyme (galsulfase) is now developed and given weekly with improvement seen in the 12 minute walk test (Brunelli et al. 2016).

MPS VII (Sly Disease)
Sly disease is a very rare disorder that may present with a wide range of phenotypic manifestations from nonimmune hydrops fetalis, through cases mimicking Hurler disease with severe neurodevelopmental delay, to cases with limited expression and without neurological features (Montaño et al. 2016). Recently an ERT has been developed and trials are starting.

MUCOLIPIDOSES
The mucolipidoses are rare disorders that have features of both the mucopolysaccharidoses and the lipidoses. Four types are described (Table 9.2; Fig. 9.3), although types 2 and 3 may be regarded as two degrees (severe and mild) of the same disease. They are transmitted as autosomal recessive characters.

Sialidosis I
(Cherry-Red Spot Myoclonus Syndrome)
Sialidosis I has a juvenile or adult onset and produces a rather pure intention and action myoclonus with a slow progression and no, or only mild, intellectual disability (Rapin et al. 1978; Young et al. 1987; Canagoglia et al. 2014). Minor dysmorphic features may appear at late stages. Also, it can present as a hydrops fetalis. Stalic acid is increased in urine. The enzyme deficient is neuraminidase, which is measured only in fibroblasts. The gene is Neu 1. Several mutations have been described.

Mucolipidosis IV
Mucolipidosis IV is a rare disease that affects Ashkenazi Jews mainly but not exclusively. Onset may vary from birth to adolescence, with clinically severe, moderate and mild forms. It is caused by mutations in the MCOLN1 gene, which encodes a transmembrane protein called mucolipin 1. In the early-onset form, failing vision and intellectual delay develop simultaneously following a normal neonatal period (Amir et al. 1987), and neurological signs such as dystonia are often present. Corneal opacities may be absent despite poor vision in the first months of life. Milder forms may variously combine ophthalmological features with various degrees of cognitive delay and neurological signs (Bargal et al. 2002; Shiihara et al. 2016).

OLIGOSACCHARIDOSIS AND SIALIC ACID DISORDERS
Oligosaccharidoses are a group of storage diseases with increased excretion of glycoproteins and decreased activity of lysosomal degradation of sugar side chains (Fig. 9.3).
These diseases are Salla disease, aspartylglucosaminuria, fucosidosis, alpha and beta mannosidosis, Schindler disease and sialidosis.

Salla Disease

Salla disease has two allelic disorders: Salla disease and infantile free sialic acid storage diseases resulting from mutations in the SLC17A5 gene that codes for sialin, a lysosomal membrane protein that transports sialic acid out of the lysosomes.

Clinical manifestations include psychomotor delay of early onset during the first year of life, later followed by slowly progressive cerebellar and extrapyramidal dysfunction with severe intellectual deterioration. Involvement of the peripheral nervous system is evidenced by the decrease in nerve conduction velocity (Varho et al. 2000). There is a severe infantile type with early death in childhood, while the Finnish type Salla disease has a milder phenotype.

Both groups have intellectual disability; the infantile type has also severe visceral involvement, cardiomyopathy, and skeletal dysplasia (Kleta et al. 2004).

The disease is frequent in Finland but cases also occur in other populations (Robinson et al. 1997). Dysmorphic features appear only at a later stage. Diagnosis can be helped by finding vacuolated lymphocytes in blood and vacuolated cells in skin and conjunctival biopsy samples, and confirmed by demonstration of high levels of sialic acid in urine. Prenatal diagnosis is possible by determination of sialic acid in amniotic fluid. Several mutations are known (Myall et al. 2007).

Aspartyl-Glucosaminuria

This disease, almost only found in Finland, is due to a deficit of aspartyl glucosaminidase.

Clinical features are intellectual disability that begins in childhood or adolescence, lenticular opacities, bony changes as seen in MPS, and mitral valve insufficiency (Arvio et al. 1993). There is a striking dysmorphism with hypertelorism, short and broad nose, simple ears and thick lips (Arvio et al. 2004).

The diagnosis can be made by chromatography indicating increased excretion of glycoasparagines. Enzymatic measurement of aspartyl glucosaminidase can be done on leukocytes and the diagnosis confirmed by analysis of the gene.

Alpha-Mannosidosis

Alpha mannosidosis is caused by several mutations in the gene for alpha-mannosidase (Beccari et al. 2003) resulting in neuronal storage of mannose-rich oligosaccharides (Fig. 9.3). A severe type (type I) has an infantile onset and is characterised by a Hurler-like appearance, intellectual disability, hearing loss, hepatosplenomegaly and dysostosis. There is often increasing macrocephaly, intellectual disability that remains stable and development of hearing loss. Recently ERT has been developed and studies are ongoing.

Type II has a juvenile onset and a milder course, but there is considerable overlap between the two forms. Cognitive deficit is variable and usually not progressive (Borgwardt et al. 2014).

Beta-Mannosidosis

Beta mannosidosis, due to deficiency of beta-mannosidase is much less frequent and variable with severe learning difficulties, behavioural problems, deafness and frequent infections.

Fucosidosis

Fucosidosis is caused by deficiency of the enzyme fucosidase which is responsible for storage of fucose in tissues. It is encoded by the FUCA1 gene in which many mutations have been characterised (Lin et al. 2007).

Three types have been described: type 1 or severe type with early infantile onset, type 2 with onset around 18 months of age, and a rare type 3 with onset in adolescence. Type 2 is most common and has a slower course. Clinically, the condition presents with skeletal anomalies, cutaneous manifestations (angiokeratoma corporis diffusum involving
preferentially the genitalia and gingiva) and neurological symptoms often in the form of dystonia. There can be epilepsy and a mild dysostosis.

Diagnosis is made by the finding of abnormal oligosaccharides in urine, enzymatic analysis and molecular confirmation of the gene.

There is no treatment.

**Galactosialidosis**

Galactosialidosis results from a combined deficiency of neuraminidase and beta-galactosidase due to the absence of a protective protein that prevents proteolysis of the active enzyme. The disorder is genetically heterogeneous (Caciotti et al. 2013).

The onset of the juvenile form is between 5 and 10 years of age with cerebellar and extrapyramidal signs. Myoclonic seizures and action myoclonus usually develop after several years, and cognitive deterioration is late. There are no bony changes except for the frequent wedging of the first lumbar vertebrae. Coarse features progressively develop. An infantile form can closely resemble type 1 gangliosidosis (Galjaard et al. 1984).

## CONGENITAL DISORDERS OF GLYCOSYLATION

There is a growing number of diseases due to defects in synthesis of the glycan moiety of glycoproteins or glycolipids and in attachment of glycans to proteins and lipids. Glycosylation of proteins is an essential step in co-translational maturation of polypeptides. This process is essential for viability and normal development. It concerns most extracellular proteins such as serum proteins (transferrin, alpha1-antitrypsin, alpha1-antichymotrypsin, some clotting factors, polipoprotein C-III), most membrane proteins such as receptors, and intracellular proteins such as lysosomal enzymes (Fig. 9.4).

For the N-glycosylation of proteins, a glycan precursor is assembled from monosaccharide units on an anchoring isoprenoid alcohol, dolichol, in membrane of the endoplasmic reticulum. Each glycan precursor is then transferred to a specific asparagine residue in the peptide chain of a protein being synthesized by a ribosome and entering the endoplasmic reticulum. Transferrin is abundant in blood and is used as an indicator of the efficiency of the glycosylation system. Transferrin has two glycosylation sites. The protein is transported to the Golgi apparatus, and the glycans are modified in multiple steps (Jaeken 2003). Each fully modified glycan is terminated with two negatively charged sialic acid residues. Thus, the transferrin molecule carries a total of four sialic acid residues. If a genetic defect impairs synthesis of the precursor glycan in the endoplasmic reticulum, one or both glycosylation sites of transferrin may remain unoccupied. Such defects are classified as congenital disorders of glycosylation type I (CDG-I).

In congenital disorders of glycosylation type II (CDG-II), the defect occurs in the modification of the already-transferred glycan. Isoelectric focusing (IEF) is used for investigating congenital disorders of glycosylation with the use of an agarose gel-based system, followed by immunoprecipitation in gel with an antibody to transferrin and staining of precipitate with Coomassie blue. Under conditions of normal glycosylation, most transferrin molecules carry four sialic acid residues (tetrasialotransferrin) and form a single major band on IEF.

**CDG-I** defects are easily identified owing to the occurrence of transferrin isoforms with two or no sialic acid residues detected by means of IEF.

In **CDG-II**, the defect can result in transferrin molecules with no, one, two, or four sialic acid residues. A patient with a CDG-II defect has bands of approximately equal intensity at all positions from 0 through 3 or a smooth gradient of intensities, whereas in most cases, tetrasialotransferrin shows a more intense signal owing to residual activity.

Disorders due to defects in mannose-alpha-O-glycosylation are associated with Walker–Warburg syndrome and different forms of congenital muscular dystrophies such as muscle–eye–brain disease, Fukuyama congenital dystrophy and related myopathies.

Disorders of N-glycosylation result in multisystemic abnormalities that usually include the CNS. Some have no CNS involvement, and these will not be discussed here.

There is now a new classification for all CDGs (Jaeken et al. 2009): N-glycosylation, O-glycosylation, defects in glycosylation of glycoproteins or glycolipids, glycophosphatidylinositol (GPI), anchor and glycosphingolipids (Freeze et al. 2015).

Examples are PMM2-CDG (CDG-Ia), PMI-CDG (CDG-Ib), ALG6-CDG (CDG-Ic), ALG3-CDG (CDG-Id), ALG12-CDG (CDG-Ig), ALG8-CDG (CDG-Ih), ALG2-CDG (CDG-Ii), DPAGT1-CDG (CDG-Ij), ALG1-CDG (CDG-Ik), ALG9-CDG (CDG-II), RFT1-CDG (CDG-In), ALG11-CDG (CDG-Ip), DDOST-CDG (CDG-Iq), TUSC3-CDG, MAGT1-CDG with new ones added every year.

**CDG type II** involves malfunctioning trimming/processing of the protein-bound oligosaccharide chain. Examples are MGAT2-CDG (CDG-Ia), GCS1-CDG (CDG-Ib).

Diagnosis of CDGs is usually performed by isoelectric focusing of serum transferrin. The patterns are divided into two types.

*Type 1* is characterised by elevated disialo- and aialotransferrin bands together with a decrease of tetrasialotransferrin.

*Type 2* is characterised by increase of trisialo- and monosialotransferrin bands.

In addition to the isoelectric focusing of transferrin, isofoocusing of other serum sialylated proteins improves the diagnosis (Fang et al. 2004). Apolipoprotein C-III (ApoC-III) isoelectric focusing is used to screen for O-glycosylation defects either in isolation or in association with N-glycosylation defects. Three types of isoforms are recognised: ApoC-III0, ApoC-III1, and ApoC-III2, depending on the number of sialic acid residues attached to the glycoprotein (Wopereis et al. 2007).
Figure 9.4 Schematic representations of the glycosylation process indicating the sites of defects in, respectively, CDG types I and II: (a) the elongation pathway in the endoplasmic reticulum; (b) the trimming pathway in the Golgi apparatus.
Examples of Type 1 CDG

PMM2-CDG (CDG-Ia)

Phosphomannomutase 2 (PMM2) deficiency (Fig. 9.5) is due to a defect in the second step of the mannose pathway (transforming mannose 6-phosphate into mannose 1-phosphate). Deficiency of GDP-mannose causes hypoglycosylation of numerous glycoproteins, including serum proteins, lysosomal enzymes, and membranous glycoproteins. PMM2-CDG is the most prevalent protein N-glycosylation disorder.

Clinical features

The clinical spectrum is very broad. The nervous system is affected in all patients and most other organs are involved in a variable way. The neurological picture starts with alternating internal strabismus and other abnormal eye movements. Congenital cataracts have been noted in a few cases. The majority of patients have some facial dysmorphism, inverted nipples, and peculiar body morphology with limb joint restrictions, thorax deformity and unusual fat pads above the buttocks over parts of the perineal region and/or on the fingers. In infancy there is poor feeding, failure to thrive and floppiness. Severe infections, hepatic failure, cardiac effusion with tamponade, and stupor occasionally associated with seizures and intracerebral haemorrhage can occur.

There is a nonprogressive intellectual disability. Most patients have an IQ around 50. Cerebellar ataxia and peripheral neuropathy, prevent independent ambulation in most cases. Recurrent episodes of dyskinetic or choreoathetotic movements may occur. Strabismus and retinitis pigmentosa regularly develop. Stroke-like episodes, related to cerebrovascular thrombosis, occur in half the patients after the age of 4–5 years with coma, seizures and transient blindness. About one-half of patients develop epilepsy.

During adolescence and adulthood the condition is static. Most patients achieve some social functioning but remain dependent.

Diagnosis

The diagnosis of PMM2-CDG is made by isoelectrofocusing (IEF) type 1 pattern and immunofixation of serum transferrin or by capillary zone electrophoresis of total serum. Other laboratory findings include increase of serum transaminases, hypoalbuminemia, hypocholesterolaemia, and tubular proteinuria.

The diagnosis is confirmed by a decreased activity of PMM2 in leukocytes or fibroblasts. Prenatal diagnosis is possible by enzymatic analysis of amniocytes or chorionic villus cells and mutation analysis of the PMM2 gene.

Several mutations have been identified in the PMM2 gene. The mutation leading to the R141H substitution is present in about 75% of the alleles of central European patients.

Brain MRI shows cerebellar and cerebral atrophy often from the neonatal period. However, this feature is not always present in newborn infants and in some patients cerebellar and cerebral atrophy can be progressive.

Figure 9.5 Carbohydrate-deficient glycoprotein syndrome type 1.
(a) Abnormal fat pads on the buttocks (b) Inverted nipples; note also feeding difficulties (tube feeding). (c) MRI, sagittal scan, showing marked cerebellar atrophy and relatively thin brainstem. (Courtesy Prof. Billette de Villemeur, Hôpital Trousseau, Paris.)
ALG6-CDG (CDG-Ic)

ALG6 encodes glucosyltransferase I. Its deficiency causes a defect in the attachment of the first glucose (of three) to the dolichol-linked Man9GlcNAc2 endoplasmic reticulum intermediate. This is the second most common protein N-glycosylation disease with at least 30 patients identified.

Clinical features are similar to those in PMM2-CDG but there is less dysmorphism and usually no retinitis pigmentosa or cerebellar hypoplasia.

Some glycoproteins have unusually low blood levels (particularly of factor XI, and coagulation inhibitors antithrombin and protein C). Analysis of the dolichol-linked oligosaccharides in fibroblasts shows an accumulation of the glycan intermediate Man9GlcNAc2.

ALG3-CDG (CDG-Io)

This is due to mannosyltransferase VI deficiency. Symptomatology includes severe psychomotor retardation, hypsarrrhythmia, postnatal microcephaly, optic atrophy, iris coloboma, hyperinsulinemic hypoglycaemia with islet cell hyperplasia, and brain and corpus callosum atrophy.

ALG12-CDG (CDG-Ie)

Due to mannosyltransferase VIII deficiency, the phenotypes show various combinations of facial dysmorphism, psychomotor retardation, hypotonia, inverted nipples, subcutaneous fat pads, skeletal dysplasia, and decreased serum IgG levels.

ALG8-CDG (CDG-ii)

This CDG is due to glucosyltransferase II deficiency. Some show a severe disease with dysmorphism and multi-organ failure resulting in early death. One patient had a milder phenotype with hepatomegaly and protein-losing enteropathy. In another patient, there was prominent CNS involvement (macrocrania, psychomotor retardation, seizures, and diffuse leukencephalopathy) besides entero-hepatic and renal disease.

ALG2-CDG (CDG-Ii)

The clinical picture in the reported patient with mannosyltransferase II deficiency was characterised by severe psychomotor retardation, Infantile spasms, irid coloboma, cataract, and severe dysmyelination on brain MRI.

DPAGT1-CDG (CDG-Ij)

Deficiency of UDP-GlcNAc dolichol phosphate N-acetylglucosamine 1-phosphate transferase is a defect in the very first step of dolichol-linked oligosaccharide biosynthesis. It was identified in a girl with severe psychomotor retardation, intractable infantile spasms, hypotonia, and microcephaly.

ALG1-CDG (CDG-Ik)

Reported patients with mannosyltransferase I deficiency showed intractable seizures, severe psychomotor retardation, and variable features such as dysmorphism, liver dysfunction, cardiomyopathy, nephrotic syndrome, hypogonadism, and depletion of b-cells.

RFT1-CDG (CDG-Ih)

This is a defect in the flippase that transfers Man5GlcNAc2-PP-Dol from the cytoplasmic to the luminal side of the endoplasmic reticulum. Intrauterine growth retardation developmental delay, hypotonia with brisk tendon reflexes, drug-resistant epilepsy, deafness, and thrombotic complications (Ondruskova et al. 2012).

TUSC3-CDG

The defect is in one of the subunits of the oligosaccharyltransferase complex. It has been reported in several families with autosomal recessive, nonsyndromic intellectual disability and suggests a crucial role of this complex in cognitive functioning (Garbashi et al. 2011). IEF of serum transferrin shows a normal pattern.

MGAT2-CDG (CDG-IIa)

Deficiency in N-acetylglucosaminyltransferase II was the first identified N-glycan processing defect. Besides neurological involvement (psychomotor retardation, drug-resistant epilepsy in three patients, behavioural disturbances), they presented with craniofacial dysmorphism, skeletal abnormalities, gastrointestinal disturbances, and growth retardation. IEF of serum transferrin showed a type 2 pattern.

MOGS-CDG (CDG-IIb)

This is a defect in glucosidase I, the first step in N-glycan processing. It was discovered in an infant with dysmorphism, hypotonia, and epilepsy. The urine showed an abnormal oligosaccharide identified as the tetrasaccharide (GLC (A1-2) GLC (A1-3) GLC (A1-3) Man). IEF of serum transferrin was normal.

Many other types have been published (Freeze et al 2015; Sparks and Krasnewich 2017).

PEROXISOMAL DISORDERS

PEROXISOMES

Peroxisomes are ubiquitous eukaryotic organelles that measure 0.1–1µm in diameter and are bound by a single membrane (Fig. 9.6). This membrane encloses the granular matrix that contains more than 70 different enzymes. Of the many metabolic pathways catalysed by the peroxisomal enzymes, the peroxisomal fatty acid beta-oxidation, alpha-oxidation, ether phospholipid (including the plasmalogens) synthesis, glyoxylate detoxification, \( \text{H}_2\text{O}_2 \) metabolism and pipecolic acid oxidation are the most relevant for human peroxisomal diseases or their diagnosis (Smith and Aitchison 2013; Braverman et al. 2016). Peroxisomes can be synthesised de novo from the endoplasmic
The main peroxisomal functions

Figure 9.6  Schematic representation of the main biochemical functions in peroxisomes.

DHAPAT, dihydroxyacetone phosphate acyltransferase; DHAP, dihydroxyacetone phosphate; Alkyl-G3P, alkyl-glycerol-3-phosphate; CoA, coenzyme A; VLCFA, very long chain fatty acids; THCA, trihydroxycholestanolic acid.

Peroxisomal Dysfunction

The peroxisomal disorders can be divided into peroxisomal biogenesis disorders (PBD), where multiple peroxisomal functions are disturbed, and the single peroxisomal enzyme deficiencies. The PBD can be further divided into three subgroups: the Zellweger spectrum disorders (ZSD), selective PTS2-related PBD, and the disorders of peroxisomal fission. Except for X-linked adrenoleukodystrophy (X-ALD), all peroxisomal disorders have autosomal recessive inheritance.

PEROXISOMAL BIOGENESIS DISORDERS

Zellweger Spectrum Disorders

Zellweger Spectrum Disorders (ZSD) are caused by defects in one of the PEX genes, except for PEX7 where mutations cause rhizomelic chondrodysplasia punctata (RCDP) or adult Refsum disease, and PEX11beta, which is involved in a disorder of peroxisomal fission (Table 9.3).

The most severe of the ZSD is the classic Zellweger syndrome (Fig. 9.7). It presents in the neonate with profound generalised hypotonia, poor sucking and swallowing with severe feeding problems, and depressed tendon reflexes. Epileptic seizures often start in the neonatal period and are typically therapy-resistant. Pigmented retinopathy and deafness are prevalent (Govaerts et al. 1985). Often cataracts develop. There is a recognisable dysmorphism, with a large anterior fontanelle, high forehead, abnormally round-shaped

**Group II: Single peroxisomal enzyme deficiencies involving beta-oxidation defects**

- X-linked adrenoleukodystrophy: Present and normal ALD protein
- Pseudo-neonatal adrenoleukodystrophy: Present and abnormal Acyl-CoA oxidase
- Pseudo-Zellweger: Present and abnormal Thiolase
- Bifunctional enzyme deficiency: Present and normal Bifunctional protein

**Group III: Single peroxisomal enzyme deficiencies without beta-oxidation involvement**

- Refsum disease: Unknown Phytanic acid oxidase
- Pseudo-rhizomelic chondrodysplasia: Unknown Plasmalogens synthesis
- Di-(tri-)-hydroxycholestanolic acidemia: Unknown Bile acid synthesis
- Mevalonic aciduria: Unknown Cholesterol

VLCFA, very long chain fatty acid; ALD, adrenoleukodystrophy.

ears, flat eyebrow ridges, a broad and depressed nasal root and often single palmar creases. Redundant neck skin folds can be seen. The liver is enlarged and jaundice frequently develops. Patients show virtually no psychomotor development, and death typically occurs before the age of 1 year. Brain MRI shows polymicrogyria, which is typically peri-sylvian, and heterotopia. Germinolytic cysts are often seen. The ventricles are often mildly dilated. Myelination is delayed and white matter volume is decreased (Poll-Thé and Gärtner 2012). EEG shows a disturbed background and multifocal spikes. Abdominal ultrasound often shows cystic kidneys and hepatomegaly. Radiographs of knees and shoulders often show calcific stippling. Metabolite analysis shows abnormalities in different peroxisomal pathways.

The ZSD define a continuum from this classic Zellweger syndrome to a milder disease with focal neurosensory involvement and sometimes normal intelligence, without obvious dysmorpism, and characterised by prolonged survival past childhood and often into adulthood (Wanders 2004). Relatively milder mutations in the same genes that cause Zellweger syndrome are responsible for this spectrum. Neonatal adrenoleukodystrophy (ALD) and infantile Refsum disease, names that were given before the molecular cause of the disorders of the ZSD was known, belong to this
spectrum, and correspond to intermediate and mild ZSD in the new classification (Braverman et al. 2016). Survival in intermediate ZSD is longer than in Zellweger syndrome, with death in the first decade. Patients with mild ZSD can reach adulthood. With decreasing severity, dysmorphism, initial development, systemic features, survival and biochemical markers improve. This also allows for more focal neurological signs to be noted and to develop, like ataxia, polymyelopathy, spasticity. Urolithiasis with oxalate stones also occurs in these patients. All patients within the ZSD are at risk for adrenal insufficiency and progressive inflammatory leukodystrophy comparable with X-ALD but the timing is unpredictable, as well as the factors that influence the onset.

Interestingly, at what is currently the mildest end of the spectrum, gene-specific disorders can be recognised. Mild mutations in PEX1 or PEX6 cause Heimler syndrome, characterised by enamel hypoplasia, nail abnormalities, variable retinal dystrophy and deafness, but normal intelligence (Ratbi et al. 2015). This contrasts with findings in mild deficiency of PEX10, PEX2, and PEX12, where ataxia is the presenting sign. This raises questions about functions of the peroxins (PEX) genes outside general peroxisome biogenesis. Clinically, these patients in the mildest end of the ZSD illustrate the need to consider peroxisomal disorders in the diagnostic process of patients with isolated neurological deficits and normal intelligence. As the abnormalities in peroxosomal metabolites become less pronounced, inconstant and are sometimes completely absent with decreasing severity, diagnosis can be difficult, and in the future will depend on incorporation of peroxisomal genes in symptom-specific next generation gene panels; for example, ataxia gene panels.

**PTS2-related PBD:**

**Deficiency of PEX7 and PEX5L**

Deficiency of PEX7 causes **RCDP type 1 (RCDP1)** and **Refsum disease.** Because of the deficiency of PEX7, ADHAPS and phytanoyl-CoA hydratase are not imported into the peroxosomal matrix. As a result, plasmalogen synthesis is impaired as well as phytanic acid oxidation. RCDP1 is characterised by rhizomelic shortening of the limbs, cataracts, intellectual disability and spasticity. Epilepsy can start at variable ages. Arthrogryposis occurs. Facial dysmorphism includes a broad nasal bridge, micrognathia, dysplastic ears and a highly-arched palate. Some patients have hepomegaly and ichthyosis. Stippled epiphysial and extra-epiphysial calcifications present during infancy, and may disappear after the age of 2 years. A severe and a mild form can be distinguished, both with moderate intellectual disability (IQ below 50) (Bams-Mengerink et al. 2013). In the severe phenotype, cerebral MRI displays delayed myelination, abnormalities in supratentorial white matter and progressive cerebral and cerebellar atrophy. In the mild phenotype, MRI is normal (Bams-Mengerink et al. 2006). The mildest form of PEX7 deficiency is a form of adult Refsum disease. As is clear from Table 9.3, the peroxisomal metabolites that are abnormal are phytanic acid, which is elevated, and plasmalogens, which are decreased.

**RCDP5,** a novel PBD caused by mutations specifically affecting the long isomorph of PEX5, was described. The phenotype fitted well with the mild form of RCDP, but there was prominent demyelinating neuropathy, attributed to the higher levels of phytanic acid in RCDP5 compared with RCDP1 (Barøy et al. 2015).

**Disorders of Peroxisomal Fission**

This is a group of disorders recently described in only a few patients. We can subdivide this group into a disorder where only peroxisomal fission is disturbed, PEX11beta deficiency, and disorders where both peroxisomal and mitochondrial fission are affected, caused by deficiency of dynamin-like protein 1, DLP1 (encoded by DNML1) or MFF. Deficiency of PEX11beta was described in one patient with congenital cataract, intellectual disability, childhood-onset progressive sensorineural hearing loss, axonal sensorimotor neuropathy, nystagmus and dry scaling skin. There were clinical deteriorations during intercurrent illness, which took a long time to recover, and the patient suffered migraine-like episodes accompanied by elevation of very long chain fatty acids (VLCFA). Peroxisomal parameters in blood and cultured fibroblasts were normal, except for the elevation of VLCFA after a migraine-like episode. Examination of peroxisome morphology in cultured fibroblasts showed excessive variation of peroxisomal size and decreased numbers of peroxisomes. Immunofluorescence for catalase showed cytosolic localisation of catalase in a small portion of the fibroblasts. This proportion increased to 90% after culturing the fibroblasts at 40°C. Sequencing of candidate genes involved in peroxisomal fission revealed nonsense mutations in PEX11beta.

Deficiency of DLP1 was first described in a single patient with combined mitochondrial and peroxisomal dysfunction. The patient presented in the first days of life with feeding difficulties, and profound hypotonia, paucity of voluntary movement, nystagmus, optic atrophy, areflexia and mild dysmorphic features. MRI showed abnormal anterior gyration and dysmyelination. Lactate was persistently elevated as were VLCFA. The infant died at the age of 5 weeks. Another patient was recently described with severe intellectual disability, refractory daily seizures, mild ptosis and normal MRI. VLCFA and lactate were normal. Deficiency of MFF caused a Leigh-like encephalopathy with infantile spasms, hypotonia, external ophthalmoplegia, optic atrophy, and mixed sensorimotor neuropathy. Lactate was only intermittently elevated, but peroxisomal metabolites were normal. MRI showed a Leigh-like pattern. In all these patients, enzymatic studies in fibroblasts were essentially normal and only morphological studies of peroxisomes (and mitochondria) were consistently able to prove the peroxisomal nature of the disorder.
DISORDERS OF PEROXISOMAL ENZYME DEFICIENCIES

Deficiencies of the Peroxisomal b-Oxidation

As can be seen in Figure 9.6, the peroxisomes contain a complete set of enzymes for the beta-oxidation of VLCFAs and branched-chain fatty acids. The most important branched-chain fatty acids are pristanic acid, derived from phytanic acids, and the bile acid precursors. This means that if the defect includes branched-chain fatty acid beta-oxidation, bile acid synthesis is disturbed, and symptoms can include malabsorption and deficiencies of the fat soluble vitamins, with sometimes a coagulation disorder caused by vitamin K deficiency.

In X-ALD peroxisomal beta-oxidation is disturbed by defects in the adrenoleukodystrophy protein (ALDP), encoded by ABDD1. ALDP is necessary for the import of VLCFA into the peroxisome. VLCFA cannot be degraded and blood levels are elevated. Variable combinations of different phenotypes occur, the most devastating of which is the cerebral form of ALD. This form occurs in 35% of affected boys, and its occurrence currently cannot be predicted and can be discordant in the same family. Adrenal insufficiency and a later onset progressive neuromyelopathy are other presentations. In the context of peroxisomal disorders, it is noteworthy that a risk for inflammatory cerebral demyelination and adrenal insufficiency appears to occur in all disorders associated with elevated VLCFA. This disorder is discussed in more detail in Chapter 10.

2-Methyl acyl-CoA racemase (AMACR) deficiency is a rare disorder with 10 reported patients, of which two were infants and eight adults. In infants, the disorder presents with cholestasis and fat soluble vitamin deficiency, while in adults the variable presentation is mainly neurological, with polyneuropathy, relapsing encephalopathy, epilepsy, thalamic lesions, tremor, cataract and retinopathy as possible symptoms. In the context of peroxisomal disorders, it is noteworthy that a risk for inflammatory cerebral demyelination and adrenal insufficiency appears to occur in all disorders associated with elevated VLCFA. This disorder is discussed in more detail in Chapter 9.

Acyl-CoA Oxidase 1 (ACOX1) deficiency is characterised by impaired peroxisomal beta-oxidation of straight-chain VLCFA. It is characterised by neonatal hypotonia, seizures, pigmentary retinopathy, hearing loss, hepatomegaly, dysmorphic features and developmental delay. The clinical course is characterised by acquisition of few developmental milestones. Death is invariably before the age of 2 years. Imaging findings include delayed myelination, polymicrogyria, heterotopias, and inflammatory demyelination. Patients are at risk for adrenal insufficiency. However, milder forms with longer survival exist. Mild D-BP deficiency causes ataxia, sensorineural deafness, polyneuropathy, ovarian failure or azoospermia, retinopathy and mild intellectual disability with survival until adult age, which has also been called Perrault syndrome.

Deficiency of a-Oxidation: Adult Refsum Disease

Adult Refsum disease is caused by deficiency of phytanoyl-CoA hydratase (PHYH). The onset generally varies from adolescence to adulthood, and it is characterised by anosmia and early-onset retinitis pigmentosa as universal findings, with variable combinations of neuropathy, deafness, ataxia, and ichthyosis. Later in life, cardiac problems, including cardiomyopathy and arrhythmia can develop. Phytanic acid levels are elevated, usually above 200µmol/L.

As all phytanic acid enters the body through the diet, mainly by consumption of dairy products, levels of phytanic acid can be reduced by a diet restricted in phytanic acid. As human milk contains only little phytic acid, phytic acid (and pristanic acid) is not a good peroxisomal marker in breastfed infants.

Deficiency of Ether-Phospholipid Synthesis

Three disorders have been described: RCDP1 (or DHAPAT deficiency), RCDP3 (or ADHAPS deficiency), and RCDP4 (or Fatty Acyl-CoA reductase 1 [FAR1] deficiency). Clinical symptoms and laboratory findings correspond to those described above for RCDP1, except that FAR1 deficiency is not associated with rhizomelia, and that phytanic acid levels are normal (Buchert et al 2014).

Deficiency of Glyoxylate Detoxification

Hyperoxaluria type 1 is characterised by increased excretion of oxalic acid in the urine, which leads without treatment to urolithiasis and nephrocalcinosis by crystallisation of calcium oxalate. As this leads to decreased renal function, levels of oxalic acid in the body increase, and complications of systemic oxalosis, including cardiomyopathy, polyneuropathy, bone disease, retinopathy, and calcium oxalate deposition in other organs follow (Wanders and Waterham 2006).

DIAGNOSIS OF PEROXISOMAL DISORDERS

Currently, clinical suspicion of a peroxisomal disorder will lead to analysis of one or more peroxisomal metabolites, generally some combination of VLCFAs phytanic acid, pristanic acid,
and plasmalogens. If one peroxisomal metabolite is abnormal, investigation of more peroxisomal metabolites from different peroxisomal pathways is performed. This allows to evaluate if the disorder is a PBD or a single peroxisomal enzyme defect. If only one pathway is affected, the enzyme activity can be measured in cultured skin fibroblasts or the gene can be sequenced directly. If metabolites from multiple pathways are deficient, analysis of peroxisomal pathways (beta-oxidation, alpha-oxidation, and plasmalogen synthesis) is done in cultured fibroblasts, together with visualization of peroxisomal morphology and correct import of peroxisomal matrix proteins like catalase. Afterwards, the fibroblasts are complemented with different PEX genes to identify the responsible gene, which is then sequenced. When a strong-founded clinical suspicion of a peroxisomal disorder is not confirmed by analysis of peroxisomal metabolites in blood, it can be useful to proceed to fibroblast studies anyway, as patients are known who had no abnormal peroxisomal metabolites in blood, but whose fibroblasts showed re-localisation of catalase to the cytoplasm due to defective PTS1 import or morphologically abnormal peroxisomes. With the increasing use of next generation sequencing, a change can be expected towards earlier use of molecular genetics, possibly even directly following clinical suspicion in the near future. Another route to diagnosis will be the incorporation of peroxisomal genes in symptom-specific panels containing many non-peroxisomal genes, leading to a diagnosis even without clinical suspicion of a peroxisomal disorder. Enzymatic and biochemical studies in fibroblasts will then be reserved for confirmation of the pathogenicity of novel mutations.

TREATMENT OF PEROXISOMAL DISORDERS

Peroxisomal Biogenesis Disorders and Zellweger Spectrum Disorders

No proven aetiological therapies currently exist. Supportive measures need to be individualised depending on the severity of the disorder (Braverman et al. 2016). At the severe end of the spectrum, adequate feeding and seizure control seem most sensible. For patients at the mild end of the spectrum, logical choices would include rehabilitation with physical, occupational and speech therapy. Evaluation of auditory and visual function and remediation with hearing aids, cataract removal or correction of refractive errors can significantly improve quality of life in mildly affected patients (Witters et al. 2016). Yearly monitoring for adrenal insufficiency, with supplementation when necessary has been advised. Evaluation of malabsorption and supplementation of bile acids and fat soluble vitamins can be considered. Supplements of docosahexaenoic acid (DHA) can be useful if a deficiency exists, and a diet restricted in phytic acid can normalise blood phytic acid levels (Noguer and Martinez 2010). Evaluation of hyperoxaluria and treatment with increased fluid intake or urine alkalisation becomes useful after the age of 4 years to prevent urolithiasis. It is important to recognise that these measures are futile in patients with Zellweger syndrome and that evidence for their usefulness in milder PBD is often merely anecdotal (Fig. 9.7).

PTS2 RELATED PEROXISOMAL BIOGENESIS DISORDERS

In PEX7-related Refsum disease, a diet restricted in phytanic acid is advisable. In RCDP5, caused by mutations in PEXSL, phytanic acid levels have been higher, accompanied by a demyelinating polyneuropathy, and a diet restricted in phytic acid is advisable (Barøy et al. 2015). Symptomatic therapy of complications is the mainstay of therapy in RCDP1.

Disorders of Peroxisomal Beta-Oxidation

'B-oxidation' X-linked Adrenoleukodystrophy

Lowering of VLCFA levels in blood with Lorenzo’s Oil has no relevant benefit in established cerebral ALD, although discussion continues about the use in the presymptomatic phase. Haematopoietic stem cell transplantation (HCST) can stop progression of the cerebral form of X-ALD if performed early in the course of the disease. This is evaluated primarily with the Loes score on MRI. As a consequence of the X-linked nature of the disease, targeted familial screening often identifies asymptomatic family members. Current guidelines involve regular MRI to detect the first signs of demyelination, and subsequent bone marrow transplantation. From the age of 3 to 12 years, MRI should be done every 6 months, and afterwards yearly MRI is sufficient. As bone marrow transplantation is itself accompanied by significant morbidity and mortality, and 40–45% of patients never develop cerebral ALD and since bone marrow transplantation does not appear to prevent adrenomyeloneuropathy at adult age, systematic bone marrow transplantation of all presymptomatic male patients is not warranted (Engelen et al. 2012). Inflammatory signs are prominent and coincide with the presence of clinical symptoms, suggesting that they play a role in the mechanism of brain lesions.

General treatment includes screening for adrenal insufficiency every 6 months and supplementation if present. No specific treatment for adrenomyeloneuropathy exists.

ACOX1 deficiency

Aside from monitoring for adrenal insufficiency and general supportive and symptomatic therapy, treatment options are limited. One patient underwent hematopoietic stem cell transplantation HSCT without benefit.

D-bifunctional protein deficiency

In classic d-bifunctional protein deficiency (D-BP), monitoring for adrenal insufficiency and general supportive and symptomatic therapy are the only therapeutic options. In milder forms, measures as described above for treatment of malabsorption and DHA deficiency can be considered.
2-Methyl acyl-CoA racemase (AMACR) deficiency
Therapy in children consists of measures for treatment of malabsorption and bile acid supplementation.

Refsum Disease: a-Oxidation
A diet restricted in phytanic acid is the mainstay of therapy. Weight loss should be avoided as this releases stored phytanic acid in the body. Acute decompensations can be treated by plasmapheresis. Symptomatic therapy with hydrating creams for ichthyosis and antiarrhythmic medication should not be overlooked.

Ether Phospholipid Synthesis (RCDP 2–4)
See RCDP1 above.

Glyoxylate Detoxification: Hyper Oxaluria Type 1
Increasing fluid intake and alkalisation of the urine help lower levels of oxalic acid in the body and the urine.

**DISORDERS OF AMINO ACID AND ORGANIC ACID METABOLISM**

**PHENYLKETONURIA AND HYPERPHENYLALANINAEMIA**
Phenylketonuria (PKU) and hyperphenylalaninaemia are due to a deficiency of phenylalanine hydroxylase (PAH) which converts phenylalanine to tyrosine in the liver. The enzyme requires tetrahydrobiopterin (BH4), which is formed from guanosine triphosphate (Fig. 9.8). The world-wide incidence of PKU is about 1 in 12,000.

**GENETICS**
HPA is one of the most prevalent disorders of amino acid metabolism in the white population, occurring in approximately 1 in 10,000 live births. This autosomal recessively inherited disorder is caused by more than 500 mutations at the PAH locus. Different groups of mutations predominate in a given ethnic population, allowing prenatal diagnosis, carrier detection, and the prediction of the PKU phenotype linked with a particular haplotype. Some PAH mutations result in PAH deficiency with a residual enzymatic activity that is enhanced with BH4. In such cases, pharmacological dose of TBH results in, at least, a 30% decrease of blood phenylalanine levels

Severe hyperphenylalaninaemia results in plasma phenylalanine values exceeding 1200 μM/L, in milder cases (HP) between 120–600 μM/L.

If untreated after a month this will lead to irreversible damage to the brain and severe intellectual disability. This is certainly necessary to keep PHe levels low within the first years of life.

Later high Phe levels can lead to concentration deficits and learning disability.

**PATHOGENESIS**
The clinical manifestations are thought to result from phenylalanine accumulation and its secondary effects on brain chemistry. The fact that PKU is most often accompanied by intellectual disability whilst HP is not, suggests that there is a threshold level of phenylalanine in extracellular fluids above which persistent postnatal (or fetal) HPA causes irreversible brain damage. If the threshold value is exceeded only later in life, after diet discontinuation in the early-treated PKU patients, reversible chemical changes appear that may affect neuropsychological function.

Abnormal myelination, reduction of brain weight and decreased myelin content are found in brain of untreated older PKU patients. These detrimental effects have been confirmed using the HPH-5 mouse model. Current and previous observations have led to the hypothesis that myelin reduction is due to inhibition of an oligodendroglial cell-specific ATP-sulfurylase that results in low content of sulfatides in myelin that in turn is exposed to proteolytic degradation. Consequently, neuronal loss and decreased interneuronal connections occur, as has been demonstrated by quantitative evaluation of neurotransmitter receptor density. If the results obtained in animals can be extrapolated to humans, special involvement of hippocampus and occipital area of the cortex could explain some of the neurophysiological disturbances observed in non- or poorly treated PKU patients. Abnormal brain protein synthesis due to polysome disaggregation and reduced rate of polypeptide chain elongation may result in low brain weight. Polysome disaggregation also occurs in heart and brain of fetal rats exposed to maternal HPA, a finding that has a bearing on the fetopathy associated with human maternal HPA.

Decreased DNA content and synthesis in neurons exposed to high levels of phenylalanine can also account for decreased proliferation of neurons, neuronal loss and impaired brain growth.

**CLINICAL FEATURES**
The clinical features of untreated PKU include intellectual disability, neurological abnormalities and extraneural symptoms (although the timing varies from patient to patient). Retarded intellectual development is often associated with microcephaly.
Abnormal EEGs are frequent (78–95% of cases), but only 25% of patients have seizures, most often of grand mal type. Psychotic behaviour with hyperactivity, destructiveness, self-injury, impulsiveness, and uncontrolled behaviour with episodes of excitement is not infrequent. The majority of patients present with lightly pigmented or eczematous skin. A peculiar musty odour has been repeatedly mentioned. The general physical development is usually good.

The clinical picture of PKU is now prevented by early diagnosis and treatment because of the implementation of neonatal screening. Phenylalanine (phe) levels are measured on dried blood spots collected during the first days of life.

Deficiencies of co-factors need to be excluded early by investigation of pterins in blood or urine. Some patients with PKU or HP are BH4-responsive with a decrease of phe levels after oral administration of BH4.

Children with early diagnosis and adequate dietary and/or BH4 treatment will develop well and will have normal IQ’s.

**TREATMENT OF PKU**

**Dietary treatment**

Recommendation on ideal levels of phe vary in different countries and change with age. The basis of diet is protein restriction, and adding amino acid mixtures without Phe (Bekhof et al. 2005; von Spronsen et al 2017).

**Tetrahydrobiopterin (BH4)**

In some patients BH4 or sapropterin (Kuvan) can reduce phe levels by more than 30% after a single dose of 10mg/kg; this is then considered as a BH4 responsive patient and daily doses of BH4 of 5–10mg/kg can continue, allowing a higher natural protein intake (Lindner et al. 2009; Thiele 2015).

**MATERNAL PHENYLKETONURIA**

Mothers with PKU and high phe levels during pregnancy because of neglecting their strict diets can have infants who at birth have microcephaly, low birthweight, congenital cardiac defects and developmental delay. This is due to fetal damage caused by the high levels of phe. Phe probably competes with other neutral amino acids for placental and brain transport and may lead to tyrosine and tryptophan deficiencies leading to insufficient neurotransmitter concentrations. Recommended phe levels should be kept between 250–360µmol/L before and during the pregnancy.
TYROSINAEMIA

Five inherited disorders of tyrosine metabolism are known:

1. Tyrosinaemia type 1 (HT1) classic tyrosinaemia;
2. HT2 (Richner-Hanhart syndrome) with keratitis and blistering lesions on hands and feet;
3. HT3 might be asymptomatic or associated with intellectual disability;
4. Hawkininuria may be asymptomatic or associated with failure to thrive and metabolic acidosis in infancy;
5. Alkaptonuria leads to symptoms in adults with osteoarthritis and blue-coloured ears.

Tyrosinaemia type 1 (HT1) is the most frequent and will be discussed here.

Tyrosinaemia Type 1

Tyrosinaemia type 1 (HT1) is an autosomal recessive disorder caused by a deficiency of fumarylacetoacetase, the final enzyme in the catabolic pathway of tyrosine. Maleylacetoacetate and fumarylacetoacetate accumulate and are metabolised to succinylacetone. Succinylacetone inhibits δ-aminolaevulinate dehydratase (ALDH) activity and is responsible for abnormally high urinary excretion of δ-aminolaevulinic acid (δ-ALA) (Fig. 9.9).

Clinical features of HT1

There are three forms according to age at onset. An acute form starts before 6 months of age with liver failure. A subacute form manifests between 6 months and 1 year with liver failure, failure to thrive, coagulopathy, hepatosplenomegaly, rickets and hypotonia. A more chronic form presents after the first year with chronic liver disease, renal tubulopathy and end-stage renal failure, rickets, cardiomyopathy and/or porphyria-like syndrome. Hepatoma and end-stage renal failure are late complications.

Neurological crises, described as porphyria-like symptoms, may arise, during intercurrent infections, in patients affected with either the acute or subacute forms. Features include rapid progression of diffuse pain, mainly localised in legs and abdomen, associated with vomiting, irritability, hypertonia, painful episodes of opisthotonic posturing and brisk tendon reflexes. A rapidly ascending paralysis associated with areflexia may follow and results in respiratory insufficiency and death in the absence of assisted ventilation. Throughout this course patients remain conscious. Oral self-mutilation, such as tongue-biting, grinding and avulsion of the teeth, is observed especially during the initial phase.

Diagnosis of HT1

The diagnosis is made using neonatal screening and measuring of succinylacetone with tandem mass spectrometry; the diagnosis can be confirmed by the measurement of fumarylacetoacetase activity in lymphocytes or fibroblasts.

Figure 9.9 Tyrosine metabolism and its relationship to haem synthesis.

Key: 1, para-OH-phenylpyruvate dioxygenase (the site of NTBC inhibition); 2, fumarylacetoacetase; 3, δ-aminolaevulinic dehydratase; 4, acute intermittent porphyria; 5, other porphyrias.

Further mutation analysis of the FAH gene can be done. The gene is localised on chromosome 15q23-q25.

Treatment of HT1

Since 1992, nitisinone, 2-(2-nitro-4-trifluoro-methylbenzoyl)-1,3-cyclohexanedione (NTBC), treatment has been introduced. This drug blocks the tyrosine degradation and prevents the downstream toxic metabolites. This is now the standard of treatment at a dose of 2mg/kg/day during acute liver failure, reduced later to 1mg/kg/day maintenance (De Laet 2013). The treatment is associated with dietary restriction of Phe and tyrosine.

Liver transplantation is recommended for patients that do not respond to NTBC or when a hepatocellular carcinoma is suspected (increase of alpha-fetoproteins, AFP).

Disorders of Branched-Chain Amino Acid Metabolism

Maple syrup urine disease (MSUD), propionic aciduria, methylmalonic aciduria (MMA) and isovaleric aciduria (IVA) have similar presentations, mostly as early-onset severe neonatal forms with acute metabolic decompensation, an acute intermittent late onset with recurrent episodes of metabolic decompensation or as a chronic progressive form presenting as hypotonia, failure to thrive and developmental delay.

Biochemical and Genetic Background

These diseases result from defects of enzymes involved in the catabolism of leucine, valine and isoleucine (Fig. 9.10). These three neutral branched-chain amino acid (BCAAs) are initially
metabolised through a common pathway: a transamination that is followed by a thiamine-dependent decarboxylation, which is deficient in MSUD (step 1). The decarboxylation defect is responsible for accumulation of BCAAs and their corresponding keto-acids.

Leucine is further metabolised to acetoacetate and acetyl-CoA. Specific enzyme deficiencies may occur at every step. Isovaleryl-CoA dehydrogenase deficiency is responsible for isovaleric aciduria (step 2), isovalerate being a highly toxic substrate. Deficiency of 3-methylcrotonyl-CoA carboxylase, a biotin-dependent enzyme (step 3), produces 3-methylcrotonyl-glycinuria, as a result of either apo-enzyme decarboxylase mutation or abnormal biotin metabolism (see biotinidase responsive diseases).

3-Methylglutaconic aciduria type I (step 4) is another rare disease due to defective leucine catabolism (Ly et al. 2003).

The catabolism of valine and isoleucine produces propionyl-CoA and methylmalonyl-CoA. Methionine and threonine, fatty acids with odd-numbers of carbons and the side-chain of cholesterol, are other precursors of propionyl-CoA. Propionyl-CoA forms methylmalonyl-CoA through a biotin-dependent decarboxylase (step 5) whose deficiency is due to an apo-enzyme decarboxylase mutation (propionic aciduria) or to abnormal biotin metabolism. Methylmalonyl-CoA is converted to succinyl-CoA in two consecutive steps by the methyl-CoA epimerase (Dobson et al. 2006) and then by the B12-dependent methylmalonyl-CoA mutase (step 6). Deficient activity of each enzyme leads to methylmalonic aciduria. Abnormal B12 metabolism is responsible for variant forms of methylmalonic aciduria.

All but one of the disorders of this group are inherited in an autosomal recessive manner; 2-methyl-3-hydroxybutyryl CoA dehydrogenase deficiency is an X-linked disorder. Antenatal diagnosis can be performed through the measurement of metabolites in amniotic fluid, specific enzyme activity in chorionic villus samples or amniotic cells, and/or the determination of pathogenic mutations. Newborn infant screening programmes coupled with mutation studies have revealed that a number of patients with
either isovaleric aciduria or 3-methylcrotonylglycinuria detected by screening have mild or even asymptomatic phenotypes.

**Pathogenesis of Branch-Chain Amino Acid Disorders**

The pathogenesis of the cerebral involvement in BCAA disorders is poorly understood. In acutely ill patients, accumulation of toxic metabolites can be responsible for energy deprivation due to inhibition of certain enzymes involved in the pyruvate oxidation, in the Krebs cycle or in the mitochondrial respiratory chain. Susceptibility of basal ganglia to energy deprivation may explain their particular involvement in all these diseases, especially in methylmalonic and propionic acidurias. In MSUD patients, high leucine levels may result in defective catecholamine synthesis secondary to defective brain uptake of the neutral amino acids tyrosine and tryptophan. Similarly, interference of methylmalonic acid with succinate may reduce gamma-amino-butyric acid (GABA) synthesis. Irreversible changes may be the result of interaction with myelin synthesis due to defective transport of all the neutral amino acids (Schwab et al. 2006). In addition, accumulated propionyl-CoA and methylmalonyl-CoA are precursors of the synthesis of odd-numbered and methyl-branched long-chain fatty acids. Their incorporation into lipid layers may be responsible for abnormal lipid membrane synthesis in the CNS.

**Clinical Features of Branched-Chain Amino Acid Disorders**

**Severe Neonatal-Onset Form**

Development of a toxic encephalopathy with ketosis or ketoacidosis within a few days after an initial symptom-free period. The first signs are poor feeding, drowsiness followed by unexplained coma; followed by respiratory distress, hiccups, seizures, apnoeas, bradycardia and hypothermia. Generalised hypertonia and boxing or pedalling movements may occur.

Affected infants may have cerebral oedema with bulging fontanels, arousing suspicion of CNS infection. EEGs often show a burst-suppression pattern. Biochemical abnormalities include metabolic acidosis and ketonuria associated with hyperammonaemia and hyperlactacidemia. The overall short-term prognosis is improving, with early diagnosis and accurate management. Later, despite the treatment, acute life-threatening intercurrent episodes often occur, with clinical manifestations resembling those of late intermittent forms.

**Maple Syrup Urine Disease**

An intensely sweet maple sugar-like odour develops within a few days after birth. These patients do not develop dehydration or metabolic acidosis and routine biochemical analysis is normal. Abnormalities are found only in the plasma BCAAs, and in the urine organic acid analysis, 2-keto-acids are present.

Figure 9.11  *Methylmalonic aciduria*. T2-weighted image showing symmetrical areas of high signal from the globus pallidus of an 8-month-old child. Delayed myelination is also evident.

(DNPH screening test). The patients can rapidly deteriorate and become comatose.

**Isovaleric Aciduria, Propionic Aciduria and Methylmalonic Aciduria**

Dehydration is a frequent finding. Patients can also have metabolic acidosis with increased anion gap and ketonuria. Hyperammonaemia is a constant finding and lactate is moderately elevated. Because of the presence of neutropenia, thrombocytopenia or pancytopenia, there can be some confusion with sepsis.

**Intermittent and Late-Onset Forms**

In approximately one-third of patients, BCAA disorders present in childhood, or even in adolescence or adulthood. Recurrent episodes are frequent, while in-between, these patients may seem entirely normal. The onset in most cases is precipitated by conditions that enhance protein catabolism (infection, trauma, etc.) or by excessive protein intake, but may equally occur without an overt cause. Recurrent coma or lethargy with ataxia are the main presentations. Most often, coma is not usually accompanied by other abnormal neurological signs. Ketoacidosis indicates a metabolic origin. Nevertheless, a few patients may present with acute hemiplegia and hemianopsia or signs and symptoms of cerebral oedema mimicking a cerebrovascular accident or a CNS tumour (Fig. 9.11).

Patients may die during such episodes. Severe cerebral oedema with brainstem compression has been reported in several MSUD patients. It appears to be a reversible cytotoxic oedema as judged from the results of diffusion-weighted imaging and magnetic resonance spectroscopy (MRS) studies.
This complication can be a major cause of death in all patients with BCAA presenting with acute decompensation. Some recover without sequel. Many children who survive severe, prolonged or recurrent metabolic disturbances are left with brain damage. Seizures are a common sequel. Neuroimaging usually shows cerebral atrophy and some delay in myelination. The most commonly affected areas are the brainstem, basal ganglia, and occipital periventricular and cerebellar white matter.

Patients with organic acidurias, and especially with methylmalonic or propionic acidurias can present with an acute or progressive extrapyramidal syndrome due to bilateral necrosis of the basal ganglia or extensive white matter degeneration.

**Chronic Progressive Forms**

Hypotonia, muscular weakness, nonspecific developmental delay and seizures are rarely the only revealing signs of isovaleric, methylmalonic or propionic acidurias. Most often they coexist with digestive and nutritional symptoms and failure to thrive.

**Other Diseases in This Pathway**

In 3-methylcrotonylglycinuria, patients identified through tandem mass spectrometry newborn screening are usually asymptomatic. 3-methylglutaconic aciduria type I may present with mild neurological impairment and speech delay (Nguyen et al. 2002). Malonic aciduria may present with isolated developmental delay or developmental delay associated with seizures, muscle weakness and cardiomyopathy (Salomons et al. 2007). 2-methylbutyrylglycinuria and isobutyrylglycinuria have been described in rare infants with muscle weakness and some developmental delay.

Isobutyryl-CoA dehydrogenase deficiency is a defect in valine metabolism and was first reported in a child with cardiomyopathy, anemia, and secondary carnitine deficiency. Through newborn screening triggered by an elevation of C4-acylcarnitine in dried blood spots, more patients were found and some were completely asymptomatic. Isobutyryl-CoA dehydrogenase deficiency can be further confirmed by molecular genetic analysis of the gene encoding isobutyryl-CoA dehydrogenase (ACAD8).

2-methyl-3-hydroxybutyl-CoA dehydrogenase deficiency may be responsible for an X-linked progressive neurodegenerative disease with signs resembling the sequelae of a neonatal hypoxic–ischaemic brain injury from the second year of life (Poll-Thé et al. 2004). Movement disorders such as chorea associated with intellectual deterioration may result from progressive forms of many organic acidurias.

**Biochemical Diagnosis of Branched-Chain Amino Acid Disorders**

The diagnosis is based on the recognition of abnormal intermediate substrates and their by-products that result from the metabolic block. In MSUD patients, amino acid chromatography is characterised by high plasma and urine levels of leucine, valine and isoleucine and the presence of alloisoleucine. In contrast, all other enzymatic blocks result in plasma accumulation and urinary excretion of organic acids and are diagnosed using gas–liquid chromatography and mass spectrometry, while amino acid chromatography does not permit the diagnosis. Tandem mass spectrometry allows the recognition of these disorders through the abnormal acylcarnitine profiles that result from the accumulation of specific acylcarnitines, or measuring propionic aciduria or MMA and leucine, valine and isoleucine on the dried blood spot. The final diagnosis requires the measurement of specific enzymatic activities in fibroblasts or leukocytes, and/or the identification of pathogenic mutations in the genes concerned.

**TREATMENT**

Treatment is aimed at reducing toxic metabolites (Ogier de Baulny et al. 2005; Baumgartner et al. 2014). In the neonatal period, most acutely ill infants require aggressive nutritional therapy often associated with exogenous detoxification procedures. Long-term dietary treatment involves restriction in protein intake and in an otherwise well-balanced diet. Because some vitamins are cofactors of specific enzymatic steps, these vitamins must be systematically tested in each case. This therapeutic trial allows the recognition of vitamin-responsive patients who are less severely affected and may do well with a less strict diet. L-carnitine supplementation is systematically used in the treatment of organic acidurias. In isovaleric aciduria and 3-methylcrotonylglycinuria, L-glycine and L-carnitine supplementations increase metabolite urinary excretions and are effective means of detoxification (Sutton 2012).

Despite early diagnosis and treatment, at any age, these children are at risk for life-threatening metabolic imbalances and neurological sequelae. In addition, many patients with methylmalonic and propionic aciduria have progressive neurological dysfunction with intellectual impairment, ataxia, muscle weakness and poor nutritional states. Other complications may involve the kidneys, pancreas and heart. Facing these long-term complications, liver and kidney transplantations have been performed. However, none of these transplantations is able to prevent acute neurological degradation with basal ganglia necrosis (Leonard et al. 2001; Chakrapani et al. 2002).

Acute and chronic management should be supervised regularly and revised, based on regular updates (Chapman et al. 2012).

**ORGANIC ACIDURIAS**

**Glutaric Aciduria Type 1 (GA I)**

GA-I is an inborn error of lysine, hydroxylysine and tryptophan catabolism characterised clinically by an extrapyramidal.
syndrome with dystonia and choreoathetosis, pathologically by striatal degeneration, and biochemically by a deficiency of glutaryl-CoA dehydrogenase (GDH) (Kölker et al. 2004; Hedlund et al. 2006; Kölker et al. 2007, 2011).

**Biochemical and Genetic Background**

GA-I is an autosomal recessive disorder caused by a defect in GDH, a riboflavin-requiring enzyme that catalyses the dehydrogenation of glutaryl-CoA to glutaconyl-CoA and further to crotonyl-CoA (Fig. 9.12). The GDH gene is Figs. 9.12 and 9.13 on chromosome 19p13.2 and encodes a flavin adenine dinucleotide-dependent mitochondrial matrix protein that is involved in the catabolic pathway of L-lysine, L-hydroxylysine and L-tryptophan. More than 200 disease-causing mutations are known (Zschocke et al. 2000).

**Diagnosis**

Urinary acids analysis shows elevated glutaric acid, 3-hydroxyglutaric acid and glutaconic acid. Glutarylcarnitine can be detected by gas chromatography/mass spectrometry (organic acids) or tandem mass spectrometry (acylcarnitines). A definitive diagnosis comes from measuring the GDH activity in fibroblasts, leukocytes or liver biopsies, although correlation between residual activity and clinical phenotype is poor.

Prenatal diagnosis is available by determination of glutaryl-CoA dehydrogenase deficiency (solid bars).

**Pathophysiology**

The excitotoxic sequence initiated by glutaric and 3-hydroxy-glutaric acids (which exhibit structural similarities to the excitotoxic amino acid glutamate) is considered to play a major role in the pathophysiology of this disease. This process might involve the N-methyl-D-aspartate (NMDA) receptors and cause apoptotic cell death. Furthermore, this conformational similarity may induce neurotransmitter imbalance in excitatory and inhibitory neurotransmission via inhibition of glutamate decarboxylase, the key enzyme in the biosynthesis of GABA (Kölker et al. 2004). Another possible pathogenic mechanism is that increased degradation of tryptophan via the kynurenine pathway may produce quinolinic acid during intercurrent inflammation. Quinolinic acid is neurotoxic and an agonist of the NMDA receptors.

The mechanism of age-specific destruction of specific cerebral structures has different hypotheses; most of the evidence points to impaired brain energy metabolism induced by accumulating glutaric acid, 3-OH glutaric acid and glutaric-CoA, which inhibits 2-oxoglutarate dehydrogenase. Glutaric acid impairs the dicarboxylic acid shuttle between astrocytes and neurons and 3-OH glutaric acid activates glutamatergic neurotransmission (Kölker et al. 2004).

**Clinical Features of GA I**

Initially, affected children develop normally for several months, although they may have mild hypotonia, irritability and jitteriness. Macrocephaly is present at birth or is acquired in the first few months of life and can be an important early sign (Fig. 9.13). In typical untreated cases, an acute neurological deterioration resembling encephalitis precipitated by febrile illness, immunisation or surgical intervention (Kölker et al. 2007, 2011) occurs within 3 to 36 months, with lethargy, hypotonia, loss of head control, seizures, opisthotonus, grimacing, tongue-thrusting, rigidity and dystonia.

The characteristic neurological damage in these crises is acute bilateral striatal necrosis and, subsequently, a complex movement disorder while intellectual disability can be mild. Dystonia is the dominant extrapyramidal symptom, usually superimposed on axial hypotonia (Herger et al. 2010). With ageing, there is a tendency for the development of a fixed dystonia and akinetic-rigid Parkinsonism.

Morbidity and mortality is high in patients who have had a crisis (Kölker et al. 2006). In 10–20% of patients, neurologic disease has been demonstrated in the absence of any documented encephalopathic crisis and has been termed insidious-onset (Busquets et al. 2000). Two patients with insidious-onset type were reported in whom striatal injuries had occurred before or shortly after birth, followed by latent periods of several months before disability was apparent. The risk for encephalopathic crises, however, declines after the age of 3 years. Appropriate treatment and especially emergency rules seem to improve the outcome, after positive neonatal screening (Kölker et al. 2011).

**Investigations in GA 1**

Cerebrospinal fluid (CSF) and neurophysiological investigations are normal. MRI studies performed in patients followed since birth show progressive CNS involvement. The radiological features characteristic of GA-1 seen in screened patients preceded the development of clinical disease. Widening of the sylvian fissure or lack of operculisation is the...
most characteristic feature. More or less severe expansion of the pericerebral fluid spaces anterior to the temporal lobes is associated with hypoplasia of the temporal lobe. The mesencephalic cistern may be involved. Acute subdural hematomas or chronic subdural collections are classically reported, raising a suspicion of child abuse. Lesions of the putamen, either in isolation or in combination with the caudate nucleus, are commonly reported. Widespread involvement of the globus pallidus and thalamus, the dentate nucleus, the medial lemniscus and substantia nigra can be other radiological findings (Twomey et al. 2003).

These findings are in agreement with neuropathological reports showing that striatal changes are minimal in young affected patients but much more marked in older children, with neuronal loss and extensive fibrous gliosis. Degeneration of the globus pallidus and marked spongiosis of subcortical white matter have also been reported.

Figure 9.13 (Top) Glutaric Aciduria type I in two children with marked dystonia of axial muscles and limbs. Note severe scoliosis. ### Treatment in Glutaric Aciduria Type I

Metabolic treatment includes a low lysine diet, carnitine supplementation and intensified emergency treatment during acute episodes of intercurrent illness. However, the initiation of treatment after the onset of symptoms is generally not effective in preventing permanent damage. Secondary dystonia is often difficult to treat, and the efficacy of available drugs cannot be predicted precisely in individual patients.

Most patients remain asymptomatic if treatment is started in the newborn period. Dietary treatment in combination with carnitine and emergency treatment has been demonstrated to be effective in preventing neurological disease (Kölker et al. 2007). Recently the relative efficacy of each single component of this therapy has been evaluated, demonstrating that outcome was best in patients who received all three interventions (low lysine diet, carnitine, and emergency treatment),
and that deviations from basic metabolic treatment (low lysine diet, carnitine) resulted in an intermediate outcome. Disregard of emergency treatment recommendations was associated with a poor outcome (Heringer et al. 2010).

The use of a diet based on low lysine intake combined with lysine-free, tryptophan-reduced amino acid supplements to maintain adequate total protein intake has been associated with the most favourable neurological outcome and normal growth in some studies (Kölker et al. 2007; Heringer et al. 2010).

Treatment of intercurrent illness with high-calorie glucose infusions, rapid correction of fluid deficits and high-dose intravenous carnitine are important preventive measures. This regimen gives unsatisfactory results in symptomatic children, but could prevent further encephalopathic crises or progression of neurological deterioration. Conversely, treatment has considerably reduced the morbidity and mortality in presymptomatic patients, and nowadays this treatable disorder is considered in neonatal screening programmes. Neuropharmaceutical management of movement disorders is unsatisfactory. Effectiveness of baclofen or benzodiazepines to reduce involuntary movements may be limited by worsening the effect of L-2-HGA. Anticholinergic drugs, intrathecal baclofen, rapid correction of fluid deficits and high-dose intravenous carnitine injections and pallidotomy are other therapeutic options that have been used in a very few or even single patients.

**Canavan Disease (N-Acetylaspartic Aciduria)**

This disorder, also known as spongy degeneration of the brain, presents clinically as a leukodystrophy. Urine or plasma analysis for N-acetylaspartic acid (NAA) can now be considered as the biochemical marker of a disorder that was previously diagnosed by brain biopsy. It is caused by a deficiency of the activity of the aspartoacylase enzyme, which normally hydrolyses NAA to aspartate and acetate. Enzyme activity is present in various tissues (brain, leukocytes, liver, kidneys, adrenals, lungs and fibroblasts).

**Hydroxyglutaric Acidurias**

There are three diseases in this category: D-2-hydroxyglutaric aciduria (D-2-HGA), L-2-hydroxyglutaric aciduria (L-2-HGA) and combined D, L-2-hydroxyglutaric aciduria (D, L-2-HGA) (Kranadijk et al. 2012).

**L-2-HYDROXYGLUTARIC ACIDURIA (L-2-HGA)**

L-2-HGA is associated with a progressive neurodegenerative process with subcortical leuкоdystrophy, cerebellar atrophy and basal ganglia involvement. The disease is due to a defective flavine adenine nucleotide (FAD)-dependent L-2-hydroxyglutarate dehydrogenase with pathogenic mutations identified in its gene. The phenotype seems to be homozygous (Steenweg et al. 2009, 2010). The onset is insidious, starting in childhood with developmental delay, epilepsy and cerebellar ataxia. Most patients experience a very slowly progressive course. There can be progressive macrocephaly and extrapyramidal symptoms such as tremor and dystonia. Acute metabolic derangement does not occur. The patients can develop brain tumours. Several such cases have now been described suggesting L-2-HG may predispose to oncogenesis.

Steenweg et al. (2009) evaluated MRIs of 56 patients and found a highly characteristic pattern of MRI abnormalities in the subcortical cerebral white matter, the dentate nucleus, the globus pallidus, the putamen and the caudate nucleus. With progression of the disease, abnormalities of white matter and basal ganglia signal intensities become more diffuse, followed by white matter atrophy. The biochemical pattern is characterised by accumulation of L-2-HGA and lysine in body fluids, with usually higher concentrations in the CSF than in the plasma. Recessive mutations in L2HGDH, summarised in Mutation Update, were reported (Steenweg et al. 2010).

**D-2-HYDROXYGLUTARIC ACIDURIA**

D-2-hydroxyglutaric aciduria (D-2-HGA), characterised by elevated levels of D-2-HG, is either autosomal recessive, resulting from mutations in D2HGDH6 (type I) or is caused by recurrent, usually de novo, dominant gain-of-function mutations in the IDH27 gene (type II).

Manifestations of both types of D-2-HGA include developmental delay, hypotonia, and seizures. Cardinal clinical manifestations common to the two genetic types include developmental delay, hypotonia and seizures. All type II patients were developmentally severely delayed more than the type I, and cardiomyopathy is only seen in type II. All other symptoms were present in the two types.

Presentation can be as a severe neonatal-onset form characterised by an early-onset epileptic encephalopathy with marked hypotonia, cortical blindness and serious developmental delay. A milder variant presents with more variable signs, most frequently hypotonia and developmental delay.

Cerebral MRI in severely affected patients shows delayed cerebral maturation, periventricular white matter abnormalities and the presence of subependymal cysts in the first months of life. In the mild phenotype, similar MRI alterations have been described. Biochemical diagnosis relies on strongly increased levels of D-2-HGA in plasma, urine and CSF that result from a defective D-2-hydroxy-glutaric dehydrogenase activity. Diagnosis is confirmed by gene sequencing and the identification of mutations in D2HGDH6 or mutations in IDH27 (Struys et al. 2005).

**COMBINED D-2-HYDROXYGLUTARIC ACIDURIA**

Combined D-2- and L-2-hydroxyglutaric aciduria (D, L-2-HGA) is characterised by elevated levels of both D-2-HG and L-2-HG acids in body fluids. Manifestation is as a severe neonatal epileptic encephalopathy, absence of developmental progress, respiratory insufficiency, developmental arrest and early death. Dismorphism has been added to the clinical picture. The disease is due to recessive mutations in the gene (SLC25A1) encoding a mitochondrial citrate carrier (Nota et al. 2013).
DISORDERS OF VITAMIN METABOLISM

BIOTIN METABOLISM

Defects in biotin metabolism with multikarboxylase deficiency (MCD) result in severe neurological impairment with hyperlactataemia. Skin rashes, alopecia and breathing problems are the main manifestations. However, they are invariant and the diagnosis should be considered in any case of hyperlactataemia (Baumgartner and Suormala 2016). Defective transport of biotin through the blood–brain barrier responsible for biotin-responsive basal ganglia disease (BRBGD) has been more recently described in patients from Middle-Eastern families (Ortigoza-Escobar et al. 2014). Because the condition is treatable with high doses of biotin, early diagnosis is important.

Biochemical and Genetic Background

Biotin acts as a cofactor in four carboxylases in humans: acetyl-CoA carboxylase, propionyl-CoA carboxylase, beta-methylcrotonyl-CoA carboxylase and pyruvate carboxylase. Isolated defects are known for the last three enzymes. Two defects in the intracellular utilisation of biotin are responsible for MCD: holocarboxylase synthetase (HCS) deficiency is a disorder of biotinylation of apocarboxylases; biotinidase deficiency is a disorder of biotin recycling. MCD leads to a characteristic organic aciduria comprising lactate, methylcrotonylglycine and propionyl-CoA derivatives. Enzyme defects are demonstrable in leukocytes or cultured fibroblasts, and biotinidase activity can be determined in serum.

Prenatal diagnosis of the two autosomal recessive disorders is feasible. The genes for biotinidase and HCS map to chromosomes 3p25 and 21q22.1 respectively (Aoki et al. 1995, Möslinger et al. 2003). A literature review (Ortigoza-Escobar et al. 2014) shows that most patients with BRBGD, the remaining patients were classified as BRBGD, the remaining patients presented with spastic paraparesis due to spinal cord demyelination.

The biochemical diagnosis is easy when lactic acidosis is associated with the specific organic aciduria. Measurement of biotinidase activity can be done on a dry blood spot and has been introduced in a number countries in the neonatal screening.

Mild intellectual disability, persistent ataxia, optic atrophy, abnormal visual evoked potentials, retinal impairment and sensorineural hearing loss may persist despite treatment (Weber et al. 2004).

Biotin-Responsive Basal Ganglia Disease

BRBGD is an autosomal recessive disorder starting in childhood with subacute episodes of encephalopathy, triggered by febrile illness and characterised by confusion, dysarthria, dystonia and quadriplegia. Biotin therapy during encephalopathic crises result in recovery within days.

Generalised convulsions have been associated in some patients during the initial period of the disease. Cerebral MRIs have revealed a uniform aspect with bilateral oedema and further necrosis of caudate heads and of the putamen.

The disease is associated with mutations in SLC19A3 which has no biochemical markers. It is linked to mutations in an SLC19A3 transporter gene mapped to chromosome 2q36.3 (Zeng et al. 2005).

Clinical Features of Multikarboxylase Deficiency

MultiCarboxylase deficiency (MCD) starts early with neurological symptoms, skin rashes and ketoadidosis, occurring usually in the neonatal period or later in infancy or childhood. In the neonatal period, patients can present with metabolic acidosis, hyperammonaemia, tachypnea, feeding problems, hypotonia and seizures. The diagnosis can be suspected by the abnormalities in the urinary organic acids.

High doses of biotin up to 200mg can give improvement but most respond at 10–20mg/day. Although there is an overlap in the age at onset, most neonatal forms are due to HCS deficiency, and the late-onset forms to biotinidase deficiency. The neonatal forms share clinical and biological features with neonatal-onset forms of other organic acidurias.

Biotinidase deficiency shows a less consistent picture: onset is insidious, with very variable neurological symptoms in the first year of life. In the severe cases (biotinidase activity below 10%), neurological and cutaneous symptoms occur between 2 and 5 months (Wolf 2010). Progressive lethargy with hypotonia and ataxia occurs following intercurrent infections. Refractory seizures and hypsarrhythmia are the most common manifestation and can remain isolated for long periods. Erythematous rashes, alopecia, conjunctivitis or blepharitis may be present at any time in the course, which is progressive even though transient recovery may occur. Chronic forms present with either a steady progression or a series of acute aggravations separated by periods of apparent normality. The most common neurological features are unsteady gait, episodes of ataxia, hypotonia and developmental regression. A few children presented with spastic paraparesis due to spinal cord demyelination.

The biochemical diagnosis is easy when lactic acidosis is associated with the specific organic aciduria. Measurement of biotinidase activity can be done on a dry blood spot and has been introduced in a number countries in the neonatal screening.

Mild intellectual disability, persistent ataxia, optic atrophy, abnormal visual evoked potentials, retinal impairment and sensorineural hearing loss may persist despite treatment (Weber et al. 2004).

Treatment of Multikarboxylase Deficiency

Oral biotin reverses all the clinical and biological signs within a few days in patients affected with MCD. Biotin requirement is usually around 5–10mg/day. However, some
patients with severe HCS deficiency may require restriction of protein intake and higher doses of biotin (Baumgartner and Suormala 2016). Many symptomatic patients with biotinidase defects show some sequelae with mild cognitive delay, and hearing and visual impairment. Conversely, patients who have been treated preventively have normal development.

Early treatment with high doses of biotin (5–10mg/day) reverses all the neurological signs of BRBGD within a few days. They reappear within 1 month if biotin is discontinued.

A systematic trial with biotin would be indicated in all patients who present with infantile bilateral striatal necrosis. In some patients, thiamine (10–40mg/kg/day) needs to be added (Ortigoza-Escobar et al. 2014).

VITAMIN B12 DISORDERS

The description of inherited disorders at each step of the vitamin B_{12} (cobalamin) metabolic pathway has allowed new insights into the pathogenesis of both cobalamin and folate deficiencies. Deficiency of cobalamin or folate during pregnancy can cause severe malformation such as neural tube defects. After birth, deficiency of cobalamin and folate can cause anaemia, failure to thrive, recurrent infections, psychiatric and neurological symptoms. Clinical features are broadly similar for all inborn errors of cobalamin metabolism, with the exception of isolated adenosylcobalamin deficiency, expression of which is identical to that of methylmalonic aciduria (Whitehead 2006).

BIOCHEMICAL BACKGROUND OF COBALAMIN DISORDERS

The term cobalamin designates a group of compounds that function as coenzymes in two cellular reactions in humans: the generation of methionine from homocysteine with methylcobalamin as coenzyme and the conversion of methylmalonyl-CoA to succinyl-CoA using adenosylcobalamin as coenzyme. Dietary cobalamin, mostly obtained from animal proteins, is absorbed, bound to intrinsic factor, and then enters the bloodstream bound to transcobalamin-II to be taken up by cells via a specific surface receptor. Once within the cell, cobalamin undergoes a series of modifications resulting in methylmalonic aciduria and homocystinuria (Whitehead 2006).

GENETIC BACKGROUND OF COBALAMIN DISORDERS

All defects of intracellular cobalamin metabolism are inherited in an autosomal recessive manner. Prenatal diagnosis can be performed by assaying amniotic fluid for amino acids and
Pathophysiology of Cobalamin and Folate Deficiencies

Many neurological, haematological and biochemical features are common to acquired cobalamin and folate deficiencies, congenital defects in absorption or transport of cobalamin and folate, and intracellular defects in cobalamin and folate metabolism. All defects result in deficiency in methionine synthetase, which plays a central role in the pathogenesis of both cobalamin and folate metabolism disturbances (Hall 1990). Methionine synthetase deficiency has several putative secondary effects including the storage of folate as methyltetrahydrofolate (CH₃THF) (folate trap putative secondary effects including the storage of folate as methyltetrahydrofolate (CH₃THF) (folate trap theory), thus preventing their use in folate coenzyme synthesis, which appears essential for DNA synthesis and haematopoiesis. Methionine synthetase deficiency also results in defective synthesis of methionine and of adenosylmethionine, which is the main methyl donor for methylation of many substrates such as neurotransmitters, myelin basic protein and phospholipids of plasma membranes. This defective methylation is thought to be the cause of subacute combined degeneration of the cord described in both acquired and congenital defects. Other factors may disturb the structure and function of the CNS in acquired and congenitally impaired cobalamin metabolism; for example, toxicity of accumulated homocysteine, which may be responsible for vascular injury and thrombembolism, and for the accumulation of methylmalonyl-CoA and propionyl-CoA due to defective mutase activity.

Clinical Features of Cobalamin Deficiencies

Congenital Vitamin B₁₂ Deficiency

Cobalamin deficiency in breastfed infants of mothers who have subclinical pernicious anaemia or who are on a vegan diet without adequate B₁₂ supplementation may result in neurological regression, abnormal movements and coma associated with megaloblastic anaemia. Vitamin B₁₂ administration rapidly improves the neurological status, but further developmental progress may remain delayed (Gutierrez-Aguilar et al. 2005).

Cobalamin Absorption and Transport Deficiencies

Abnormal cobalamin absorption and transport may result from absent or abnormal intrinsic factor, defective ileal receptors or deficient transport into the cells.

Defects in cobalamin absorption and transport are responsible for a cobalamin deficiency syndrome characterised by a progressive disease with onset from 1 month to a few years of age. Usually the first symptoms are gastrointestinal, with failure to thrive, muscular weakness, drowsiness and megaloblastic anaemia. A few months later, peripheral neuropathy, myelopathy and encephalopathy develop, with marked developmental delay. Defects in absorption are due either to intrinsic factor deficiency or to defect in the cubilin–amnionless complex that acts as receptors for the IF-Cbl complex (Imerslund–Gräsbeck syndrome). Imerslund–Gräsbeck syndrome mutations are found in the ileal cobalamin receptor cubilin (CUBN) or its facilitator amnionless (AMN). Intrinsic factor deficiency mutations in the gastric intrinsic factor (GIFS) can be found.

Clinically, Imerslund–Gräsbeck syndrome and intrinsic factor deficiency overlap: starting with megaloblastic anaemia between 1 and 10 years, with anorexia, FTT and variable neurological symptoms such as neuropathy, cognitive problems, dementia; also recurrent infections due to neutrophil dysfunction. Patients with intrinsic factor deficiency can also present at a later age.

Defective transport which is essentially due to transcobalamin deficiency may, despite treatment, lead to severe neurological impairment (Trakadis et al. 2014). It can present very early in life and lead to early neurological symptoms if treatment is not started in time.

Defects in Intracellular Metabolism

Intracellular cobalamin deficiencies impairing the synthesis of methylcobalamin alone or of both methyl- and adenosylcobalamin present as three main types. The most frequent is a severe early-onset form described in newborn infants and young infants below 3 months of age. There is an increased homocysteine level and, in some, methylmalonic aciduria, low plasma methionine and S-adenosylmethionine.

CblF is a rare disorder (Rutch et al. 2009). The gene is LMBDRI, encoding for a lysosomal membrane protein, thought to act as a lysosomal exporter of cobalamin. Patients present early in life with poor feeding, failure to thrive, developmental delay, megaloblastic anaemia, pancytopenia and stomatitis.

CblC is the most frequent disorder of cobalamin metabolism (Carillo-Carascoet al. 2012). The disease starts, usually early, with progressive lethargy, hypotonia, abnormal movements, and/or seizures associated with pancytopenia and megaloblastic anaemia. Some patients also have multisystemic involvement including renal failure with haemolytic uraemic syndrome, cardiomyopathy and interstitial pneumonia. Retinal involvement with granular dyspigmentation of the macula and further peripheral pigmented retinitis is an early sign in many CblC patients. Communicating hydrocephalus can be a further complication.

The early-onset form is related to specific mutations in the MMACHC gene, one of which (c271dupA) accounts for 40% of all disease alleles (Lerner-Ellis et al. 2009). A small number of patients present in childhood with progressive neurological deterioration, microcephaly, episodic seizures and megaloblastic anaemia, which usually leads on to the diagnosis. If untreated, acute neurological deterioration may occur with signs and symptoms resembling subacute degeneration of the cord. Rare affected adolescents and adults have presented
similar subacute degeneration of the cord preceded by an acute deterioration of intellectual function and, sometimes, behavioural disturbances. In older patients, megaloblastic anaemia may be subtle, and borderline macrocytosis should be given particular attention (Fisher et al. 2014).

ClbD with mutations in the gene \textit{MMADHC} has three biochemical phenotypes with deficient synthesis of both cobalamin coenzymes causing combined methylmalonic aciduria and homocystinuria; deficiency of methylcobalamin synthesis causing isolated homocystinuria, or deficient adenosylcobalamin causing isolated methylmalonic aciduria.

Clinical symptoms are quite similar as in ClBc with the possibility of onset in infancy to adolescence (Miousse et al. 2009).

**TREATMENT OF COBALAMIN DEFICIENCIES**

Responsiveness to vitamin B12 supplementation must be systematically tested. Depending on the defect implicated, use of parenteral versus oral routes, pharmacological or high doses versus minute doses and hydroxycobalamin (1mg/day) versus natural cobalamin substrates (methyl-adenosylcobalamin) should be discussed. In both transport and intracellular defects, methionine replenishment with oral betaine or with extra methionine as well as folate could be essential. As predicted by the metabolic pathway of betaine, addition of folic acid can be helpful in long-term betaine therapy.

Because endogeneous carnitine synthesis depends on methionine, carnitine supplementation can be useful in these conditions of methionine synthesis impairment. A normal-protein diet with avoidance of high protein intake is a logical support.

**DEFECTS IN FOLATE METABOLISM**

Folate is a methyl donor for homocysteine methylation to methionine. There are three independent types of membrane systems responsible for cross membrane transport of folate monoglutamate forms. These are the membrane folate receptor, the reduced folate carrier 1 (RFC1) and the proton-coupled folate transporter/heme carrier protein 1 (PCT/HCP1).

Several inherited disorders of folate metabolism and transport have been described Figure 9.15: MTHFR deficiency, MTR deficiency (caused by mutations in \textit{MTR} or \textit{MTRR} genes), cerebral folate deficiency (CFD) caused by \textit{FOLR1} mutations, hereditary folate malabsorption and glutamate formiminotransferase (FTCD) (Kirsch et al. 2013).

**BIOCHEMICAL AND GENETIC BACKGROUND**

Folates are derived from folic acid. Dietary folates are transported inside the intestinal cells by a specific carrier
system, then transferred into the circulation, mainly in the form of CH$_3$THF. Circulating CH$_3$THF enters the tissues through a high-affinity carrier linked to intracellular methionine synthetase activity, which generates tetrahydrofolate (THF). Within the cell, a series of reactions (Kirsch et al. 2013) leads to the formation of the various folate coenzymes that constitute the donors or acceptors of single carbon units required for several metabolic processes. Defect in this specific folate transporter results in low levels of folates in serum and CSF and secondary deficiencies in folate-dependent reactions.

Purine and pyrimidine synthesis defects result in megaloblastic anaemia; deficiency in glutamate formimino transferase explains formimino glutamic acid (FIGLU) excretion and defective methionine synthesis is responsible for combined homocystinuria and hypomethioninaemia. Glutamate formimino transferase and forimino-THF-cyclodeaminase activities are performed by a single protein, defects of which result in histidine catabolism deficiency with urinary excretion of FIGLU without involvement of crucial folate coenzymes that may be supplied by dietary sources.

CH$_3$THF reductase deficiency leads to defective synthesis of CH$_2$THF, the methyl donor for methionine synthesis from homocysteine, resulting in combined homocystinuria and hypomethioninaemia. Mutations responsible for the severe form of CH$_3$THF reductase deficiencies have been described in addition to polymorphisms that result in intermediate enzyme activity (Banka et al. 2011).

Cerebral folate deficiency is a clinically heterogeneous condition which leads to a severe decrease of CSF 5-methyltetrahydrofolate (5MTHF) in the presence of normal peripheral folate status. In 2009, Steinfeld et al. presented the first case associated with a mutation in the FOLR1 gene. Clinically patients present with stagnation or regression in development in the second year of life, with ataxia, autistic features and refractory myoclonic epilepsy. MRI of the brain commonly discloses hypomyelination and cerebral atrophy with, on spectroscopy, reduction of choline and inositol peaks (Pérez-Dueñas et al. 2010). Administration of oral folic acid improved (1–5mg/kg/day) some patients but, in others, intravenous high doses of folic acid (25mg/kg/day) were necessary (Delmelle et al. 2016).

**Clinical Features of Folate Defects**

**Methylenetetrahydrofolate (MTHF) reductase deficiency**

Patients present with many neurological signs and symptoms similar to those described in intracellular cobalamin defects involving methionine synthase. However, they do not have megaloblastic anaemia. In the neonatal-onset form, multi-organ involvement and retinopathy have not been described. Onset in childhood, with progressive neurological deterioration, is the most frequent course. A period of a few months’ normal development is followed by several months to several years of developmental slowing or arrest with poor head growth. Episodic seizures of various types are the rule. Hypotonias, ataxic gait and extrapyramidal movements are encountered in a few patients. In the absence of effective treatment, a third period of rapidly progressive deterioration follows with unexplained bouts of apathy, lethargy or coma often accompanied by central respiratory failure leading to death. Preceding or following these episodes the neurological signs worsen with further cognitive deterioration, gait disturbances, muscular weakness, spastic paresis and sometimes extrapyramidal symptoms with parkinsonian rigidity and tremors. In a few young patients, the second period is not observed, and they deteriorate abruptly following an acute event such as generalised tonic–clonic seizures. In adolescence and adulthood, many signs are similar to the late stage described above, except that most patients have normal development before the onset, the first sign being rapid cognitive deterioration and, in a very few patients, signs of schizophrenia. Less commonly, cerebrovascular complications may reveal the disorder. Biochemical investigations reveal mild homocystinuria and hypomethioninaemia in association with low to normal folate levels. Low CSF neurotransmitter levels have been reported (Burd et al. 2015). CT and MRI reveal non-specific cortical and subcortical atrophy and periventricular demyelination.

**HEREDITARY FOLATE MALABSORPTION**

Hereditary folate malabsorption is a clinical syndrome starting within the first few months of life. There is an impaired intestinal folate absorption and impaired folate transport into the CNS. After birth, affected infants develop severe folate deficiency with megaloblastic anaemia, diarrhoea, oral mucositis and recurrent infections. Poor feeding, failure to thrive, developmental delay and seizures can develop. The diagnosis is based on low levels of folate in serum, red blood cells and CSF, with undetectable amounts of CH$_3$THF. Mutations have been found in the SLC46A1 gene encoding for the PCFT which is present in the intestine and choroid plexus. Treatment with large doses of folic acid can normalise folate levels. Supraphysiological folate concentrations are necessary to increase folate in CSF. However, methyltetrahydrofolate in red blood cells and in CSF can remain low. Supplementation with betaine or methionine may prevent neurological deterioration. Some patients remain intellectually disabled with variously combined neurological signs such as recurrent seizures, ataxia, athetosis and peripheral neuropathy.

**GLUTAMATE FORMIMINOTRANSFERASE DEFICIENCY**

The clinical expression of this disorder is variable (Whitehead 2006). In type I, intellectual disability, hypotonias, abnormal EEG and cortical atrophy are reported in half the cases, in association with folate-responsive megaloblastic anaemia. These
features appear between the ages of 2 weeks and 18 months. In type II, intellectual disability is mild with only a speech defect. There is no evidence of folate deficiency, and the biochemical hallmark is spontaneously high excretion of FIGLU. Mutations in the formiminotransferase cyclodeaminase (FTCD) gene have been identified in three children with the mild phenotype.

HOMOCYSTINURIAS

Inherited homocystinurias have, in common, accumulation of homocysteine with neurotoxicity; they encompass two distinctive clinical entities: classic homocystinuria due to cystathionine beta-synthase (CBS) deficiency and the rare inborn errors of cobalamin and folate metabolism. Classic homocystinuria is due to cystathionine beta-synthase deficiency. Clinically, the disease involves the eyes, bones, brain and vascular system. Intellectual disability can be present, but some patients have normal intelligence. Neurological signs include seizures, spasticity and psychiatric disorders.

Biochemical Background

In humans, methionine is catabolised to homocysteine through the transmethylation pathway (Fig. 9.16). Homocysteine is further degraded via the transulphuration route, yielding the end products sulphite and sulphate. Cystathionine beta-synthase catalyses the first step of this degradative pathway and requires vitamin B6 as a cofactor. Deficient activity of cystathionine beta-synthase is responsible for accumulation of homocysteine and methionine and decreased synthesis of cysteine (Schiff and Blom 2012).

About 50% of the homocysteine formed is remethylated to methionine. Enzymatic defects that affect remethylation are responsible for homocystinuria and hypomethioninaemia.

Genetic Background

Based on neonatal screening, the incidence of this autosomal recessive disease is about 1 in 335,000 live births. Three biochemically determined groups of patients are defined following B6 administration: one group is unresponsive, the second is clearly responsive, and the last has intermediate responsiveness.

The human cystathionine beta-synthase (CBS) gene maps to chromosome 21. More than 100 mutations have been characterised, some of them associated with B6-responsiveness.

Cystathionine beta-synthase deficiency is expressed in cultured fibroblasts, lymphoblasts, cultured amniotic fluid cells and chorionic villus samples, allowing postnatal and prenatal diagnosis. In families where the mutations are known, direct analysis of the CBS gene allows rapid prenatal diagnosis.

Figure 9.16 Biochemical pathways in homocystinuria.

THF, tetrahydrofolate.

Pathophysiology

While some data are available concerning homocystinuria, thrombosis and atherosclerosis, the relationship between the biochemical abnormalities and the development of intellectual disability, ectopia lentis or skeletal abnormalities remains obscure (Schiff and Blom 2012).

Clinical Features of Homocystinurias

Homocystinuria is a progressive multisystem disorder. The risk of developing manifestations of the disease increases with age.

B6-responsive patients are more mildly affected than B6-unresponsive ones. Four organ systems show major involvement: the eye, the bones, the CNS and the vascular system. Ectopia lentis is the most consistent finding. It is rarely present before the age of 2 years.

Severe myopia should lead to further investigation. Fifty per cent of B6-unresponsive and responsive untreated patients have ectopia lentis by 6 and 10 years respectively. However, a normal ophthalmological examination at any age is no reason for rejecting the diagnosis. Optic atrophy, retinal degeneration or detachment, cataracts and corneal opacities appear to be secondary to lens dislocation. Individuals are often tall and slender with a marfanoid habitus and are prone to osteoporosis. Scoliosis and crush vertebral fractures can develop. Other frequently associated deformities include pectus carinatum, pes cavus, genu valgum, biconcave vertebrae and epimetaphyseal widening.

Intellectual disability is often the first recognised feature. Walking may be delayed and some patients have a ‘Charlie Chaplin-like’ gait. The IQ varies widely. B6-responsive patients have higher IQs (median 78) than B6-unresponsive ones (median 56).
Patients with homocystinuria have potentially life-threatening thromboembolic events. Vascular occlusions occur in any vessel at any age and may be the first manifestation. Cerebrovascular accidents may be responsible for optic atrophy, hemiparesis or seizures. Occlusions also occur in kidney, pulmonary artery, iliac vein, vena cava or coronary vessels. The risk of thromboembolic complications seems higher following intercurrent infections and surgery, and is responsible for a high mortality rate.

**Biological Findings in Homocystinurias**

Various abnormalities of clotting factors and platelets, and mildly low levels of folates and B_{12} may be found. Usually, the cyanide–nitroprusside test (Brand reaction) in urine is positive, which is also positive in cystinuria and in the presence of sulphur-containing drugs. Definitive diagnosis is based on plasma and urine amino acid chromatography, which shows increase of homocysteine (50–200mmol/L); excess plasma and urine amino acid chromatography, which shows of sulphur-containing drugs. Definitive diagnosis is based on detection of sulphites in plasma and urine amino acid chromatography. In combined SO-XO deficiency (molybdenum deficiency), the previous pattern is associated with hypo-uricaemia and xanthinuria that inconstantly results in xanthine urolithiasis.

In both conditions, deficient sulphite oxidase activity, measured in skin fibroblasts, confirms the diagnosis. Prenatal diagnosis can be made by measuring sulphite oxidase activity or by DNA mutation analysis on chorionic villus samples (Johnson et al. 2002; Reiss and Johnson 2003). For the molybdenum cofactor deficiency, mutations can be found in MOCS1, MOCS2 or GHPN – the three genes responsible for the synthesis of the molybdenum cofactor from GTP (Reiss and Hahnewald 2011).

**Pathogenesis of Sulfite Oxidase Deficiency**

Neuronal migration abnormalities on MRI suggest that the toxicity is initiated prenatally. However, the pathogenesis of the disease is only speculative. Accumulated sulphite may have direct CNS toxicity. Lack of sulphate may interfere with the synthesis of sulphate esters and of mucopolysaccharides. S-sulphocysteine may have neuroexcitatory properties and may be responsible for seizures (Fig. 9.17).

**Clinical Features of Sulfite Oxidase Deficiency**

Most patients present in the neonatal period with intractable seizures, feeding difficulties and severe developmental delay. The EEG may show a suppression–burst pattern. Further course is characterised by spastic quadriplegia, axial hypotonia and microcephaly. Seizures most often remain unchanged but spasms and choreoathetoid movements may appear. Peculiar facial dysmorphism is often noted. Ectopia lentis is mentioned during the clinical course in about 50% of cases. Most patients die within the first 2 years of life.

MRI studies show a rapidly progressive cystic leukoencephalomalacia that may suggest severe perinatal asphyxia (Dublin et al. 2002, Hobson et al. 2005). Pathologically there is severe cerebral atrophy, with uleogria and multi-cystic subcortical lesions in the white matter. Severe neuronal loss, astrogliosis, microcavitations and spongiosis affect the whole cortex. A less severe form with prolonged survival and mild presentation has been described in a very few patients (Touati et al. 2000).

**Treatment of Sulfite Oxidase Deficiency**

Severe neonatal-onset forms are not amenable to any dietetic or pharmaceutical treatment. Some clinical improvement has been noted in two mildly affected patients treated with a low-cystine and low-methionine diet (Touati et al. 2000).

**Treatment of Homocystinuria**

The management of homocystinuria should be directed towards lowering the body accumulation of homocysteine and increasing the cysteine content. This is easily achieved in B_{6}-responsive patients by oral administration of 50–500mg/day of pyridoxine, folinic acid (1–5mg/day) and OH-B_{12} 1mg/day to 1mg/week, depending on the serum B_{12} level (Schiff and Blom 2012). Patients who are unresponsive to B_{6} require a low-methionine diet with cysteine and betaine supplementation (up to 20g/day).

Prevention of thromboembolic episodes is best achieved through strict metabolic control, administration of anti-aggregant molecules (dipyramidol and/or aspirin), and with good hydration. Early treatment of patients detected in the neonatal period is effective in preventing intellectual disability and in delaying lens dislocation. Late treatment may improve development and behaviour.

**SULPHITE OXIDASE DEFICIENCY**

Sulphite oxidase deficiency, isolated or in association with xanthine oxidase deficiency (SO-XO deficiency or molybdenum cofactor deficiency) is a rare metabolic disorder. The chemical diagnosis is based on detection of sulphites in urine. Both disorders appear to be inherited in an autosomal recessive manner.

**Metabolic Pathways and Biochemical Hallmarks**

The terminal step in the methionine transulphuration pathway is conversion of sulphite to sulphate catalysed by sulphite oxidase. Sulphite oxidase is a complex enzyme that requires a pterin-containing molybdenum cofactor. Thus sulphite oxidase deficiency can arise as a result of a defect in sulphite oxidase apoenzyme or in molybdenum cofactor synthesis. Both conditions are characterised by low sulphaturia and increased sulphituria that could be detected using ‘sulphite-test strips’, but samples must be fresh. A more reliable screening test is the identification of S-sulphocysteine in plasma and urine amino acid chromatography. In combined SO-XO deficiency (molybdenum deficiency), the previous pattern is associated with hypo-uricaemia and xanthinuria that inconstantly results in xanthine urolithiasis.

In both conditions, deficient sulphite oxidase activity, measured in skin fibroblasts, confirms the diagnosis. Prenatal diagnosis can be made by measuring sulphite oxidase activity or by DNA mutation analysis on chorionic villus samples (Johnson et al. 2002; Reiss and Johnson 2003). For the molybdenum cofactor deficiency, mutations can be found in MOCS1, MOCS2 or GHPN – the three genes responsible for the synthesis of the molybdenum cofactor from GTP (Reiss and Hahnewald 2011).
Figure 9.17  CT scans of a 2-month-old infant with sulfite oxidase deficiency and convulsions since birth. There is symmetrical cavitation of both pallida and frontal cortical atrophy.

In molybdenum cofactor deficiency (with mutations in MoCD1) a treatment with cyclic pyranopterin monophosphate (cPMP), a biosynthetic precursor of the cofactor, has led to better outcomes (Schwann et al. 2015).

**DISORDERS OF NEUROTRANSMITTER METABOLISM**

**BIOPTERIN AND CATECHOLAMINE METABOLISM**

Recognition of inborn errors of monoamine metabolism relies mostly on the analysis of CSF and other body fluids for the detection of bioterins, catecholamines, serotonin, and their metabolites. Defects may be secondary to abnormal synthesis of tetrahydrobipterin (BH4), the cofactor for Phe, tyrosine and tryptophan hydroxylases, or affect the metabolic pathways of catecholamines and/or serotonin. They are responsible for dystonic syndromes, parkinsonism and progressive encephalopathies with abnormal movements (Table 9.4).

In neonates, these disorders may present with severe epileptic encephalopathy. Hyperphenylalaninaemia (HPA) is a leading sign in disorders where BH4 is defective in both liver and brain. Conversely, HPA is absent when the Tetra-HydorBiotpterin (THB) defect is expressed only in the brain, as well as in other defects of monoamine synthesis (Pearl et al. 2005). In addition, pyridoxal phosphate, the biologically active form of pyridoxine (vitamin B6), is a cofactor for aromatic L-amino acid decarboxylase. Thus, defects in pyridoxal phosphate are responsible for altered neurotransmission (Fig. 9.18).

We can distinguish disorders of:

1. Monoamine synthesis: (a) Without hyperphenylalaninaemia: including Segawa disease (autosomal dominant GTP cyclohydrolase 1 deficiency); tyrosine hydroxylase (TH)

DHPR, dihydropteridine reductase; GTP-ch, guanosine triphosphate cyclo-hydrolase; PTPS, pyruvoyl-tetrahydropteridin synthetase; PCD, pteridine carbinolamine dehydratase.
Epinephrine and norepinephrine. It is an autosomal recessive disease on chromosome 11p15.5 resulting in cerebral catecholamine deficiency. Willemsen et al. (2010) showed that there are two phenotypes: an infantile-onset, progressive, hypokinetic-rigid syndrome with dystonia and a complex encephalopathy with neonatal onset.

The infantile-onset patients develop normally during the first months of life. Psychomotor development can be normal or only slightly delayed during the first 2 to 5 years of life. Thereafter, progressive motor signs appear. Affected individuals become hypokinetic and rigid, and dystonia develops. In the early stages, generally only one leg is involved, but with time both legs and also the arms, trunk, face and oropharyngeal musculature become affected. Initial complaints thus encompass abnormal posturing and walking difficulties, or frequent falls in those who already learned to walk before onset of symptoms. These children become wheelchair dependent within some years (Table 9.5).

Severity of dystonia may fluctuate during the day (generally worse in the afternoon), but can also fluctuate within days, giving the impression of a paroxysmal dystonia especially in the early stages of the disease. Mild, nonprogressive intellectual disability can be found in patients with relatively early onset of motor symptoms, while cognitive functions appear unaffected in patients who develop symptoms after the first year of life. Besides the hypokinetic-rigid syndrome with dystonia, other features like tremor, chorea, oculogyric crises and ptosis, as well as behavioural or autonomic disturbances.

Segawa disease (GTP1 cyclohydrolase 1 deficiency)

This was first described by Segawa in 1971. The hallmark of the disease was dystonia with diurnal fluctuation (see Chapter 19). The symptoms can start unilaterally or can present as an atypical spastic diplegia starting at school age or earlier. The enzyme is a rate-limiting step in synthesis of tetrahydrobiopterin, the cofactor for synthesis of catecholamines. The diagnosis can be suspected by low homovanillic acid, neopterin and 3-O-methyldopa in CSF. It is an autosomal dominant disease and the gene is located to 14q22.12-q22. The treatment, consisting of a low dose of L-dopa 3–7mg/kg/day, will immediately improve the symptoms.

Tyrosine hydroxylase deficiency

Tyrosine hydroxylase catalyses the conversion of tyrosine into L-dopa. This leads to impaired synthesis of dopamine, epinephrine and norepinephrine. It is an autosomal recessive disease on chromosome 11p15.5 resulting in cerebral catecholamine deficiency. Willemsen et al. (2010) showed that there are two phenotypes: an infantile-onset, progressive, hypokinetic-rigid syndrome with dystonia and a complex encephalopathy with neonatal onset.

The infantile-onset patients develop normally during the first months of life. Psychomotor development can be normal or only slightly delayed during the first 2 to 5 years of life. Thereafter, progressive motor signs appear. Affected individuals become hypokinetic and rigid, and dystonia develops. In the early stages, generally only one leg is involved, but with time both legs and also the arms, trunk, face and oropharyngeal musculature become affected. Initial complaints thus encompass abnormal posturing and walking difficulties, or frequent falls in those who already learned to walk before onset of symptoms. These children become wheelchair dependent within some years (Table 9.5).

Severity of dystonia may fluctuate during the day (generally worse in the afternoon), but can also fluctuate within days, giving the impression of a paroxysmal dystonia especially in the early stages of the disease. Mild, nonprogressive intellectual disability can be found in patients with relatively early onset of motor symptoms, while cognitive functions appear unaffected in patients who develop symptoms after the first year of life. Besides the hypokinetic-rigid syndrome with dystonia, other features like tremor, chorea, oculogyric crises and ptosis, as well as behavioural or autonomic disturbances.

DHPR, dihydropteridine reductase; CSF, cerebrospinal fluid; HVA, homovanillic acid; HIAA, hydroxyindoleacetic acid; GTP, guanosine triphosphate; GABA, gamma-Aminobutyric acid.
are absent or – if present – are found as a mild feature and in a minority of patients.

In almost all patients with this type, treatment with L-dopa results in an excellent response, sometimes even a miraculous improvement of the neurological condition. During follow-up, all patients continue to be asymptomatic or display only mild motor or cognitive impairment while on a low dose of L-dopa. They show no evidence of progressive disease, and tolerate L-dopa well during many years.

The second presentation according to Willemsen et al. (2010) is a complex encephalopathy with onset in the neonatal period or early infancy. Immediately after birth, or after a symptom-free interval of a few weeks, these patients rapidly develop a complex disorder. In most patients, the presenting signs are initially attributed to a complicated perinatal history, which makes estimation of age at onset difficult. The initial signs may differ between infants, but they all develop a varied neurological disorder that generally includes marked hypokinesia, bradykinesia and hypotonia, mixed with focal or generalised dystonic features and (often excessive) jerky movements like tremor and myoclonus, and that can also encompass bilateral ptosis and oculogyric crises. Diurnal fluctuation of symptoms may be present. However, especially in the most severely affected infants, dystonic crises occur within regular intervals of 4–5 days. Autonomic functions are often disturbed, especially during periods of dystonia or so-called lethargy-irritability crises, leading to excessive drooling, sweating, body temperature instability and marked periods of ‘pyrexia of unknown origin’. True epileptic seizures and non-epileptic paroxysms may further complicate the clinical picture. L-dopa treatment does not improve all signs equally, and it may take months before all effects of treatment become clear. Hypersensitivity to L-dopa is an important management problem in many of these patients, necessitating (extremely) low L-dopa doses at start, divided over four to six doses per day, and only increased over periods of weeks or months. Compared to the first type, prognosis with regard to final outcome is worse for motor as well as cognitive functions.

**Diagnosis and treatment**

CSF analyses will point to an impairment of dopamine synthesis with low levels of homovanillic acid (HVA) and methoxy-hydroxy-phenylglycol (MHPG), the end products of the dopamine pathway, contrasting with normal 5-HIAA and 3-O-methyl-dopa, the end products of serotonin and epinephrine pathways respectively. Serum prolactin is elevated due to dopamine deficiency. Pls tyrosine and pterin levels are all normal.

Treatment with L-dopa substitution is often poorly tolerated in the second group. Even low doses may result in side effects. However, with progressive increase from 2 to 6mg/kg/day over weeks or months, some improvement can be obtained. This can be combined with selegiline 5mg/kg day in a single dose (Dionisi-Vici et al. 2000).

**AROMATIC L-AMINOACID DECARBOXYLASE DEFICIENCY**

Aromatic L-Aminoacid Decarboxylase Deficiency (AADC) deficiency leads to a combined deficiency of catecholamines and serotonin as described in BH4 deficiency. Aromatic amino acid decarboxylase catalyses the decarboxylation of L-dopa and 5-hydroxytryptophan to dopamine and serotonin. The gene is located on 7p11.

Affected neonates can have feeding difficulties, autonomic dysfunction, hypothermia and hypotonia. However, they usually develop the characteristic signs at around 6 months with a progressive delay in motor acquisitions, oculogyric crises and a movement disorder with diurnal fluctuations. Serotonin deficiency leads to temperature instability, sleep disturbances, and irritability that can be linked to defective synthesis of melatonin from serotonin. Brun et al. (2010) reported 78 patients of whom most presented during infancy, but there were a few cases in adolescence with a milder phenotype.

CSF metabolites are characterised by reduced levels of HVA and 5-HIAA and increased levels of 3-O-methyl-dopa, high L-dopa and L-hydroxytryptophan. Pterin profiles, Phe and tyrosine are normal. The levels of histidine and taurine are also elevated. The finding of vanillactic acid on urinary organic acids analysis can suggest the diagnosis.

AADC activity can be measured in plasma and the diagnosis can be confirmed by gene analysis. CSF concentration of pyridoxal phosphate can be low.

**Treatment** Effects of treatment are limited. The combination of cofactor supplementation vitamin B6 pyridoxal phosphate, MAO inhibitors, high-dose L-dopa and serotonergic agents can give some improvement. (Manegold et al. 2009) Table 9.6.

**SEPIAPTERIN REDUCTASE DEFICIENCY**

Sepiapterin reductase is the final step in the synthesis of BH4. The phenotypic spectrum of sepiapterin reductase deficiency (SRD) ranges from motor and cognitive deficits to sometimes minimal findings. Most affected individuals have nonspecific features in infancy including developmental delay and axial hypotonia; other features develop over time. Clinical features in the majority include motor and speech delay, axial hypotonia, dystonia, weakness, and oculogyric crises; symptoms show diurnal fluctuation and sleep benefit. Other common features include parkinsonian signs (tremor, bradykinesia, masked facies, rigidity), limb hypertension, hyperreflexia, intellectual disability, psychiatric and/or behavioural abnormalities, autonomic dysfunction, and sleep disturbances (hypersomnolence, difficulty initiating or maintaining sleep, and drowsiness). Friedman et al. (2012) reported a large series.

The diagnosis is made by CSF analysis and by analysis of the gene SPR.

**Treatment**

L-dopa in combination with carbidopa is the main therapy used to correct CNS dopamine deficiency; 5-hydroxytryptophan (5-HTP), also in combination with carbidopa, has shown additional clinical benefit in some. When L-dopa/5-HTP/carbidopa are not tolerated or sufficiently effective, some individuals may benefit from use of other agents such as monoamine oxidase inhibitors, serotonin reuptake inhibitors, melatonin, dopamine agonists, anticholinergics, and methylphenidate.

**DOPAMINE B-HYDROXYLASE DEFICIENCY**

Dopamine B-hydroxylase deficiency is characterised by disturbed noradrenergic function but normal parasympathetic cholinergic function. Clinically, patients present with orthostatic hypotension. The combination of ptosis of the eyelids in children together with hypotension is suggestive. The diagnosis is made by the absence in plasma of norepinephrine and epinephrine and increase of plasma dopamine as well as the anamnysis for mutations in the gene for this disorder.

L-dihydroxyphenylserine (L-Dops) can improve orthostatic hypotension (Man in’t Veld et al. 1987).

**MONOAMINE SYNTHESIS WITH HYPERPHENYLALANINAEMIA**

This is due to pyruvoyl-tetrahydropterin synthase (PTPS) deficiency and dihydropteridine (DHPR) deficiency. These children present with a positive neonatal screening for phenylalaninaemia, but despite a controlled diet develop signs of neurotransmitter deficiencies such as hyper and hypotonia, oculogyric crises, dystonia and diurnal fluctuation. Treatment is such as described for the cases above.

**MONOAMINE OXIDASE DEFICIENCIES**

Monoamine oxidase A and B catalyse the deamination of serotonin, epinephrine and norepinephrine. Both the genes are located on the X chromosome. Point mutations and large deletions including MAO-A and B have been described in boys with a severe intellectual disability (Guo et al. 2008).

**INBORN ERRORS OF GAMMA-AMINOButRYIC ACID METABOLISM**

GABA (4-aminobutyric acid), a major inhibitory neurotransmitter amino acid, is synthesised from glutamic acid via glutamate decarboxylase. The catabolic steps comprise transamination, which yields succinate semialdehyde, and oxidation to succinate, which finally enters the Krebs cycle. Pyridoxal phosphate is a coenzyme for all these three reactions. A secondary route, catalysed by a dehydrogenase, converts succinate semialdehyde to gamma-hydroxybutyrate, which is further oxidised (see Fig. 9.18). In addition, the major precursor of glutamate in neurons is glutamine, which is synthesised in glial cells via glutamine synthetase. Glutamine is then transported to neurons, where glutamate and then GABA are metabolised. This GABA shuttle between neurons and glial cells allows the maintenance of this system. Homocarnosine is the dipeptide form of GABA. The most frequent defect in
GABA metabolism is succinic semialdehyde dehydrogenase. GABA transaminase deficiency and homocarnosinosis are very rare disorders (Fig. 9.19) (Pearl et al. 2015). Defective glutamine synthesis is a newly described disorder in neonates with severe brain malformation.

4-HYDROXYBUTYRIC ACIDURIA

4-hydroxybutyric aciduria is inherited in an autosomal recessive manner, and is characterised by the accumulation of gamma-hydroxybutyric acid (GHB) and GABA in body fluids secondary to succinic semialdehyde dehydrogenase (SSADH) deficiency. Deficient SSADH activity has been demonstrated in lymphocytes and fibroblasts. The gene responsible for SSADH has been identified, with many mutations in these patients. Prenatal diagnosis can be based on evaluation of GHB accumulated in amniotic fluid, measurement of enzyme activity in cultured amniocytes, or molecular analysis on chorionic villi DNA.

PATHOPHYSIOLOGY

The disorder results in accumulation of GHB and GABA coupled with low glutamine levels in the CSF of affected patients. GHB is a neuropharmacologically active compound that may play a role in the brain as a neurotransmitter or neuromodulator. In physiological concentrations, GHB acts at the GHB-receptors. In high concentrations, GHB may be responsible for a disruption of the normal balance between glutamatergic excitatory activity and GABAergic inhibition. This imbalance can be due to the agonist effect of GHB at the GABA-receptor and to the uncoupled glutamine and GABA levels. In addition, metabolites formed via the oxidation of GHB can interfere with energy production and create oxidative damage. Finally, GHB alters catecholamine turnover causing increased HVA and 5-HIAA (Pearl et al. 2014).

CLINICAL FEATURES

About a hundred cases are known, with a variable clinical phenotype. The most frequent features are delayed motor, language and intellectual development. Muscular hypotonia, areflexia, and nonprogressive ataxia are frequently described. The other signs are seizures, behavioural problems, ocular dyspraxia, macrocephaly, myopathy, choreoathetosis, nystagmus and conjunctival telangiectasia. EEG studies result in nonspecific findings, with various background abnormalities and epileptiform features. Structural neuroimaging may reveal mild cerebral and cerebellar atrophy. MRI studies have regularly revealed bilateral abnormal signals in the globus pallidus, the subcortical white matter and, occasionally, the brainstem and the dentate nuclei. MRS may reveal increased GABA and GABA metabolites (Novotny et al. 2003).
Biochemical Diagnosis
The diagnosis is confirmed by high levels of GABA in plasma, CSF and urine, in association with abnormal urinary excretion of several GHB by-products. In CSF, there is a significant increase in GHB, free GABA and homocarnosine. In addition, the dopaminergic end products are increased.

Treatment
The most widely employed treatment has been vigabatrin, the irreversible GABA transaminase inhibitor. However, its long-term efficacy is limited and it may be contraindicated due to retinal toxicity. Other agents have been investigated in knockout mice models. Benzodiazepines may be useful to control anxiety and aggressiveness. Sodium valproate to control seizures is contraindicated as it may inhibit any residual SSADH enzyme activity.

Nonketotic Hyperglycinemia (NKH)
Nonketotic hyperglycinemia (NKH) or nonketotic glycine encephalopathy is an inborn error of amino acid catabolism in which large amounts of glycine accumulate in body fluids. The classic phenotype is a life-threatening illness that develops in the neonatal period, during which most patients die. Survivors have severe intellectual disability and seizures. Atypical variants with variable age at onset and clinical manifestations have less severe prognosis. Rare patients may present a transient neonatal form characterised by biological normalisation (Hoover-Fong et al. 2004; Swanson et al. 2015).

Pathogenesis of NKH
Although the mechanism underlying the neurological dysfunction is not fully understood, glycine itself has an important role in the pathogenesis. Glycine is an inhibitory neurotransmitter whose receptors are mainly located in the spinal cord and brainstem. These glycine receptors are specifically antagonised by strychnine and competitively inhibited by benzodiazepines. This inhibitory neurotransmission can explain hypotonia and apnoea. Another strychnine-insensitive site associated with the NMDA receptor plays a major role in excitatory transmission in the cortex and diencephalon. NMDA-mediated neurotoxicity is markedly potentiated by glycine and excessive activation of NMDA receptors may directly result in neurotoxicity (Hoover-Fong et al. 2004).

Clinical Features of NKH
Classic Early-Onset Phenotype
This is the most frequently occurring type of NKH. Symptoms may appear from hours postpartum to the first few days of life. Lethargy and muscular weakness appear first. Shallow breathing follows and rapidly yields to apnoeic spells. Affected infants are flaccid and unresponsive to stimuli but often present with erratic myoclonias and subtle partial seizures. The burst-suppression pattern on the EEG though nonspecific, is an important diagnostic feature (Fig. 9.20).

A majority of patients die in this early period. For some infants, episodes of apnoea and respiratory depression are transient difficulties, and they may survive. However, no effective treatment is known, and early survivors invariably develop...
a severe epileptic encephalopathy and die within the first few years of life. They display spastic cerebral palsy, associated in most cases with infantile spasms or less often with partial convulsions. The periodic EEG pattern most often disappears after a few months and changes to atypical hypsarrhythmia or multifocal epileptic discharges.

**Atypical cases of NKH**

There are three major types: neonatal, infantile, and late-onset (Dinopoulos et al. 2005). The presentation of the neonatal type is similar to that of classic NKH but the psychomotor development is better.

The infantile type is the most frequent presentation of atypical NKH. It can be easily misdiagnosed as a static encephalopathy. After a neonatal period that may be uneventful, these children have developmental delay that can progress to moderate or profound intellectual disability (60% of cases). Most have some upper motor neuron signs, poor fine motor coordination, expressive speech deficit, hyperactivity and aggressive behaviour. About 50% develop seizures of any type. An acute deterioration induced by intercurrent febrile illness or trauma has been described in some patients with lethargy, hypotonia, ataxia, and seizures that are often difficult to control, or unusual symptoms such as myoclonic jerks, abnormal twitching movements, agitated delirium, chorea, ataxia and vertical gaze palsy.

The late-onset form is very rare and more heterogeneous. The presentation is after the second year of life and even in adulthood, mainly with mild cognitive decline and behavioural problems. In a few cases, spinocerebellar degeneration with optic atrophy and neuropathy has been described. The cause of the hyperglycinæmia in these late-onset cases is uncertain, since they all lack enzymatic or genetic confirmation.

MRI shows progressive cerebral atrophy and delayed myelination of the supratentorial white matter. Agenesis or hypoplasia of the corpus callosum is a frequent sign. There is a high signal in the pyramidal tracts, middle cerebellar peduncles, and dentate nuclei. Serial diffusion-weighted and diffusion tensor imaging (DWI, DTI) show increased T2-signal intensity and restricted diffusion consistent with hypoxic-ischaemic changes, peduncles, and dentate nuclei. Serial diffusion-weighted imaging shows increased signal in the pyramidal tracts, middle cerebellar peduncles, and dentate nuclei. MRI shows progressive cerebral atrophy and delayed myelination of the supratentorial white matter. Agenesis or hypoplasia of the corpus callosum is a frequent sign. There is a high signal in the pyramidal tracts, middle cerebellar peduncles, and dentate nuclei. Serial diffusion-weighted and diffusion tensor imaging (DWI, DTI) show increased T2-signal intensity and restricted diffusion consistent with vacuolating myelinopathy, mainly in the brainstem (Mourmans et al. 2006).

The high peak of glycine individualised on proton MRS allows non-invasive measurement of glycine concentration in the brain in classic NKH (Dinopoulos et al. 2005).

**Biochemical basis of NKH**

Glycine is implicated in numerous biochemical reactions, among which glycine-serine interconversion appears to be the most important for maintaining glycine homeostasis. This reaction involves two reversible enzymatic steps, one subserved by serine hydromethyltransferase, the other by the glycine cleavage system. This last step serving the catabolism is defective in NKH. The glycine cleavage system (GCS) is a mitochondrial enzyme complex made of four individual constituents. These are a P-protein (pyridoxal phosphate-dependent glycine decarboxylase, [GLDC]), a T-protein (tetrahydrofolate requiring aminomethyltransferase, [AMT]), an H-protein (glycine cleavage system hydrogen carrier protein, [GCSH]), containing lipoic acid), and an L-protein (lipoamide dehydrogenase). These four specific proteins allow the degradation of glycine in the liver, kidney, and brain.

The diagnosis is confirmed by the finding of elevation of glycine (control values 125–320mmol/L) (Korman and Gutman 2002). Glycine levels should be measured simultaneously in plasma and in CSF (glycine control values <10mmol/L). In NKH, all other amino acids are unremarkable, remaining within normal values. The diagnosis of NKH is based on a finding of either an increased absolute value of glycine in CSF or an increased CSF to plasma glycine ratio (control values <0.02). In classic neonatal NKH this ratio is very high (>0.08).

Secondary hyperglycinæmia with inhibition of the glycine cleavage system is due to accumulation of several metabolites (for example organic acids, sodium valproate). The clinical setting and a rapid screening of urine organic acids and blood acylcarnitines profile would exclude most other metabolic disorders. Definitive diagnosis relies on enzymatic studies on liver or transformed lymphoblasts in classic forms without residual activity. Atypical and transient forms may have normal activity in lymphoblasts and should have their enzymatic activity measured in liver and/or extensive molecular analysis for diagnosis.

Most patients with the neonatal form of the disease have a very low GCS activity and late-onset patients have some residual activity. About 75% of patients with NKH have a defect in the P-protein, and the remainder have a defect in the T-protein. L- or H-protein deficiencies are apparently very rare (Van Hove et al. 2005).

**Genetics of NKH**

NKH is transmitted as an autosomal recessive trait. Mutations are found in the genes encoding AMT, GLDC, and GCSH (Kure et al. 2006).

**Treatment of NKH**

Therapeutic approaches including dopamine receptor agonists, monoamine oxidase inhibitors, antiepileptics and serotonergic agents give modest or transient improvement in many patients, while side effects with dystonic and dyskinetic reactions are frequent. However, early treatment has resulted in better outcome in young patients (Pons et al. 2004).

Treatment with high-dosage sodium benzoate is directed towards reducing plasma and CSF glycine levels. Dextromethorphan, ketamine and tryptophan would antagonise the excitatory effect of glycine on NMDA receptors. They all have been used in isolation or in combination without consistent improvement (Dinopoulos et al. 2005; Korman et al. 2006).
SERINE DEFICIENCY SYNDROMES

Serine deficiency syndromes are rare autosomal recessive disorders due to defective synthesis of the amino acid L-serine. So far three disorders have been described: 3-phosphoglycerate dehydrogenase (3-PGDH) deficiency, 3-phosphoserine phosphatase (3-PSP) deficiency and phosphoserine aminotransferase deficiency (3-PSAT). All result in a severe encephalopathy but are potentially treatable (de Koning et al. 2000, de Koning 2006).

BIOCHEMICAL BASIS

L-serine can be derived from different sources. However, its biosynthesis from 3-phosphoglycerate is a predominant route, notably in the CNS. In the L-serine synthetic pathway, 3-phosphoglycerate is converted to L-serine in three consecutive steps. The two disorders described here concern the first and third steps (see Fig. 9.18) and result in important defective brain metabolism. In situ, L-serine is the precursor for the synthesis of the neurotransmitter L-glycine and the neuromodulator D-serine. The folate metabolite 5, 10-methylene tetrahydrofolate, which is generated along with glycine, is a key metabolite especially for purine and pyrimidine synthesis, and for various methylation reactions. Finally, L-serine is a precursor for the synthesis of phosphoglycerides, sphingolipids and glycolipids.

GENETIC BACKGROUND OF SERINE DEFICIENCIES

3-PGDH deficiency is an autosomal recessive disorder. The 3-PGDH gene is located on chromosome 1q12, and mutations have been identified. Molecular investigation is the only tool for prenatal diagnosis in the absence of enzymatic data in chorionic villi and amniocytes.

PATHOGENESIS OF SERINE DEFICIENCIES

L-serine deficiency is thought to reduce cell proliferation. This hypothesis is sustained by the 3-PGDH knockout mouse model that shows a lethal developmental defect with severe brain atrophy. From the experience with prenatal follow-up and treatment of one patient, it seems that the onset of symptoms occurs after the 27th week of gestation. Within this period, the brain development is marked by glial cell proliferation, neuronal differentiation, dendritogenesis and apoptosis. These late pathological consequences may explain the therapeutic effectiveness with serine supplement.

Clinical Features of Serine Deficiencies

A deficiency in 3-Phosphoglycerate Dehydrogenase (3-PGDH) mainly affects the CNS. Three clinical phenotypes have been described: a severe infantile phenotype, a milder juvenile type and a late-onset polyneuropathy phenotype.

In the severe form, patients present with congenital microcephaly and intrauterine growth retardation. Severe psychomotor delay develops in the first months of life followed by intractable epilepsy. Seizures can be tonic–clonic in type or flexor spasms in infants. In older children, tonic, atonic, myoclonic, absence and gelastic seizures have been observed. EEGs show either hypersynchrony or severe multifocal epileptic abnormalities with poor background. Other neurological signs include hyperexcitability, generalised hypertonia, spastic quadriplegia and nystagmus. The most severe end is the Neu-Laxova syndrome, with severe facial dysmorphism, ichthyosis, skeletal anomalies and perinatal lethality. Some children have cataracts, hypogonadism, adducted thumbs, inguinal and umbilical hernias and megaloblastic anaemia (Tabatabaie et al. 2009). On MRI the brain is atrophic with striking lack of white matter, delayed myelination and hypomyelination, only seen in the 3-PGDH deficiency (de Koning et al. 2000).

Milder juvenile forms include children with a normal early development, subsequent moderate developmental delay, atypical absence seizures but no microcephaly. In adolescence they tend to have behavioural problems.

An adult was reported with polyneuropathy, congenital cataracts, intellectual disability and a polyneuropathy in his thirties (Méneret et al. 2012).

DIAGNOSIS OF 3-PGDH

Low concentrations of serine and, to a variable degree, of glycine in plasma and CSF are the biochemical hallmark of the disease. In plasma, the abnormality can be missed if it has been sampled after the patient has eaten. In contrast, serine levels in CSF are not influenced by meals. Therefore, CSF amino acid analysis is preferable over plasma analysis. Amino acid analysis in urine is not informative. Besides deficiency of serine and glycine in CSF, low levels of 5-methyltetrahydrofolate and low D-serine in CSF folate have been observed with normal neurotransmitter amines. The diagnosis is confirmed by measurement of enzymatic activity in fibroblasts and by molecular analysis.

TREATMENT OF 3-PGDH

Oral L-serine supplementation has been effective to control seizures and to improve spasticity, well-being and behaviour of these patients. High dosages up to 600mg/kg/day in four or six divided doses, are required to normalise the biological abnormalities. If seizures are not controlled, glycine can be added at a dose of 200–300mg/kg/day. In patients treated after their first year of life, little or no progress in psychomotor development was observed. In some patients, a marked increase in the white matter volume and progression of myelination was observed in MRI follow-up. No effect on the psychomotor development is observed if the patient is already symptomatic (de Koning 2006).

A girl diagnosed prenatally was treated in utero with oral L-serine supplementation given to the mother from the 27th
week of gestation. This normalised the fetal head growth and with subsequent postnatal therapy this 3-year-old girl had normal development. In the juvenile presentations results were better with L-serine 100–150mg/kg/day resulting in cessation of seizures.

**Phosphoserine Aminotransferase Deficiency**

Phosphoserine Aminotransferase Deficiency (PSAT) the second defect in serine metabolism, was reported in two siblings (Hart et al. 2007). There is an early presentation with feeding difficulties and intractable seizures. On MRI, there was cerebral atrophy and hypoplasia of the cerebellar vermis and pons, as well as white matter changes. Early treatment within hours of birth resulted in a good outcome (Hart et al. 2007).

3-Phosphoserine Phosphatase deficiency was described in a patient with Williams syndrome.

**OTHER GABA-RELATED DISORDERS**

**Pyridoxine Dependency**

Pyridoxine dependency is a rare disease characterised by the occurrence of intractable seizures that are controlled only by the administration of pyridoxine. It is transmitted as an autosomal recessive character.

Pyridoxine dependency is due to a defect of a specific dehydrogenase, antiquitin, required for lysine and pipercolic catabolism in the brain. Defective activity of antiquitin results in accumulation of α-aminoadipic-semialdehyde (α-AASA) and piperideine-6-carboxylic acid (P6C). This latter compound condenses with pyridoxal phosphate resulting in its inactivation. The antiquitin gene (ALDH7A1) has been cloned, and various mutations have been identified in several families (Mills et al. 2006; Plecko et al. 2007; Stockler et al. 2010). This peculiar pyridoxal phosphate deficiency may account for low levels of GABA in brain. The clinical features are described in Chapter 27. The diagnosis can be made by demonstration of elevated levels of urinary α-aminoadipic semialdehyde (Bok et al. 2010).

**Pyridox(am)ine 5′-Phosphate Oxidase Deficiency**

In humans, vitamin B₆ is present in various forms, one of which, pyridoxal 5′-phosphate, is the cofactor for numerous enzymes including AADC, glycine cleavage enzyme and threonine dehydratase (see also Chapter 27). In tissues, the conversion of pyridoxine to the active form of vitamin B₆ requires pyridox(am)ine 5′-phosphate oxidase (PNPO). Neonates and infants with a pyridoxine-resistant epileptic encephalopathy can react to pyridoxal phosphate administration. This condition is due to an autosomal recessive defect in PNPO (Mills et al. 2005, 2014). CSF and urine analyses show evidence of secondary deficiencies of the several PLP-dependent enzymes. The CSF concentrations of dopamine and serotonin metabolites are similar to those described in AADC deficiency. In addition, CSF amino acid analysis reveals raised levels of glycine and threonine due to reduced activity of the glycine cleavage system and threonine dehydratase.

**GABA Transaminase Deficiency**

GABA transaminase deficiency and homocarnosinosis have been described in a few patients (Pearl et al. 2015).

**UREA CYCLE DISORDERS**

Patients with urea cycle disorders (UCDs) can present from birth to adulthood with symptoms depending on the degree of the enzyme defect. Hyperammonaemia, the common biological hallmark, clearly has a toxic effect on the CNS. At any age, hyperammonaemia may be responsible for acute toxicity, which can be fatal or result in severe CNS sequelae. In less severe forms, mild and chronic hyperammonaemia may lead to cerebral impairment (Leonard and Morris 2002, Smith et al. 2005).
**Biochemical Background**

The urea cycle subserves the incorporation of nitrogen, not used for protein synthesis, in urea, the waste nitrogen substrate in mammals. The complete cycle, as illustrated in Figure 9.21, is localised in liver, which specifically has the first three required enzymes. The following steps are expressed both in liver and in other tissues. The urea cycle is also part of the biochemical route for de novo arginine synthesis. Hereditary disorders have been described at each enzymatic step. In addition, a defect of ornithine transport across the mitochondrial membrane causes the hyperammonaemia, hyperornithinaemia, homocitrullinuria (HHH) syndrome. In lysinuric protein intolerance, transport of dibasic amino acids (lysine, arginine, ornithine) across the cell membrane results in urea cycle disruption.

In UCDs, the major biochemical finding is hyperammonaemia. Figure 9.22 outlines the diagnostic approach, which is based on determinations of the acid-base status, plasma and urinary amino acids, and oroticuria. In the case of carbamoylphosphate accumulation (ornithine carbamoyltransferase [OCT] deficiency, lysinuric protein intolerance, HHH syndrome) or overproduction (hyperargininaemia), orotic acid is produced through cytosolic activated pyrimidine synthesis.

Definitive diagnosis requires enzymatic assays in appropriate tissues and molecular confirmation.

**Genetic Background**

The OCT gene is located on the X chromosome. Female heterozygotes have a mosaic of normal and affected liver cells as a result of lyonisation and may present with various clinical manifestations from asymptomatic state to severe chronic symptomatology and unexpected acute metabolic crises occurring at any age. For genetic counselling, screening for carriers is essential. Heterozygotes can be detected by protein load or an allopurinol test and by molecular genetic techniques. All the other UCDs are inherited in an autosomal recessive mode. With the genes for all urea cycle enzymes being characterised, antenatal diagnosis for fetuses at risk rely on molecular investigations in chorionic villus tissue.

**Pathophysiology**

Ammonia appears to be the major cause of the acute encephalopathy. During acute hyperammonaemia, neurological symptoms appear to be secondary to swelling of astrocytes responsible for cerebral oedema and alteration of cerebral
blood flow. Astrocyte swelling is thought to be due to the intracellular osmotic effect of glutamine, whose increased concentrations are evidenced both in the CSF and by MRS in patients during hyperammonaemic encephalopathy. Some manifestations of chronic hyperammoniaemia such as anorexia, vomiting and sleep disturbances might be due to increased brain uptake of tryptophan and thus increased brain serotonin turnover (Gropman and Batshaw 2004).

Neurotoxic effects of the other accumulated metabolites such as citrulline and argininosuccinate are still in debate. Arginase deficiency is a disorder characterised by progressive spastic paraparesis and accumulation of arginine, guanidino compounds and creatine, which are potential neurotoxins (Sin et al. 2015).

**Neuropathology**

Abnormalities due to hyperammonaemia are difficult to differentiate from secondary anoxic lesions. In neonates, neuropathological changes include cerebral haemorrhage, prominent cerebral oedema, and generalised neuronal cell loss. In older children, lesions comprise ulegyria, cortical atrophy, ventriculomegaly and cortical neuronal loss.

**Clinical Manifestations of Urea Cycle Disorders**

**Neonatal-onset Forms**

The majority of patients presents with symptoms in the neonatal period. Every UCD may be expressed in the newborn infant, but severe neonatal-onset forms are commonly due to OCT or carbamoylphosphate synthetase deficiencies, citrullinaemia or argininosuccinic aciduria. The most important diagnostic features in neonates are vomiting, hypotonia, lethargy progressing to coma, and seizures developing within
hours or days after a symptom-free period of 24 hours or more. Severe hyperammonaemia (>700μmol/L) and respiratory alkalosis are the characteristic biological signs leading to specific biochemical investigations: amino acid chromatography and urinary orotic acid levels. Severe CNS depression and cardiorespiratory failure result in death. Cerebral imaging reveals cerebral oedema during the acute phase. In survivors of prolonged coma, changes observed months later include ventriculomegaly, white matter lesions and cerebral atrophy (Takanashi et al. 2003; Gropman and Batshaw 2004).

Late-onset forms
An increasing number of patients are diagnosed later in childhood or even in adulthood. Whatever the defect, most of the clinical symptomatology is secondary to hyperammonaemia, but some additional signs may indicate specific disorders.

Symptomatology Common to All Hyperammonaemias
Acute hyperammonaemia may be responsible for variously associated signs such as episodes of lethargy and ataxia, coma with infrequent seizures, recurrent vomiting or altered cognitive state manifested by irritability, agitation, incoherent speech and confusion. Such episodes are often associated with vomiting, high protein intake or intercurrent infections, catabolic states although, not infrequently, there is no overt cause. Mild crises abate with cessation of protein intake. Severe or persistent hyperammonaemia can be responsible for severe cerebral oedema, which can progress to diffuse or localised cortical or subcortical atrophy, and diffuse grey and white matter hypodensity. Proton MRS may reveal decreased myo-inositol and choline concentrations, and increased glutamate plus glutamine peaks. Central pontine myelinolysis is a rare complication that leads to an unusual neurological course. These features can to some extent be reversible, and their severity is usually correlated with the duration of hyperammonaemic coma. Such acute manifestations often lead to the misdiagnosis of encephalitis, cerebral tumour or vascular accident. Hepatomegaly and hepatic failure are frequent, and Reye-like syndrome or drug toxicity are often discussed. Chronic hyperammonaemia may result in protein avoidance, anorexia, vomiting and failure to thrive, mimicking various food intolerances. Hyperactivity, nocturnal episodes of restlessness, destructive behaviour and progressive intellectual disability are often misdiagnosed as psychiatric problems.

In both acute and chronic forms, diagnosis is based on plasma ammonia levels. Marked hyperammonaemia accompanies acute episodes. In milder forms, ammonia levels may be normal after an overnight fast, so determinations should be made following protein intake (see Fig. 9.22).

Specific Clinical Signs of Urea Cycle Disorders
Argininosuccinic aciduria and some cases of citrullinaemia may present with brittle hair, trichorrhexis nodosa and prominent hepatomegaly.

In arginase deficiency the major features include early progressive spastic paraparesis, associated with loss of cognitive skills. Seizures, ataxia and athetosis can be additional signs. This progressive neurological impairment is often accompanied by minor signs of chronic hyperammonaemia, while acute episodes of metabolic decomposition are rarely noted (Scaglia and Lee 2006).

HHH syndrome may present in the neonatal period or late in childhood with mild symptoms of hyperammonaemia associated with muscle hypotonia. Progressive spastic paraparesis that commonly develops during adolescence can arise earlier in children treated with high doses of arginine supplementation. Cognitive development varies widely from normal intelligence to severe intellectual disability.

Lysinuric protein intolerance presents in infants with anorexia, recurrent vomiting, lethargy, growth failure, muscle hypotonia, hepato-splenomegaly, pancytopenia and osteoporosis. Drowsiness or coma often results from forced feeding with high-protein foods.

Treatment of Urea Cycle Disorders
Neonatal-onset forms and some acute late decompensations require rapid exogenous detoxification procedures. Long-term therapy aims at limiting the endogenous and exogenous nitrogen load, at supplying deficient metabolites (e.g. citrulline, arginine, ornithine, aspartate), and at increasing the disposal of nitrogen by means other than urea formation.

Nitrogen load is reduced by restricting protein intake and promoting anabolism. Disposal of ammonia by means of benzoate and phenylacetate, which conjugate respectively with endogenous glycine and glutamine, helps eliminate waste nitrogen as hippurate and phenylacetylglutamine. Arginine becomes an indispensable amino acid for patients affected with OCT and carbamoylphosphate synthase that require supplemental arginine. Conversely, treatment of hyperargininaemic patients is based on an arginine-controlled diet. In other disorders, chronic supplementation with high doses of arginine may result in toxicity. The rare patients affected with N-acetylglutamate synthetase defect (NAGS), as well as some patients with partial carbamoylphosphate synthetase, can be treated with N-carbamoyl glutamate supplementation.

Therapy has to be specifically tailored to the specific UCD, and each individual patient must be evaluated for metabolic profile before an optimal therapy can be instituted. Despite careful management, liver transplantation may represent the only available therapeutic approach for children with severe recurrent acute decompensations (Silva et al. 2013). Only patients who are NAGS deficient can be successfully treated with N-carbamoyl glutamate supplementation without specific diet.
The metabolic pathways involved in glycolysis, neoglucogenesis, glycogen synthesis, and metabolism of galactose and fructose are discussed here. Most of these diseases have more general symptoms, and neurological symptoms may arise as a result of deranged metabolism such as hypoglycaemia.

**GLYCOGEN STORAGE DISEASES**

This group of diseases is involved in deranged synthesis or degradation of glycogen and is often associated with hepatomegaly. Most involve liver dysfunction, with hypoglycaemia as a consequence. An exception is the glycogen myopathies which will be discussed in Chapter 26.

There are more than 12 different enzyme deficiencies in this pathway. Most can be studied in leukocytes, in others a liver biopsy is necessary. Treatment includes frequent meals and uncooked corn-starch at bedtime (0.5–1g/kg).

**DISORDERS OF PENTOSE METABOLISM**

The pentose phosphate pathway generates nicotinamide adenine dinucleotide phosphate (NADPH) (required for a number of anabolic reactions) and pentoses (5-carbon sugars). A number of single deficiencies are described.

**Ribose-5-Phosphate Isomerase Deficiency**

There are a few patients described with intellectual disability and epilepsy, developing ataxia and neuropathy and demonstrating on MRI extensive abnormalities in white matter (Wamelink et al. 2008).

**Transaldolase (TALDO) Deficiency**

This disease manifests as a severe, early-onset multisystem disease with hepatosplenomegaly, thrombocytopenia, anemia, bleeding diathesis, liver failure and tubulopathy. Defareshas been described (Eyaid et al. 2013).

Increased polyol concentrations with high concentrations of erythritol, ribitol, arabitol, sedoheptitol, perseitol, sedoheptulose and sedoheptulose-7-phosphate are found in the urine. The disease can be confirmed by molecular analysis of the TALDO gene (Tylki-Szymanska et al. 2014).

Disorders of galactose and fructose metabolism do not present with major neurological features if treated with an adequate diet. In galactosaemia, verbal apraxia can occur in some patients not related to diet control.

**TRANSPORTER DEFECTS**

**GLUCOSE TRANSPORTER TYPE 1 DEFICIENCY SYNDROME**

The disease leads to impaired glucose transport to the brain resulting in brain energy deficiency.

The initial glucose transporter type 1 deficiency syndrome (GLUT1DS) clinical description included young infants with intractable seizures needing to be treated early and with a successful outcome with a ketogenic diet. Besides intractable seizures, other phenotypes are also described in life such as early ocular movement disorders or early-onset absence seizures, a non-classic phenotype with intellectual disability or a movement disorder without epilepsy (Leen et al. 2010).

Seizures in GLUT 1 deficiency can be of all types ranging from severe myoclonic–atonic seizures, through generalised tonic–clonic, absences, and nocturnal or early morning seizures (see also Chapters 16 and 19).

**Diagnosis**

The sole biochemical abnormality is a very low CSF glucose with a low CSF–blood glucose ratio of less than 0.4 and low CSF lactate. The diagnosis can be confirmed by analysis of the SLC2A1 gene. Most patients carry heterozygous de novo mutations but autosomal dominant transmission has also been identified.

A ketogenic diet (Klepper et al. 2005; Klepper 2012) or a modified Atkins diet is the treatment of choice, to provide ketones as an alternative fuel for the brain. However, persistence with the diet can be difficult to sustain. Other diets such as low-index glucose and corn-starch to keep glucose levels constant have been tried more recently (Almuqbil et al. 2015).

**CEREBRAL FOLATE TRANSPORTER**

**Thiamine Transporter-2 Deficiency**

Thiamine transporter-2 deficiency is caused by mutations in the SLC19A3 gene. Early administration of thiamine and biotin has a dramatic and immediate clinical effect (see also biotin-responsive basal ganglia disease in the Biotin Metabolism section).

In patients, free-thiamine was remarkably reduced in the CSF of five SLC19A3 patients before treatment. Thiamine supplementation led to clinical improvement in patients early treated and restored thiamine values in fibroblasts and CSF.

**Riboflavin Transporter Deficiency**

Riboflavin transporter deficiency neuropathy is characterised by motor neuropathy (manifest as proximal and distal limb weakness, often with severe distal wasting and breathing
problems due to paralysis of the diaphragm), sensory neuronopathy, and cranial neuronopathy (manifest as optic atrophy, sensorineural deafness, and bulbar palsy). Onset is usually in infancy or in childhood before the age of 8 years.

Several transporters have now been described. RFVT2 (SLC52A2) and RFVT3 (SLC52A3) present with Brown-Vialetto-van Laere syndrome (Bosch et al. 2011; Foley et al. 2014).

**Genetics**

Riboflavin transporter deficiency neuronopathy is inherited in an autosomal recessive manner.

**MITOCHONDRIAL MEDICINE**

**RESPIRATORY CHAIN DISORDERS**

The respiratory chain is the main biochemical system used to yield aerobic energy in all eukaryotic organisms. In humans, its dysfunction is responsible for numerous and highly variable mitochondrial diseases that all have in common defective ATP production along with insufficient energy provision in one or several tissues or organs. This effect may vary from one tissue to another, according to their dependence on phosphorylative oxidation. Muscle tissue in general is particularly sensitive to diminished ATP supply, resulting in various symptoms such as ptosis, ophthalmoplegia, muscle weakness, exercise intolerance, and cardiomyopathy. The nervous system is also highly susceptible, resulting in encephalopathy, sensorineural signs and peripheral neuropathies. Other tissues may also be affected depending on the extent and severity of the defect. Kidney, liver, pancreas and gastrointestinal tissues are the most often implicated organs. Clinically, mitochondrial disorders are extremely heterogeneous. They may affect a single organ or tissue but most often cause multisystemic disorders, among which syndromic conditions have been described for years (Zeviani and Di Donato 2004; DiMauro and Hirano 2005).

**Functional Organisation of the Respiratory Chain**

The mitochondrial respiratory chain is a group of five enzyme complexes embedded in the inner mitochondrial membrane. Each complex is composed of multiple polypeptide subunits and prosthetic groups (Table 9.7). In addition, the respiratory chain contains two electron carriers, coenzyme Q$_0$ and cytochrome c. The respiratory chain is especially organised to accept electrons from NADH and FADH$_2$, the reducing factors generated from the intermediary metabolism (Fig. 9.23). These electrons flow down the respiratory chain to molecular oxygen to produce water. Simultaneously, the energy liberated during this flux is used by complexes I, III and IV to pump protons (H$^+$) out of the mitochondrial matrix into the intermembrane space. Complex V allows protons to flow back into the mitochondrial matrix and uses the released energy to synthesise ATP from ADP and inorganic phosphate (DiMauro and Schon 2003).

**Genetic Background**

Mendelian mitochondrial defects can affect five components of mitochondrial biology (DiMauro et al. 2013): subunits of respiratory chain complexes (direct hits); mitochondrial assembly proteins; mtDNA translation; phospholipid composition of the inner mitochondrial membrane or mitochondrial dynamics. A sixth category – defects of mtDNA maintenance – combines features of Mendelian and mitochondrial genetics.

Human mtDNA contains the genes for 13 OXPHOS (respiratory chain, electron transport chain) subunits, as well as for the 22 transfer RNAs (tRNAs) and the two ribosomal RNAs (rRNAs) required for the intramitochondrial synthesis. The remaining structural proteins are encoded by nDNA.

nDNA also encodes hundreds of additional factors required for subunit protein expression, transport, translation, elongation and assembly as well as for mtDNA synthesis, expression and stabilisation. In addition, mitochondria are not static organelles and other nuclear encoded factors govern their mobility, fission and fusion. In total, it is estimated that respiratory chain functions require about 1000 separate proteins, mostly encoded by nDNA, with mutations potentially responsible for Mendelian inherited diseases.

In consequence, mitochondrial diseases may be caused by mutations in genes from either mtDNA or nDNA. However, clinically indistinguishable disorders may be caused by separate mutations in different genes on different genomes. Conversely, one specific mutation may result in a number of distinct clinical symptoms in different individuals even in one family.

**Diagnosis/Testing**

A pattern of blood acylcarnitines and organic acids in urine suggests multiple acyl-CoA dehydrogenase deficiency can can be confirmed by the demonstration of mutations in either SLC52A2 or SLC52A3.

**Management**

High-dose oral supplementation with riboflavin between 10 and 50mg/kg/day improves symptoms and signs on clinical examination, and normalises acylcarnitine levels.
**Mutations in mtDNA**

These include point mutations and large-scale rearrangements. Point mutations were first described in genes encoding various tRNAs resulting in widespread impairment of protein synthesis. They usually are heteroplasmic, only maternally inherited and associated with a striking variety of multisystem disorders. More than 260 pathogenic mutations and 120 large-scale rearrangements (single mtDNA deletions) have been identified in the mtDNA.

Point mutations in protein-coding genes affect one of the mitochondrial encoded subunits in complex I (ND), complex III (Cyt b), complex IV (COX) or complex V (ATPase6). ND5, which encodes the subunit 5 of complex I, is the site of numerous point mutations associated with various multisystem disorders such as Leigh encephalopathy.

**Large-scale rearrangements** consist of a single deletion/duplication in mtDNA. They differ in size from one patient to another and delete several protein-coding and tRNA genes. They tend to arise spontaneously and are heteroplasmic. However, some cases may be maternally inherited with variable phenotypic expression between the affected female and her offspring.

**Mutations in nuclear genes**

These include mutations in genes that encode complex subunits, ancillary proteins, protein factors required for intergenic signalling, and protein factors necessary for membrane maintenance, phospholipid of inner mitochondrial membrane, and for mobility of mitochondrion. These mutations are responsible for Mendelian autosomal recessive, dominant or X-linked inherited diseases.
Mutations in genes encoding respiratory chain subunits are increasingly recognised. Various mutations in genes encoding subunits of complex I (NDUFS and NDUFV) and complex II (SDH) are mainly responsible for Leigh or Leigh-like syndromes. Mutations in genes encoding enzymes implicated in the biosynthetic pathway of CoQ have been identified. They include PDSS2, PDSS1, PDSS1, C6Q6, ADCK3 and C6Q9 giving rise to five clinical syndromes with variable tissue affection (Emmanuelle et al. 2012; Scalais et al. 2013).

The nuclear gene (BCSL) involved in complex III deficiency was the first reported assembly defect. Mutations are responsible for an early and severe multisystem disorder first described in Turkish patients and also called GRACILE syndrome (growth retardation, aminoaciduria, cholestasis, iron overload, lactic acidosis and early death) in Finland, where it has a high incidence. Mutations in the COX-assembly gene SURF1 are frequently associated with Leigh syndrome due to complex IV deficiency. Other mutations in seven more COX-assembly genes (SCO1, SCO2, COX10, COX14, COX15, GoA5, FAM366 and TACO1) have been described in patients affected with Leigh-like encephalopathy and preferentially affecting the brain. Some, such as mutations in COX10, COX15 COA5, have more severe cardiomyopathy whereas mutations in SCO1 cause hepatopathy (DiMauro et al. 2013).

A group of COX-deficient Leigh syndrome patients is due to mutations in the LRPPRC gene which has been described in French Canadian families. Patients with muscle COX deficiency and ethylmalonic aciduria have mutations in the ETFE1 gene. Dysfunction of ETFE1 results in excessive accumulation of hydrogen sulphide which is a powerful COX inhibitor (Tirant et al. 2009).

Finally, mutations in the ATP12 gene impair the assembly of complex V and are responsible for a lethal encephalomyopathy (De Meirleir et al. 2004).

**Mutations in genes encoding factors for mtDNA maintenance**

**Defects in the replication machinery**

The replicative machinery includes the catalytic subunit of polymerase (POLG) and the replicative helicases Twinkl (encoded by PEO1 and DNA2) (Horvath et al. 2006; Ronchi 2013).

Depending on which of the three POLG domains (polymerase, exonuclease or linker region) the clinical phenotype ranges from severe hepatocerebral disorder (Alpers syndrome) to adult-onset autosomal dominant or autosomal recessive progressive external ophthalmoplegia, parkinsonism and other clinical phenotypes including sensory ataxic neuropathy, dysarthria and ophthalmoparesis (SANDO) or mitochondrial respiratory chain disorders, due to choline kinase beta (CHKB) gene defects has been characterised by intellectual disability, autistic features, ichthyosis-like skin changes, and altered cardiomyopathy (Haghighi et al. 2014).

The mitochondrial-associated endoplasmic reticulum membrane also has several functions important in energy metabolism. A new form of congenital muscular dystrophy (CMD) with multisystem involvement and characteristic mitochondrial structural changes, due to choline kinase beta (CHKB) gene defects has been characterised by intellectual disability, autistic features, ichthyosis-like skin changes, and altered cardiomyopathy (Haghighi et al. 2014).

**Defects involving the dNTP pool**

These Mendelian disorders with qualitative (deletions) or quantitative (depletion) alterations in mtDNA result from an imbalanced supply of deoxyribonucleotides to the mitochondrial (Alberio et al. 2007). Six genes have so far been implicated in the pathogenesis of mitochondrial depletion syndromes (MDS) namely, the thymidine kinase (TK2) gene in myopathic forms, the beta-subunit of the ADP-forming succinyl-CoA synthetases (SUCLA2, SUCLG1 and RRM2B) in encephalomyopathic MDS, and deoxyguanosine kinase (DGUK) in hepatocerebral MDS.

Mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), is due to mutations in TYMP (Hirano et al. 2005) involved in pathways for the synthesis of deoxyribonucleotides (ANT1 and RRM2B).

**Defects in mtRNA translation**

The translation process comprises several steps requiring initiation factors (IF2 and IF3), elongation factors (EF-Tu, EF-Ts and EFG1), encoding an elongation factor, releases factors (eRF1 and ICT1n, as well as several translational activators TACO1 and LRP130) and specific tRNA base modifiers (TRMU and PUS1). The PUS1 gene, which encodes the mitochondrial enzyme pseudouridine synthetase, is associated with myopathy, lactic acidosis and sideroblastic anaemia (MLASA).

Mutations in genes encoding mRNA polyadenylation factors, ribosomal proteins, ribosomal protein assembly factors, aminoacyl-tRNA synthetases and many other genes have been recently described.

**Defects of the mitochondrial inner membrane lipid milieu**

Among these defects is Barth syndrome (X-linked mitochondrial myopathy, cardiomyopathy, neutropenia, and 3-methyl glutaconic aciduria) with low cardiolipin levels due to mutations in TAZ, the tafazzin gene. Cardiolipin, a major phospholipid component of mitochondrial inner membrane, modulates the activities of several respiratory chain complexes.

**Sengers syndrome** primarily affects heart and muscle and is associated with congenital cataracts. Using whole exome sequencing the responsible gene, AGK, encoding acylglycerokinase was found.

The mitochondrial-associated endoplasmic reticulum membrane also has several functions important in energy metabolism. A new form of congenital muscular dystrophy (CMD) with multisystem involvement and characteristic mitochondrial structural changes, due to choline kinase beta (CHKB) gene defects has been characterised by intellectual disability, autistic features, ichthyosis-like skin changes, and altered cardiomyopathy (Haghighi et al. 2014).

Alteration of MIM phospholipid composition was also found in MEGDEL 3-methyl glutaconic aciduria, deafness, Leigh [MEGDEL] syndrome due to mutations in the SERAC1 gene (Wortmann et al. 2012).
Defects of mitochondrial dynamics

Defects in proteins required for mitochondrial mobility have been described in autosomal dominant hereditary spastic paraplegia with mutations in one kinesin gene (KIF4A). Defects in (dynamin) the protein required for mitochondrial fusion have been reported in autosomal dominant optic atrophy (OPA-1) and in an autosomal dominant variant of Charcot–Marie–Tooth type 2A with defects in mitofusin 2 (MNF2).

Biological Features and Diagnostic Tests

In paediatric patients, the majority (90%) of proven respiratory chain defects present with raised lactate in blood, urine or CSF, often accompanied by a raised lactate to pyruvate ratio signifying a change in cellular redox state. Cerebral or CSF, often accompanied by a raised lactate to pyruvate ratio signifying a change in cellular redox state. Cerebral MRS is a non-invasive and useful means to evaluate lactate accumulation in brain. In addition, it allows an easy diagnosis of the rare complex II deficiency by the presence of an abnormal peak of succinate (Brokkmann et al. 2005). Some patients do not display lactic acidosis at rest, depending on the severity of the energy defect, the organ involvement, and the consequence of the primary defect on the oxidation rate. In some cases, lactic acidosis can spontaneously be precipitated by infection or functionally provoked by a glucose loading test. Those patients most affected with exercise intolerance may develop a severe hyperlactataemia after non-strenuous exercise. However, lactic acidosis is not an absolute requisite for diagnosis, especially in late childhood or adolescence. Apart from the usual lactaturia, rare patients have abnormal urinary excretion of Krebs cycle intermediates such as fumarate, malate, alpha-ketoglutarate, succinate or 3-methylglutaconic acid. Mild methylmalonic aciduria has been found associated with a SUCLA2 gene mutation responsible for mtDNA depletion syndrome (Carrozzo et al. 2007). Ethylmalonic aciduria is indicative of ethylmalonic encephalopathy, a condition harbouring marked complex IV deficiency in muscle. High levels of thymidine, deoxyuridine and uracil in blood and urine are indicative of MNGIE with thymidine phosphorylase deficiency. Carnitine deficiency in serum and muscle may reflect inefficient fatty acid oxidation. Serum creatine kinase values can be high in myopathic forms of mtDNA depletion syndrome.

MRS may be useful in children over 8 years of age, adolescents and adults. Measurement of the phosphocreatine/inorganic phosphorus ratio during muscle exercise may indicate an ATP-synthesis defect. An aerobic forearm test can raise a suspicion of a mitochondrial disorder when failure of O$_2$ uptake occurs during the test. In patients with a clearly defined clinical syndrome, it may be possible to confirm the diagnosis with a simple molecular genetic test on DNA extracted from blood. Good examples of this are MNGIE (TYMP), the infantile encephalohydropathy (DGUK) and infantile encephalobulopathy (BCS1L). Investigation in the remaining patients is more difficult, especially because pathogenic mutations may not be detectable in blood. An mtDNA heteroplasmic mutation test can sometimes be more sensitive in urine. A histochemical examination on muscle biopsy using Gomori, cytochrome c oxidase and succinate dehydrogenase (SDH) stains that revealed mitochondrial proliferation and mosaicism would be suggestive of mtDNA mutations and complex II or IV deficiencies.

Biochemical investigations include two main, and non-exclusive, procedures using mitochondria-enriched fractions from fresh tissue for polarographic studies or using frozen tissue for analysis of individual respiratory chain enzyme activities by spectrophotometry. For this purpose, skeletal muscle biopsy specimens are most often used. However, specific studies can be performed on fibroblasts, blood cells, liver, kidney or brain. In principle, the relevant tissues the one that is clinically affected, i.e. investigation on a liver sample is recommended in hepatoneuropathy. In cases with dubious biochemical results when the clinical level of suspicion is high, investigations in several tissues should be performed.

A structured approach to molecular investigations could include a southern blot of muscle mtDNA looking for mtDNA rearrangement and sequencing of the mtDNA. Further molecular screening, guided by the clinical phenotype, family history and results of biochemistry would help to define an increasing number of pathologies allowing proper genetic counselling.

The major challenge to the accurate diagnosis of mitochondrial disease is the absence of a definitive biomarker that characterises the disorder in all patients. To aid the interpretation, genetic counselling.

Clinical Features of Mitochondrial Disorders

Due to the complexity of mitochondrial genetics and biochemistry, the clinical manifestations of these disorders are extremely heterogeneous. They range from lesions in a single tissue or organ such as the optic nerve in Leber hereditary optic neuropathy, to more widespread lesions including myopathies, encephalomyopathies, cardiomopathies or complex multisystem syndromes with onset ranging from the neonatal period to adulthood. Certain associations have long been identified as distinct entities such as Kearns–Sayre syndrome (KSS), myopathy, encephalopathy, lactic acidosis and stroke-like (MELAS), myoclonic epilepsy with ragged red fibers syndrome (MERRF), neurogenic weakness, ataxia and retinitis pigmentosa (NARP), Leigh syndrome and Alpers disease. However, not all patients with respiratory chain disorders may be so easily categorised, and many overlaps between clinical syndromes have been documented. Consequently, respiratory chain disorders must be considered in patients presenting with an unexplained and progressive association of neuromuscular and non-neuromuscular symptoms (DiMauro and Schon 2003; Robinson 2006).
**Myopathic Forms of Respiratory Chain Disorders**

Myopathic forms are characterised by progressive weakness of the limbs with variable exercise intolerance, muscle pain, breathlessness, tiredness and nausea. Symptoms may appear within the first 2 years of life, with hypotonia and delayed motor skills, or later in childhood, adolescence or adulthood. Patients can die from early cardiorespiratory failure or remain stable for years. Lactataemia at rest can be normal or mildly increased. Short aerobic exercises can provoke severe lactic acidosis. Except in very young children, morphological and histochemical abnormalities in biopsied muscle are often characteristic. These isolated myopathic forms are associated with mtDNA point mutations in genes encoding subunits of complexes I, III (cytochrome b) or IV. A defect due to mutations in the cytochrome b gene is probably the most characteristic example as it mainly presents with isolated and progressive myopathy and exercise intolerance.

Primary CoQ10 deficiency, an autosomal recessive condition with a large clinical spectrum, has a pure juvenile myopathic form with exercise intolerance and eventually myoglobinuria. Other presentations are: (1) encephalomyopathy with brain involvement and recurrent myoglobinuria; (2) severe infantile multisystem disease; (3) cerebellar ataxia; (4) Leigh syndrome with ataxia and deafness. These patients with ragged red fibres and undetectable CoQ10 in tissues are amenable to treatment with high doses of exogenous CoQ10.

The myopathic presentations of cytochrome c oxidase (complex IV) deficiency include three main variants: a fatal infantile myopathy, a benign reversible infantile myopathy, and a late-onset (adult) myopathy. Both fatal and benign forms present in newborn infants with severe and generalised weakness, respiratory distress and lactic acidosis. Patients with the fatal form usually die of respiratory failure within months. Some remain more stable and some patients with a benign form improve spontaneously despite initial severe weakness, and are usually normal by early childhood. (Horvath et al. 2009). Some severe forms mimicking spinal muscular atrophy have been described with mutations in the nuclear encoded SCO2 gene, with the mitochondrial encoded COX1 gene, and with mtDNA depletion due to mutations in the nuclear gene encoding thymidine kinase 2 (TK2).

**Multisystem Forms of Respiratory Chain Disorders**

These involve mainly the CNS and present in the neonatal period or later in childhood, adolescence or even in adulthood.

**FATAL INFANTILE FORM**

This features neonatal lactic acidosis with hypotonia, seizures and respiratory distress, and results in death within a few months. As in complex IV deficiency, renal, cardiac and hepatic involvement may be seen. Severe hyperlactataemia is present, while morphological studies of muscle can be normal or reveal a nonspecific lipid–glycogen storage. MRI may show cortical and subcortical atrophy and dysmyelination. This syndrome is frequently, but not exclusively, associated with complex I and complex IV deficiencies.

**PROGRESSIVE ENCEPHALOPATHY/ENCEPHALOMYOPATHY**

Severe encephalopathy may start later in infancy or childhood after a period of apparently normal development. The following manifestations can be present: developmental delay, hypotonia, weakness, ataxia, pyramidal signs, seizures, myoclonia, retinopathy, ptosis, PEO, sensorineural deafness, mild dysmorphism and growth retardation.

Plasma lactate levels can be normal but high CSF lactate and lactatauria are of great diagnostic value. Some patients present with bouts of drowsiness following intercurrent infections during which high plasma lactate levels occur. Ragged red fibres are frequently associated with lipid–glycogen storage. MRI may be normal or reveal cerebral and/or cerebellar atrophy and bilateral hyperdensity in the basal ganglia or white matter abnormalities. Altered EMG, nerve conduction velocities and visual or brainstem evoked potentials can be found. Cases have been described with defects in all respiratory chain complexes due to various point mutations in either the mt- or nDNA. Specific associated neurological signs such as polymicrogyria, or associated visceral signs such as cardiomyopathy, nephropathy or hepatopathy may be helpful to lead to the diagnosis.

**SUBACUTE NECROTISING ENCEPHALOPATHY: LEIGH SYNDROME**

Leigh syndrome is an inherited, progressive, metabolic disease of infancy and childhood. It causes striking neuropathological features of focal, bilateral and symmetrical necrotic lesions associated with demyelination, vascular proliferation, and gliosis in the brainstem, diencephalon, basal ganglia, cerebellum, and occasionally in the white matter (Farina et al. 2002) (Fig. 9.24).

The neuropathological changes involve most consistently the brainstem in a bilateral, roughly symmetrical distribution. The lesions are sharply delineated and cut across grey and white matter with preponderance in the former. The pathological complex of Leigh syndrome consists of a marked spongiosis involving mainly the neuropil, while neurons are relatively preserved. White matter lesions include loss of myelin and, eventually, of axons. An intense capillary proliferation with endothelial swelling is an essential feature. Lesions of this type characteristically affect the tegmentum of midbrain andpons, the peri-aqueductal grey matter, the substantia nigra and posterior colliculi, the floor of the fourth ventricle, and the dentate nuclei. Lesions of the basal ganglia, especially the putamen and caudate nucleus, are common (Fig. 9.25). The
Figure 9.24  **Leigh syndrome.** Typical histological appearance of tissues: note sharply demarcated area of marked spongiosis with intense capillary proliferation.

Figure 9.25  **Leigh necrotizing encephalomyelopathy.** Cavitation of both lenticular nuclei. Head of left caudate nucleus is hypodense. There is marked atrophy of head of right caudate nucleus with widening of corresponding frontal horn.
mamillary bodies are only rarely affected, which is important for distinguishing the condition from Wernicke disease in which similar lesions are present but regularly involve these structures.

The clinical manifestations are extremely variable, and the diagnosis is very difficult as no biochemical markers are available in a majority of cases. Some common features such as deterioration with slow recovery following infections, exercise intolerance, poor somatic growth and abrupt changes in respiratory or cardiac rate may suggest the diagnosis of mitochondrial disorder.

In the infantile form, signs usually appear within the first few years of life and consist of hypotonia, failure to thrive, psychomotor regression, pyramidal tract signs, and brainstem and basal ganglia dysfunction. This basal ganglia involvement results in ataxia, abnormal ocular movements such as ptosis or ophthalmoplegia, dystonia or rigidity, and swallowing difficulties. Movement disorders including choreoathetosis, dystonia and sometimes myoclonus are not infrequent. Involvement of the peripheral nervous system is not rare. In a few cases, it may be the predominant manifestation and may simulate Guillaumin–Barré syndrome. Seizures occur in some patients and may present as infantile spasms. As a whole, the course is often rapidly progressive with alternating periods of remissions and exacerbations. These are often precipitated by infections or fasting. Acute fulminating cases, protracted illness with periods of stabilisation, and cases with very slow progression have all been recorded.

Later forms are less commonly encountered but may occur throughout childhood and adolescence and well into adulthood. Predominant extrapyramidal manifestations such as dystonia or abnormal movements, hypokinesia and rigidity could be predominant signs. In some cases, mild psychomotor retardation with slight neurological abnormalities may remain unchanged for years until rapid deterioration occurs, sometimes only in adulthood.

Although mostly due to autosomal recessive inheritance, dominant, X-linked and maternal inheritance is also possible. This genetic heterogeneity has been confirmed with the identification of functional or molecular defects in several enzymes involved in energy production, including pyruvate dehydrogenase, pyruvate carboxylase and respiratory chain complexes involved in energy production, including pyruvate dehydrogenase, pyruvate carboxylase and respiratory chain complexes involved in energy production, including pyruvate dehydro-

event, on T1-weighted images. Lesions are mainly found in the medulla oblongata, the pons and the midbrain. Involvement of the cerebellum is frequent, mainly centred on the dentate nuclei with extension to the surrounding white matter. Basal ganglia, thalami and subthalamic nuclei are a third site. Extensive lesions in the deep cerebral white matter and progressive cerebral atrophy or infarction may be additional features.

KEARNS–SAYRE SYNDROME

KSS is usually a sporadic multisystemic disorder characterised by an invariant triad comprising onset before age 20 years, PEO and pigmentary retinal degeneration, plus at least one of the following: heart block, elevated CSF protein content and cerebellar dysfunction (Zeviani and Di Donato 2004). Still other clinical abnormalities are present in many cases, and two constant pathological features have been described: ragged red fibres and spongy degeneration of the brain. The signs and symptoms may progress in various sequences.

Pearson syndrome, which can evolve into KSS with age, is characterised by sideroblastic anaemia in neonates or infants, associated with exocrine pancreatic dysfunction. This syndrome has similar large-scale single deletions/duplications of mtDNA, as seen in KSS.

Children with KSS usually have normal early development. Ptosis and PEO are usually the first neurological manifestation of the disease, often associated with degenerative pigmentary retinopathy and sometimes with optic atrophy. The most common neurological feature is a cerebellar syndrome that may become severe. Intellectual disability or regression may be present. Deafness can also develop.
Seizures do not occur, unless there is concomitant hypocalcaemia with hypoparathyroidism. Heart block is a late sign that may be responsible for syncopal episodes or sudden death despite pacemaker insertion. Rarely, congestive heart failure and supraventricular tachycardia are encountered. Associated endocrine disorders may include short stature with growth hormone defect, latent diabetes and hypoparathyroidism. Renal dysfunction often includes a proximal tubular defect, distal tubulopathy, glomerulopathy, and renal failure. Mild lactic acidosis and high CSF protein are typical laboratory findings.

Neuroimaging shows both grey and white matter lesions, most often localised in the brainstem tegmentum, cerebral and cerebellar white matter, and basal ganglia. Calcifications in the basal ganglia or deep white matter are commonly seen. Involvement of the subcortical U-fibres with relative sparing of the periventricular white matter is typical of KSS. However, these classic lesions develop progressively with age, and MRI can be normal in early stages of the disease. An extinguished EEG and abnormal visual evoked potentials may precede ophthalmoscopic evidence of retinopathy. EMG and nerve conduction velocity studies in some cases may indicate peripheral neuropathy or myopathic changes.

Histochemical and electron microscopic studies of skeletal muscle demonstrate ragged red fibres and altered mitochondria. Altered type I fibres lacking histochemical cytochrome c oxidase activity coexist with normal fibres. Eighty per cent of patients with KSS have a single deletion in mtDNA. Most often the KSS cases are sporadic, and only a few patients have a maternally inherited form of the disease.

**PROGRESSIVE EXTERNAL OPHTHALMOPLEGIA**

PEO is a clinically and genetically heterogeneous condition associated with single or multiple mtDNA deletions and sporadic, autosomal dominant or autosomal recessive inheritance. Classically, the first signs arise in adulthood, with a few cases arising in adolescence or in early adulthood. Ophthalmoplegia, proptosis and muscle weakness with exercise intolerance are the main signs. Sensory motor neuropathy, sensorineural hearing loss, cataracts and cerebellar involvement are other progressive symptoms.

Cognitive deterioration with psychiatric manifestations may develop. Similarly to KSS, single deletions/duplications in mtDNA are responsible for lactic acidosis, ragged red fibres and a mosaic pattern of defective cytochrome c oxidase on muscle histochemical investigations.

Autosomal dominant forms of PEO (adPEO) are mainly caused by mutations in four nuclear genes: **POLG1**, *twinkle*, **DNA2** and **ANT1**. They are associated with ragged red fibres in skeletal muscle and multiple deletions of mtDNA. The typical clinical features of adPEO are progressive muscle weakness, most severely affecting the external eye muscles. Ataxia, depression, hypogonadism, hearing loss, peripheral neuropathy and cataracts are various other signs.

Other sporadic or recessively transmitted PEO cases can be linked with **POLG** mutations (Zeviani and Di Donato 2004).

**MYOCLONIC EPILEPSY WITH RAGGED RED FIBRES**

MERRF is a maternally inherited encephalomyopathy, characterised by myoclonus, cerebellar ataxia and mitochondrial myopathy. Seizures, hearing loss, dementia, peripheral neuropathy and multiple symmetric lipomas are frequently associated (Zeviani and Di Donato 2004).

In most cases, symptoms begin between the ages of 5 and 13 years with cerebellar ataxia, tremor and myoclonic jerks (see also Chapter 16) induced by action or intended movement. Many patients have generalised or massive myoclonic seizures and some become demented. Hearing loss, optic atrophy and proprioceptive sensory loss may occur. PEO, retinal degeneration or stroke-like episodes are not present. The severity of symptoms along a maternal lineage varies greatly from severe to mild manifestations, sometimes with only abnormal visual evoked response and EEG pattern. CSF and serum lactate levels may be slightly increased. Endocrine disorders may occur.

EEG records abnormal background activity, variously associated with spike–wave patterns and a photoparoxysmal response. Visual, auditory and somatosensory evoked response studies may show abnormal latencies, while EMG shows myopathic changes. CT and MRI may indicate cerebral and cerebellar atrophy. At post-mortem examination, degeneration of the cerebral hemispheres, cerebellar dentate nuclei, posterior spinal column and spinocerebellar tracts has been found.

COX-depleted ragged red fibres and ultrastructurally abnormal mitochondria in biopsed muscle are constant and may be the only sign in asymptomatic individuals within a family. The typical mitochondrial DNA mutation is in the tRNAlys gene *A8344G*. Other mutations in the same gene have been reported in association with MERRF, MERRF/ MELAS overlap syndrome and other complex phenotypes.

**MITOCHONDRIAL MYOPATHY, ENCEPHALOPATHY, LACTIC ACIDOSIS AND STROKE-LIKE EPISODES**

Mitochondrial myopathy, encephalopathy lactic acidosis and stroke-like episodes (MELAS) generally presents in children or young adults after normal early development. Symptoms include recurrent vomiting, migraine-like headache, and recurrent stroke-like episodes causing cortical blindness, hemiparesis or hemianopia. Seizures are often preceded by strokes or episodes of migraine with aura and are invariably partial motor in type. Intellectual regression and behavioural problems are prominent. The myopathy is usually asymptomatic or expressed as muscular weakness and mild amyotrophy.
Additional features include short stature, diabetes mellitus, sensorineural hearing loss, mild retinal degeneration and cardiac involvement. Lactate levels in plasma and CSF are usually high, and creatine kinase can be increased. The CSF protein content is normal.

The EEG is usually abnormal, with occasional spike and wave or focal spike discharges. Neuroimaging shows focal lucencies or increased T2 signal, generally not in a vascular distribution, affecting various sites of the white matter, cortex or brainstem, and areas of calcification or high T2 signal in the basal ganglia. Cerebral and cerebellar atrophy may be associated. Focal necrosis and laminar cortical necrotic changes are the histopathological signs of the disease, together with neuronal degeneration and mineral deposits within the basal ganglia. The pathogenesis of the infarct-like lesions is presumably due to a mitochondrial micro-angiopathy with deficient energy metabolism in the endothelium of small pial arterioles and capillaries. Ragged red fibres, lipid droplets and abnormal mitochondria are present in muscles.

The most common mtDNA mutation is in A3243G, the trNAleu (UUR) gene. However, many other mutations are associated with MELAS. Conversely, this A3243G mutation has been detected in patients with maternally inherited PEO or diabetes mellitus and deafness, and isolated myopathy or cardiomyopathy.

**ALPERS DISEASE**

Alpers–Huttenlocher syndrome (AHS), an autosomal recessive hepatocerebral syndrome of early onset, is a degenerative disease that primarily affects the cerebral grey matter. The typical course of AHS includes severe developmental delay, intractable seizures, cortical blindness, progressive liver dysfunction, acute liver failure after exposure to valproic acid and death in childhood. AHS is one clinical phenotype associated with a mitochondrial depletion syndrome due to POLG1 mutations resulting in mtDNA depletion and multiple respiratory chain defects in all affected tissues (Horvath et al. 2006). Seizures and EEG abnormalities are much more prominent than in Leigh syndrome, which is a reflection of the extensive involvement of cortical grey matter. Variable visceral involvement may be associated.

**MITOCHONDRIAL NEUROGASTROINTESTINAL ENCEPHALOMYOPATHY**

MNGIE is an autosomal recessive disease clinically defined by gastrointestinal dysmotility, cachexia, ptosis, ophthalmoparesis, peripheral neuropathy and white matter changes in brain MRI. This devastating disorder is linked to nuclear mutations in the thymidine phosphorylase gene. They induce pathological accumulation of thymidine and deoxyuridine, and imbalance of the mitochondrial pool impairing mtDNA replication and/or maintenance, with deletion, multiple deletions and point mutations (Nishino et al. 2001).

MNGIE usually manifests in late adolescence with gastrointestinal dysmotility characterised by dysphagia, gastroparesis and recurrent vomiting that lead to cachexia. Neurological impairments comprise ptosis and ophthalmoparesis, with late onset and progressive axonal and demyelinating sensorimotor polyneuropathy. Cognitive impairment is typically absent. Lactic acidosis is usually mild, and the protein level in CSF is increased in most patients. T2-weighted and fluid attenuated inversion recovery MRI brain sequences show large confluent hyperintense signal changes indicating leukoencephalopathy. They are mainly localised in the periventricular areas, and may affect the cerebral peduncles, brainstem and pons.

**Treatment of Respiratory Chain Deficiencies**

No satisfactory therapy is presently available for respiratory chain deficiency. Treatment remains largely supportive and does not alter the course of the disease (Pfeffer et al. 2012). Among the symptomatic therapies, seizures should not be treated with valproate, which inhibits the respiratory chain.

Primary deficiency of CoQ<sub>10</sub> can be treated with high doses of COQ<sub>10</sub> with improvement of the clinical course. However, it may not be sufficient to prevent neurological deterioration (Auré et al. 2004).

In MELAS, L-arginine (intravenous or oral) treatment should be given and seems to prevent possible strokes.

In MNGIE, several attempts to restore normal levels of thymidine are being pursued by dialysis, platelet transfusions and even bone marrow transplantation.

Beside these few specific aspects, various ‘cocktails’ of vitamins and cofactors are used including CoQ<sub>10</sub>, phylloquinone or menadione in conjunction with ascorbate, succinate, thiamine and riboflavin. Riboflavin is useful in patients with defects in ACAD9, an assembly gene of complex I.

Pharmaceutical therapy with dichloroacetate to treat lactic acidosis does not improve clinical outcome (Stacpoole et al. 2006). Creatine supplementation to allow storage of phosphocreatine (an energy compound) has variable effects.

**PYRUVATE DEHYDROGENASE DEFICIENCY**

Pyruvate dehydrogenase complex (PDHc) deficiency is an important cause of encephalopathy associated with lactic acidosis. The clinical symptoms vary considerably, ranging from early lactic acidosis to intermittent ataxia, Leigh syndrome and progressive neurodegenerative disease with intellectual disability (Betendzen et al. 2006; Debray et al. 2006; De Meirleir et al. 2006) (see Fig 9.23).
**BIOCHEMICAL AND GENETIC BACKGROUND**

PDHc controls the entry of pyruvate, the glycolytic end-product, into mitochondria for oxidative metabolism and thus plays an important regulatory role in cellular energy metabolism in glycolytic-dependent organs such as the CNS. In the brain, PDHc is required for the formation of acetylcholine from acetyl-CoA. Thus, PDHc defects are expected to involve the nervous system.

PDHc is a mitochondrial multi-enzyme complex comprising three catalytic enzymes (E1, E2, E3), two regulatory enzymes (PDH kinase and phosphatase), and three coenzymes (thiamine, lipoic acid, FADH2). Additionally, an E3 binding protein (E3BP) probably has a structural function. The E1 component is a hetero-tetramer of two alpha- and beta subunits that share a thiamine pyrophosphate binding site. All components are encoded by nuclear genes located on the autosomes with the exception of the E1 alpha-subunit, which is located on chromosome Xp22.3.

The vast majority of patients have a defect in the E1 alpha-subunit with an X-linked transmission. More than 80% of disease-causing mutations in the PDHA1 gene have been identified. Most of the mutations originate de novo, and in 25% of cases, the mother is a carrier. Males and females are equally affected with severely affected females not as common, depending on the X-inactivation pattern in different tissues, notably in the brain (Tulinius et al. 2005; Willemsen et al. 2006). There are more than 20 reported cases of E3 defect with a common mutation found particularly in Ashkenazi Jewish patients. About the same number of E3BP deficiency cases have been reported without prevalent mutations (Brown et al. 2006; Miné et al. 2006). Mutations in the genes for the defects in E1 alpha subunit, PDH phosphatase and E2 component have been identified in a few patients (Head et al. 2005).

Genetic counselling is possible and reliable antenatal diagnosis relies on molecular analyses in families whose molecular defect has been determined.

**CLINICAL FEATURES OF PDH DEFICIENCY**

Male patients with PDHE1alpha deficiency can present with an overwhelming lactic acidosis in the neonatal period or in infancy. Hypotonia and apnoeic spells are the most frequent features. Most patients die within the first few months of life after a clinical course marked by failure to thrive, developmental delay, hypotonia, respiratory difficulties and seizures. In some patients, congenital brain malformations are present. Partial hypoplastic or thin corpus callosum, asymmetrical dilatation of ventricles and migrational defects are common. A second type of presentation, especially in males, includes Leigh syndrome (see previous sub-section). Symptoms occur after an apparently uneventful period of a few months. Seizures or episodes of weakness, respiratory failure, ataxia or dystonic posturing are the first manifestations. Later, these episodes may recur, and varying degrees of progressive neurological impairment and developmental delay are seen. Optic atrophy, ptosis, ophthalmoplegia and retinal degeneration have been mentioned.

In girls, atypical hypersrrhythmia or severe myoclonic seizures have been described. Facial dysmorphism suggesting fetal alcohol syndrome has been seen in patients with E1 deficiency. Many patients die within a few years but some survive with severe disability.

Finally, a small subset consists of patients who are clinically normal or have mild developmental delay and who experience intermittent neurological episodes of recurrent ataxia, acute dystonia, extrapyramidal movement disorders or muscle weakness with myopathy and/or peripheral neuropathy (Tulinius et al. 2005; Debray et al. 2006; Willemsen et al. 2006).

PDHE1alpha defects are the most frequent abnormality within these last two groups. However, the rare reported cases of PDH2, PDH3 and PDH phosphatase deficiencies can be associated with these clinical forms. E3BP deficiency may present in the neonatal period with lactic acidosis. However, most have survived well into childhood or even adulthood with variable impairment (Brown et al. 2006).

In neonatal-onset forms, MRI studies have shown severe abnormalities including agenesis or dysgenesis of the corpus callosum, heterotopias and pachygyria, asymmetrical ventriculomegaly, periventricular and subependymal cysts, and hypomyelination. In late-onset forms, progressive lesions in the basal ganglia and brainstem are common. A high peak of lactate on brain MRS is an indicative sign. Neuropathological findings confirm brain dysgenesis. Dysplasia and ectopia of the inferior olivary nuclei, dysplasia of the dentate nuclei, absence or hypoplasia of the medullary pyramids, periventricular neuronal heterotopias and deficient myelination are other findings (Head et al. 2005).

**BIOCHEMICAL FEATURES**

The most important laboratory tests for diagnosis are the measurement of lactate and pyruvate in blood and CSF. Both are usually elevated with a low to normal lactate to pyruvate ratio. These can be severe during the neonatal period or during episodes of deterioration. Definite diagnosis is made by assay of PDHc activity and molecular investigations.

**TREATMENT OF PDH DEFICIENCY**

Thiamine has been beneficial in a few patients. Dichloroacetate inhibits PDH kinase and is effective in lowering plasma lactate levels, although clinical improvement is not obvious (Berendzen et al. 2006; Stacpoole et al. 2006). By providing alternative energy fuel, the ketogenic diet is probably the most effective therapeutic approach.

**PYRUVATE CARBOXYLASE DEFICIENCY**

This is a rare autosomal recessive disorder presenting with lactic acidosis and neurological involvement.
**BIOCHEMICAL BACKGROUND**

Pyruvate carboxylase is a biotin-containing enzyme that catalyses the first step of gluconeogenesis by converting pyruvate to oxaloacetate. Pyruvate carboxylase also plays an anaplerotic role mainly in the brain and muscle by replenishing the tricarboxylic cycle. Pyruvate carboxylase is an astrocytic-specific enzyme that allows neurotransmitter synthesis by supplying glutamine, and is a key factor for myelin synthesis by providing citrate (Brun et al. 1999). Pyruvate carboxylase activity is expressed in fibroblasts with various residual enzymatic activities without frank correlation with clinical phenotypes. The most severe form (French or B phenotype) is associated with the absence of apoprotein on Western blot analysis, while in the milder form (North American or A phenotype) a detectable apoprotein is present. Various mutations in the pyruvate carboxylase gene have been found in both A and B phenotypes. Prenatal diagnosis is possible by measurement of pyruvate carboxylase activity in cultured amniocytes or in fresh chorionic villus samples, or by DNA analyses.

**CLINICAL FEATURES OF PYRUVATE CARBOXYLASE DEFICIENCY**

Three different clinical presentations are described according to the severity of clinical and biochemical manifestations (García-Cazorla et al. 2006). The French phenotype is a neonatal-onset form with an overwhelming lactic acidosis. Patients present within the first hours of life with acute and relentless neurological deterioration and metabolic ketoacidosis. They have hypokinetic lethargy, axial hypotonia, large-amplitude tremors, seizures, and abnormal ocular movements such as nystagmus.

Some patients have hepatic failure with persistent cytolysis and/or cholestasis. In addition, they may suffer a severe renal tubular acidosis with loss of bicarbonate. Death in the first few months of age is the rule.

Patients with the North American phenotype have a later onset with a progressive developmental delay, pyramidal signs, ataxia and nystagmus. In addition, they suffer intermittent metabolic ketoacidosis exacerbated by intercurrent infections. They have a longer survival. A third benign form has been described in rare patients with nearly normal development and who display intermittent ketoacidosis that improves with symptomatic treatment.

The biochemical pattern in neonatal forms is notable for the presence of a secondary hyperammonaemia with citrullinaemia, and a very high lactate/pyruvate ratio contrasting with a low beta-hydroxybutyrate/acetoacetate ratio. In CSF, lactate, lactate/pyruvate ratio, and alanine are increased and glutamine is decreased.

On neuroimaging, the most specific changes are ischaemic-like lesions with a diffuse white matter abnormality and periventricular cysts that are almost invariably haemorrhagic. Subdural, intraventricular and intracerebellar haemorrhages have also been reported. A similar description reported in two cases during the last trimester of pregnancy (Brun et al. 1999) underlines the prenatal severity and the irreversibility of brain involvement. In milder forms, leukodystrophy is the main sign. No basal ganglia lesions have been reported. CNS pathology has shown poor myelination involving cerebral and cerebellar white matter and sometimes the base of the pons, loss of neurons in the cerebral cortex, ventricular enlargement, thinning of the corpus callosum and proliferation of astrocytes.

**TREATMENT**

Therapeutic trials have attempted to replenish the Krebs cycle using glutamate, aspartate, citrate and odd-numbered fatty acid (triheptanoine) supplementation, but all have failed to prevent neurological deterioration (Mochel et al. 2005; García-Cazorla et al. 2006).

**DEFECTS IN KREBS CYCLE**

Defects in the Krebs cycle include dihydrolipoamide dehydrogenase deficiency, fumarase and alpha-ketoglutarate dehydrogenase deficiency.

**DIHYDROLIPOAMIDE DEHYDROGENASE DEFICIENCY**

Dihydrolipoamide dehydrogenase deficiency (DLD) is a component of a number of mitochondrial multienzymes, including pyruvate dehydrogenase, alpha-ketoglutarate dehydrogenase and branched-chain alpha-ketoacid dehydrogenase (Cameron et al. 2006). The clinical phenotype of DLD deficiency may range from a severe neonatal disorder to less severe presentations in childhood. In infancy, patients present with intermittent ketoadicosis, neurological signs, microcephaly and Leigh syndrome resulting in intellectual disability, ataxia, and hypotonia. A less severe form in childhood is characterised by episodic vomiting, ketoacidosis, liver dysfunction, hypotonia, and exercise intolerance between episodes in a few patients. Biologically, periods of decompensation are marked by hyperlactacidaemia accompanied by increased urinary excretion of alpha-ketoglutaric acid and, less constantly, by increased levels of branched-chain amino acids in plasma. Brain imaging investigations reveal various patterns from nonspecific periventricular white matter lesions to signs of Leigh syndrome with involvement of the basal ganglia. Mutations in the DLD gene have been reported, with a common mutation (229G>C in exon 9) in patients with Ashkenazi Jewish ancestry.

**FUMARASE DEFICIENCY**

Fumarase deficiency has been reported in a few children with severe neurological impairment (Kerrigan et al. 2000). The clinical phenotype is characterised in infancy by severe
developmental delay with hypotonia, seizures, facial dysmorphism, growth failure, relative macrocephaly, and death in the first years of life. Hyperlactacidaemia can be mild, but urinary excretion of fumaric acid is diagnostic. On brain MRI, lesions can be severe with ventriculomegaly, polymicrogyria, agenesis of the corpus callosum, decreased white matter volume and relative hypoplasia of the brainstem. Autopsy in a case has revealed hypomyelination and heterotopia located in cerebellum, occipital and parietal areas. The defect involves both cytosol and mitochondrial isoforms and appears to be autosomal recessive (Deschauer et al. 2006).

**ALPHA-KETOGLUTARATE DEFICIENCY**

Alpha-ketoglutarate deficiency has been described in a few neonates and infants (Bonnefont et al. 1992). The clinical presentation resembles that of early-onset PDH deficiency or the mitochondrial encephalomyopathies. Mild hyperlactacidaemia is associated with abnormal alpha-keto-glutaric acid in urine with or without increased excretion of other Krebs cycle intermediates. All patients had cortical atrophy but with striatal necrosis in some cases.

**MITOCHONDRIAL FATTY ACID BETA-OXIDATION DEFECTS**

Inborn errors in mitochondrial fatty acid oxidation represent a group of disorders that affect energy metabolism during fasting and metabolic stress. As a consequence, common features include acute metabolic decompensations associated with fasting, recurrent hypoglycaemia, Reye-like syndrome and unexplained sudden infant death. Chronic involvement of fatty-acid-dependent tissues may result in myopathy, cardiomyopathy, seizures and intellectual disability. More than 25 different defects are known (Longo et al. 2006; Tein et al. 2013).

**BIOCHEMICAL BACKGROUND OF MITOCHONDRIAL FATTY ACID OXIDATION**

The general pathway of mitochondrial fatty acid oxidation and the sites of the different known enzymatic defects are shown in Figure 9.26. Long-chain fatty acids converted to their CoA esters are first converted into long-chain acylcarnitines by carnitine palmityltransferase I (CPT-I) on the inner side of the outer mitochondrial membrane and are transported into the mitochondria by a carnitine acylcarnitine translocase (CACT)
and are then converted back to their CoA esters by CPT-II on the inside of the inner mitochondrial membrane. Medium and short-chain fatty acids readily diffuse into the mitochondrial matrix where they are then activated into their CoA esters for ensuant intramitochondrial beta-oxidation. Primary carnitine deficiency, CPT-I, CPT-II and translocase deficiencies impair mitochondrial transport of long-chain fatty acids and consequently beta-oxidation and ketogenesis. Intramitochondrial beta-oxidation involves four sequential steps with chain-length-specific enzymes. The first step requires four distinct acyl-CoA dehydrogenases, the very long-(VLCAD), long-(LCAD), medium-(MCAD) and short-chain acyl-CoA dehydrogenases (SCAD) which transform fatty acyl-CoA to enoyl-CoA. All four acyl-CoA dehydrogenases release electrons that pass to the respiratory chain via the electron transfer flavo-protein system. The latter specific electron transfer system is shared with other flavoprotein dehydrogenases: glutaryl-CoA- and isovaleryl-CoA-dehydrogenases. The three remaining steps of beta-oxidation can be performed by either a single trifunctional protein (TFP) for long-chain substrates, or by three chain-length-specific enzymes for short-, medium- or long-chain substrates. Each four-step beta-oxidation cycle releases acetyl-CoA, which enters the Krebs cycle in tissues such as heart and muscle. In liver, during the fasting state, acetyl-CoA is converted to ketones (ketogenesis), which are exported to peripheral organs, such as the brain, for final oxidation (ketolysis) and energy delivery.

Multiple acyl-CoA dehydrogenase (MAD) deficiency, called glutaric aciduria type II, is caused by a defect in the electron transfer system. Several alternative pathways become important when mitochondrial beta-oxidation is impaired. Omega-oxidation in microsomes and peroxisomes results in the production of characteristic dicarboxylic acids, and intramitochondrial conjugation of acyl-CoA to glycine and carnitine is an important mechanism of detoxification.

The biochemical diagnosis is based on the identification of abnormal dicarboxylic acids and their by-products (glycine, carnitine) in urine. Glutaric and branched-chain organic acidurias are associated in MAD deficiency. It should be emphasised that these specific patterns are best detected during an acute crisis, whereas in the homeostatic state the most reliable tests are the determination of total and esterified plasma carnitine levels and the identification of abnormal acylcarnitine profiles in plasma or dried blood spots.

Measurement of fatty acid oxidation rates in fresh lymphocytes or cultured skin fibroblasts is a useful tool to narrow the search for the specific defect involved. Direct enzymatic assay may then be performed for definitive diagnosis. Most defects are expressed in cultured fibroblasts; however, certain of these defects, such as muscle CPT-I and SCHAD deficiencies, may be tissue-specific (Sim et al. 2002).

**Genetic Background**

Overall, these disorders are frequent, but MCAD and CPT-II deficiencies are the most common. All the disorders that have been identified are inherited as autosomal recessive traits. Heterozygotes are usually normal. However, mothers with heterozygous long-chain 3-hydroxyacyl-CoA dehydrogenase (LCHAD) carrying an affected fetus may develop acute fatty liver of pregnancy in the third trimester. All the implicated genes have been cloned, and various disease-causing mutations have been described. Prevalent mutations are associated with MCAD, adolescent–adult form of CPT-II deficiency, and alpha and beta subunit of TFP deficiency. Antenatal diagnosis is available by measuring the enzymatic activity in cultured amniocytes or in chorionic villus samples, and more reliably, by molecular analysis. The high prevalence of these disorders associated with the availability of effective treatments and/or preventive measures make them good candidates for expanded newborn neonatal screening, which has been implemented in a number of countries, particularly for MCAD deficiency (Wilcken et al. 2003).

**Clinical Findings in Fatty Acid Oxidation Defects**

Patients affected with fatty acid oxidation defects have in common certain clinical presentations that are related to acute energy deprivation that may occur at any age from the neonatal period to adulthood. However, neonates, infants and young children are the most susceptible to decompensations during metabolic stress due to their limited glucose reserves. At birth, the affected neonates are unable to cope with the energy demand. In infants and young children, prolonged fasting and intercurrent infections are the most frequent precipitating factors. In older children, infections, fever and prolonged exercise may induce decompensations.

Clinically, these acutely ill patients may manifest life-threatening episodes of hypoketotic hypoglycaemia, cardiomyopathy and arrhythmia, coma and multi-organ failure. Hepatic encephalopathy with lactic acidosis and hyperammonaemia may mimic Reye syndrome and these children are at risk for recurrent ‘Reye-like’ episodes. Various degrees of rhabdomyolysis and/or cardiomyopathy are frequently associated, particularly in the long-chain fatty acid oxidation (FAO) disorders. In some cases, rapid unexpected death may suggest sudden infant death syndrome (SIDS). In most situations, this abrupt deterioration is associated with hypoketotic hypoglycaemia, lactic acidosis, hyperammonaemia, signs of liver failure, and muscular involvement with increased creatine kinase. Despite correction of blood glucose levels, some patients may display persistent lethargy, seizures, or opisthotonus due to concomitant cerebral oedema which suggests that elevated levels of fatty acid intermediates are neurotoxic. The mortality rate is high, particularly in the neonatal period. In survivors, many patients appear asymptomatic between episodes. Others display chronic involvement of muscle and heart, or suffer neurological sequelae with seizures and developmental delay. These neurological sequelae have been observed with MCAD deficiency, a disorder that is otherwise considered as the mildest fatty oxidation defect.

CPT II deficiency has three distinct clinical entities: an adult, infantile, and a perinatal form, all with an autosomal recessive inheritance pattern.
The adult CPT-II clinical phenotype is more benign and requires additional external triggers such as high-intensity exercise before the predominantly myopathic symptoms are elicited. The perinatal and infantile forms involve multiple organ systems. The perinatal disease is the most severe form and is invariably fatal. The introduction of mass spectrometry to analyse blood acylcarnitine profiles has revolutionised the diagnosis of fatty acid oxidation disorders including CPT-II deficiency. Its use in expanded neonatal screening programmes has made presymptomatic diagnosis a reality. An increasing number of mutations are being identified in the CPT-II gene with a distinct genotype–phenotype correlation in most cases.

**Specific features of fatty acid oxidation defects**

In neonates, beyond the acute presentation, abnormal organogenesis with dysmorphic features has been described. Cystic dysplasia of the brain and kidneys and polymicrogryia are encountered in some MAD and severe neonatal CPT-II-deficient patients (North et al. 1995). In SCAD deficiency, primary neurological signs such as hypotonia, hyperactivity, and developmental delay suggest severe impairment of cerebral maturation, potentially due to specific neurotoxicity of short-chain fatty acid metabolites (Tein 2002).

Recurrent episodes of rhabdomyolysis during mild to moderate prolonged exercise and proximal muscle weakness resulting from insufficient ATP production are characteristic signs of fatty acid oxidation defects, particularly of the long-chain fatty acid oxidation disorders. Chronic muscle weakness with lipid storage myopathy has been described in all these defects with the exception of liver-CPT-I deficiency. Muscular weakness associated with a progressive hypertrophic and/or dilated cardiomyopathy is a characteristic feature of primary systemic carnitine deficiency due to OCTN2 deficiency that most often presents in infancy. Later onset in adulthood associated with cardiac arrhythmia has been described. The mild form of MAD in adolescence and adulthood may present with progressive muscular weakness and exercise intolerance. The diagnosis is of importance since certain patients are clearly riboflavin-responsive.

Acute episodes of rhabdomyolysis are frequent and serious complications of defective long-chain fatty oxidation, i.e. CPT-II, VLCAD, LCHAD, TFP, and MAD deficiencies, but have also been seen in M/SCHAD deficiency. The most common cause of recurrent rhabdomyolysis in both male and female children is the mild adolescent–adult form of CPT-II deficiency. It is characterised by episodes of rhabdomyolysis without other organ involvement and without muscular weakness or creatine phosphokinase elevation between acute episodes. These episodes are triggered by prolonged exercise, fasting, intercurrent infections or cold exposure. Investigation for a fatty acid oxidation defect and particularly for CPT-II deficiency should be included in the diagnostic work-up of all patients presenting with recurrent myoglobinuria particularly if triggered by FAO stressors and should also be considered following a first attack of rhabdomyolysis if there are no obvious exogenous factors (e.g. toxins, trauma, vascular compromise, inflammation, etc.). The recurrent episodes of rhabdomyolysis may contribute to the ongoing muscle weakness in patients with trifunctional protein or VLCAD deficiency, who may also develop progressive axonal neuropathy and pigmentary retinopathy (den Boer et al. 2003; Spiekerkoetter et al. 2004; Tyni et al. 2004).

**Treatment in fatty acid oxidation defects**

The mainstay of therapy is the prevention of fasting and catabolic states, avoidance of mild to moderate prolonged exercise and cold exposure (shivering thermogenesis) and the prompt treatment of infection and fever. In acute situations, intravenous glucose infusion (8–10mg/kg/min) should be started without delay. There is no clear evidence that restricting dietary fat is useful in MCAD deficiency. In contrast, in patients with defects of long-chain fatty acid metabolism, a high carbohydrate, low-fat frequent feeding diet supplemented with medium-chain triglycerides may be beneficial. Essential fatty acids (EFA) should also be supplemented during a fat-restricted diet to prevent EFA deficiency. In patients with primary systemic carnitine (OCTN2) deficiency, lifelong high-dose oral carnitine supplementation (100–300mg/kg/day) is life saving and reverses the cardiomyopathy and myopathy within a few months. Some patients with mild variants of MAD and SCAD deficiencies may respond to riboflavin supplementation. Docosahexaenoic acid supplementation may improve/ameliorate the neuropathy and retinopathy in patients with LCHAD/TFP. Prevention of muscular pain and exercise intolerance by pre-exercise supplementation with oral corn-starch (provided there is not excessive weight gain) or medium-chain triglycerides may be beneficial (Gillingham et al. 2006; Ogier de Baulny and Superti-Furga 2006).

### Defects of Cholesterol Metabolism

#### Mevalonic aciduria

Mevalonic aciduria is an inborn error of cholesterol biosynthesis due to mevalonate kinase deficiency. This defect is associated with two clinical entities: hyper-IgD and periodic fever (HIDS), and classic mevalonic aciduria. HIDS is characterised by recurrent febrile crises that usually start in the first year of life without apparent neurological abnormalities.

Conversely, mevalonic aciduria is typically characterised by developmental delay, ataxia and dysmorphic features. Patients also experience acute episodes of fever.
The febrile seizures are often associated with hepatosplenomegaly, lymphadenopathy, abdominal symptoms, arthralgia and skin rashes. Presently, both disorders are considered to represent a unique disease with a clinical and biochemical continuum (Simon et al. 2004; Waterham and Clayton 2016).

**Biochemical Background and Pathogenesis**

Mevalonate kinase (MVK), which phosphorylates mevalonic acid, is a central enzyme in the isoprenoid pathway with cholesterol, dolichol and ubiquinone as major end products, rendering this pathway crucial for cell proliferation and cellular function (Fig. 9.27). The respective pathogenic roles of end-product shortage and toxicity of mevalonate accumulation are unclear. Either appears sufficient to explain multi-organ involvement and the teratogenic aspects of the disorder suggested by the high rate of miscarriages and stillbirths of malformed fetuses in affected families.

Postnatally, cerebellum and retina seem to be very susceptible to oxidative stress and/or to the toxicity of mevalonic acid. The mechanism of the autoinflammatory process remains unclear.

**Genetic Background**

Mevalonic aciduria and HIDS are autosomal recessive disorders with about 180 disease-causing mutations identified in the **MVK** gene. Some mutations are preferentially linked to the HIDS phenotype and three others are relatively common. Most patients are compound heterozygotes for two different mutations whose combined effect on residual enzymatic activity may account partially for phenotypic variability. Mevalonate kinase activity is expressed in fibroblasts, leukocytes, amniotic cells and chorionic villi. Prenatal diagnosis has been performed by assaying chorionic villus samples for enzymatic activity and amniotic fluid for mevalonic acid. More reliably, it can be performed by molecular testing in the gene for **MVK** (Waterham and Clayton 2016).

**Clinical Features**

The disorder may manifest from infancy to childhood with marked phenotypic heterogeneity. Severe forms may be lethal in early infancy or even lead to intrauterine death. Conversely, mild forms may survive infancy and lead to various disabilities. Mevalonic aciduria and HIDS have in common recurrent...
autoinflammatory episodes that last 3–5 days. They may recur as often as twice a month in infancy and tend to be less frequent later in childhood. They are marked by high fever, abdominal pain, vomiting and diarrhoea, lymphadenopathies, hepatosplenomegaly, arthralgias and skin rashes. In addition, patients affected with mevalonic aciduria have psychomotor retardation of varying degree. Most patients over 2 years develop progressive ataxia, dysarthria and progressive cerebellar atrophy. Muscle hypotonia with weakness is present in all patients. Reduced growth velocity, anaemia, permanent hepatosplenomegaly and lymphadenopathy are common. Mild dysmorphism was present in 8 of 11 cases reported by Hoffmann et al. (1993). Cataracts, uveitis, progressive retinal dystrophy and optic atrophy lead to progressive visual impairment. Partial or generalised tonic–clonic seizures have been described in a few patients. Less severely affected patients may survive until adolescence and even adulthood with mild disability and many fewer acute episodes of fever (Simon et al. 2004).

Biochemical Diagnosis
The diagnosis relies on organic acid analysis to identify mevalonic acid accumulation in body fluids. Mevalonic aciduria is usually elevated in the classic phenotype but may not be diagnostic in less severe forms. Permanent hyper-IgD and/or IgA is observed in HIDS, while in the mevalonic aciduria phenotype, it is inconstant. The best diagnostic tools are measurement of enzyme activity in leukocytes or fibroblasts, and the molecular investigation.

Treatment
No effective therapy is available. Supplementation with presumably deficient end products such as cholesterol, bile acids and ubiquinone has not produced any clinical or biochemical improvement. Blocking mevalonate hyperproduction by low doses of HMG-CoA reductase inhibitor (lovastatin) has resulted in severe crises in two patients with mevalonic aciduria. The best therapeutic approach seems to be intermittent corticosteroid therapy.

Other Disorders of Cholesterol Metabolism
Smith–Lemli–Opitz Syndrome
This syndrome results from a defect in the biosynthesis of cholesterol due to a block at the level of the enzyme 3-beta hydroxysterol D-7 reductase (Wätherham 2006). It is an autosomal recessive disease with intellectual disability and with severe automutilation. Typical dysmorphic findings are microcephaly, short upturned nose, often cleft palate or uvula, short stature, postaxial polydactyly and 2–3 toe syndactyly. Cardiac and genital defects are also common. Severe photosensitivity can be present. A clue to the diagnosis can be a low cholesterol and increase of 7-dehydrocholesterol and confirmed by genetic analysis in the DHCR7 gene.

Treatment with cholesterol supplementation and HMG-CoA reductase inhibition has shown some benefit on the failure to thrive and seems to have some effect on neuromotor development (Svoboda et al. 2012).

Other rare malformation syndromes due to defects in the biosynthesis of cholesterol include CHILD disease (congenital hemidysplasia with ichthyosiform erythroderma and limb defects), Conradi–Hünermann syndrome (X-linked dominant chondrodysplasia punctata) and desmosterolosis (Haas et al. 2001) (see Fig 9.25).

Niemann–Pick Disease Type C
Biochemical and Genetic Background
Niemann–Pick disease type C (NPC) is a neurovisceral and degenerative disorder of autosomal recessive inheritance. The estimated prevalence of NPC is 1:150 000. Biochemically, it is characterised by abnormal intracellular trafficking of endocytosed LDL-cholesterol resulting in accumulation of unesterified cholesterol in the endosomal/lysosomal system and impairment of the retrocontrolled reactions. In addition, partial inhibition of sphingomyelinase by free cholesterol is responsible for mild sphingolipid storage. In NPC fibroblasts, accumulation of free cholesterol is demonstrated by filipin staining, and study of LDL-induced cholesterol ester formation. Both tests serve the biological diagnosis and differentiate between classic and variant phenotypes (Vanier et al. 1991). Genetically, the disorder is due to mutations in two different genes that encode for two proteins functioning in tandem or in sequence in this metabolic pathway (Blom et al. 2003; Vanier and Millat 2003; Sleat et al. 2004). Approximately 95% of patients have mutations in the NPC1 gene (mapped at 18q11), which encodes a large membrane glycoprotein with late endosomal localisation. The remainder have mutations in the NPC2 gene (mapped at 14q24.3), encoding a small soluble lysosomal protein (Verot et al. 2007). More than 200 disease-causing mutations are described in the NPC1 gene as well as many polymorphisms. Reliable prenatal diagnosis uses molecular investigations on chorionic DNA when familial mutations have been clearly defined.

Clinical features of Niemann–Pick type C
In the neonatal period, NPC is mainly a visceral disease with hydrops fetalis, prolonged jaundice, or severe interstitial pneumonia, especially in patients with NPC2. A cholestatic icterus with hepatomegaly may be present in half the cases during the neonatal period. A few of these patients develop severe hepatic failure, leading to death before the appearance of neurological symptoms. Survivors have persistent hepatosplenomegaly, while jaundice spontaneously disappears before the age of 3 months. The onset of neurological problems can occur at any time over years or even decades in this group of patients.
Neurologically, patients are classified based on the age at onset, which is an indicator of prognosis despite some overlap between groups (Imrie et al. 2007; Vanier 2010).

In severe cases, patients present in infancy. They have hepatosplenomegaly, hypotonia, and delayed motor development before 2 years of age. Deterioration is rapid, mainly marked by loss of acquired skills, spasticity, and atonic episodes of a cataplectic nature but without epilepsy. Many of these patients die before 5 years of age without having developed ophthalmoplegia.

In late infantile forms, the onset is usually in early school years. The affected children suffer increasing physical and intellectual disability. Poor school progress and unsteady gait are usually the first neurological manifestations. Hepatomegaly and/or splenomegaly are often associated signs. Progressive additional features are cataplectic episodes seizures, vertical supranuclear ophthalmoplegia and swallowing difficulties. Many patients become wheelchair-dependent and incapable of continuing in school. Death occurs during the second decade of life in about 50% of cases. Death before 10 years of age and survival beyond the second decade are not unusual.

In the juvenile form (6–15 years), the onset of neurological signs is more insidious. Learning difficulties are the main initial signs and may be isolated for years before another neurological sign such as cerebellar ataxia, vertical gaze palsy (especially marked in downward movements) or psychiatric problems, lead to the diagnosis. Visceromegaly is not a prominent sign at this age. However, a neonatal history of prolonged icterus, present in about half the cases, could be a leading retrospective sign. Cataplexy and seizurs develop in about 20% of patients. The course of the disease is further marked by disabling cerebellar ataxia, dystar-thria, dysphagia and dementia. Other striking manifestations are psychiatric disturbances, dystonia, movement disorder and grimacing. Death usually occurs within the second decade.

In adults, the symptomatology is insidious, and patients mainly present with either prominent psychiatric signs or predominant movement and gait impairment (Klarner et al. 2007; Sévin et al. 2007; Sedel 2016).

Neuroimaging is generally not contributive towards diagnosis. Foamy histiocytes found in bone marrow aspirate stain with filipin. The definitive diagnosis requires cultured fibroblasts to perform the filipin staining test and the functional analysis of cholesterol esterification. Nowadays, confirmation of diagnosis is performed by mutational analysis.

No specific treatment is available. Cataplexy can be improved by clomipramine or modafinil. Inhibition of glycolipid synthesis by miglustat has been studied in a number of patients and can improve or stabilise the neurological features (Sedel 2016).

Wolman Disease and Cholesterol Ester Storage Disease

Wolman disease and cholesterol ester storage disease (CESD) are two phenotypic expressions of lysosomal acid lipase (LAL) deficiency, which results in massive accumulation of cholesteryl esters and triglycerides in most tissues. Wolman disease represents the early-onset form, which is uniformly fatal, while CESD is a more benign type with later onset (Aassmann and Seedorf 1995). Both disorders are autosomal recessive. Structural mutations of the \( \text{LAL} \) gene, which has been localised to chromosome 10 (10q23.2–23.3), have already been identified without clear genotype–phenotype correlation (Muntoni et al. 1995).

Prenatal diagnosis is available by assaying LAL activity in amniotic cells or chorionic villus samples.

Clinical features include severe diarrhoea, hepatomegaly and failure to thrive. Hypotonia and intellectual disability become apparent after initially normal development. In Wolman disease, massive calcification of the adrenals is characteristic. Hepatomegaly, increased transaminases, progressive liver fibrosis and cirrhosis can be seen in children and adults (Burton et al. 2015).

Diagnosis is based on the demonstration of LAL deficiency in cultured fibroblasts, lymphocytes or other tissues. Hyperlipoproteinaemia is common in CESD but absent in Wolman disease.

Recently ERT with Sebelipase alfa was developed and studies resulted in a reduction in multiple disease-related hepatic and lipid abnormalities in children and adults with LAL deficiency.
older than 2 years is 200–430 µmol/L (30–65 mg/dL). Low levels are frequent in infants and younger children and are of no diagnostic value. Plasma level is elevated during pregnancy, with high oestrogen concentration, liver cirrhosis, malignant disease and hyperthyroidism. Ninety-five per cent of patients with Wilson disease have markedly diminished ceruloplasmin levels. However, this is not a constant finding and ceruloplasmin levels as low as those in Wilson disease (e.g. in nephrosis patients) may not be associated with symptoms. The same applies to familial ceruloplasmin deficiency, in which clinical manifestations include blepharospasm and retinal degeneration. This rare disease is associated with iron storage in CSF and is due to a deficit of a copper ferroxidase essential for iron equilibrium (Xu et al. 2004).

The basic defect is liver accumulation of free copper, due to deficient ceruloplasmin, that acts as a toxic substance. The basic molecular defect is absence or reduced function of a protein that has copper-transporting ATPase activity and a marked amino acid homology with the copper transport protein that is mutated in Menkes kinky hair disease (Tanzi et al. 1993). This impedes transport of copper from hepatocytes to bile and results in accumulation of copper. The gene coding for this protein maps to 13q14.3, and a large number of mutations are known (Thomas et al. 1995). Most patients appear to be compound heterozygotes for different mutations, and the genotype seems to affect clinical findings, particularly the age at onset (Houwen et al. 1995).

Accumulation of copper initially damages hepatocyte mitochondria and peroxisomes. Eventually, excess copper leaks from the liver into blood and is taken up by tissues. In the brain, the basal ganglia are particularly affected with secondary damage.

Pathologically, the liver shows focal necrosis with secondary postnecrotic cirrhosis. Copper is initially diffusely spread within the cytoplasm and secondarily becomes sequestered within lysosomes. In the brain, the basal ganglia show spongy degeneration, loss of neurons and large numbers of large protoplasmic astrocytes (Alzheimer type II glia). The frontal lobe cortex is similarly involved. Copper is present in the cornea and is deposited in clumps close to the endothelial surface of Descemet’s membrane, which is responsible for the Kayser–Fleischer ring.

**Clinical features of Wilson disease**

Wilson disease is transmitted as an autosomal recessive trait with a frequency of 1 in 100 000 in homozygous form. In about one-third of cases, the disorder presents at 3–5 years of age with hepatic manifestations. Of all patients, 30% present with neurological symptoms, usually after eight years of age. In about 10% of children, Wilson disease first presents as an acute or intermittent haemolytic anaemia (Prella et al. 2001); the remainder may show a mixture of hepatic and cerebral changes. Psychiatric symptoms are frequent (Oder et al. 1991), sometimes so predominant as to constitute a psychiatric form of the disorder.

Neurological manifestations usually begin from 10 years of age onwards, except that, in some populations, rare patients may have neurological symptoms as early as 3 years. All types of movement disorder can be seen including tremor and myoclonus. Facial grimacing is a classic feature. Four major clinical types are recognised: the dystonic form, the ‘pseudosclerotic’ type, a parkinsonian–rigid form (Oder et al. 1991), and a choreic form.

Most cases of the neurological form with onset before adulthood are of the dystonic type with facio-linguo-pharyngeal involvement causing facial masking, dysarthria and dysphagia, associated with or preceded by intellectual deterioration or psychiatric problems (Medalia et al. 1988). Speech is often severely impaired. Choreic and myoclonic movements are frequently present.

![Figure 9.28 Wilson disease. (a) T1-weighted image showing bilaterally low signal from the basal ganglia and thalami. Global atrophy of brain is also evident. (b) T2-weighted image of another patient showing intense signal from both putamina.](image)
observed, and painful spasms are common. Pyramidal signs are infrequent. The course may be acute, but, in most cases, it is slowly progressive. During the late stages, muscular rigidity is generalised, bizarre dyskinesias often appear and the patients are severely incapacitated. Psychiatric manifestations are often prominent with severe psychotic or depressive symptoms. The pseudosclerotic form of Wilson disease is rare in adolescents, but intermediate types are not uncommon. In such cases, dystonia, intention tremor and asterixis are prominent.

Hypokinesia and rigidity, sometimes with tremor at rest are features of the rigid–akinetic type. In many cases, several different syndromes coexist or occur in succession. In a few cases, tongue dyskinesia or tongue tremor with dysarthria are the sole manifestations.

Almost all patients with neurological features have a Kayser–Fleischer ring that may be seen with the naked eye or require slit lamp examination. It may be complete or incomplete and may be present even in the presence of normal liver function.

**DIAGNOSIS OF WILSON DISEASE**

The diagnosis of Wilson disease rests on a high index of suspicion. Wilson disease must be thought of first in any child or adolescent with dystonia and an extrapyramidal syndrome, and in those with psychiatric and behavioural disorders, because this is a treatable disease. The Kayser–Fleischer ring is an essential clue.

In about half the cases, neuroimaging shows symmetrical areas of hypodensity in the thalamus and basal ganglia (Fig. 9.25) that are visible both with CT and MRI (Roh et al. 1994) as low T1 and high T2 signals. Such abnormalities may decrease or disappear with chelating treatment.

Urinary copper is high (in excess of 0.8µmol/day), as is non-ceruloplasmin-bound copper. Serum ceruloplasmin level is generally higher than 13–17µmol/L (100mg/L), and serum copper is higher than 9µmol/L (50mg/dL; normal value 14–30µmol/L, 90–160mg/dL). Increased urinary excretion of copper (greater than 100micrograms per 24hrs), especially after challenge with D-penicillamine 500mg and a repeated lamp examination. It may be complete or incomplete and may be present even in the presence of normal liver function.

**TREATMENT TREATMENT IN WILSON DISEASE**

Initial therapy needs to eliminate excess copper in symptomatic patients and patients then need lifelong maintenance therapy to reduce copper level and prevent reaccumulation of copper. Various agents are used. They include chelators of copper, including D-penicillamine, triethylene tetramine (trientine) and tetrathiomolybdate. Chelators are used to produce a negative copper balance and decrease the copper load.

The first effective chelating treatment was D-penicillamine (15–25mg/kg/day; 0.5–0.75 mg/day for children under 10 years, 1 mg/day in older patients), given orally in divided doses. Pyridoxine 25mg/kg/day is added because of the antivitamin effect of penicillamine.

Treatment should be started progressively and the dosage should be slowly increased. Side effects are frequent and may be severe in up to a quarter of cases. They include lupus erythematosus, nephrotic syndrome, fever, rashes, pyridoxine deficiency, thrombocytopenia and, rarely, myasthenic symptoms.

Triethylene tetramine (trientine) at a dose of 40–50mg/kg/day seems to be very efficacious; it is well tolerated and is regarded as the first-choice drug by some authorities (Brewer et al. 2006). Its association with zinc seems particularly effective. It is clearly indicated when penicillamine is poorly tolerated or as initial treatment in moderate or severe forms of the disorder. However, it may also produce transient aggravation.

Treatment with chelators must be closely monitored clinically and by watching copper excretion, which often increases dramatically upon starting treatment then returns to normal over a few months. When effective, the Kayser–Fleischer rings begin to fade in a few weeks and should disappear completely in about a year.

Oral zinc sulphate treatment, at a dosage of 300–600mg/day (Hoogenraad 2006), is meant to decrease toxic free copper by binding it to metallothionine, decreasing gut absorption of copper and rendering it non-toxic. It is often used as a complement to chelators and is also effective alone as shown by normalisation or decrease of free blood copper and disappearance of Kayser–Fleischer rings. Some investigators consider it to be the first-choice treatment (Hoogenraad 2006). Others prefer to use it together with trientine for moderate or severe forms and advise zinc for mild neurological cases or non-neurological presentations (Brewer et al. 2006). Zinc has been used successfully for presymptomatic children with subclinical liver involvement as indicated by high levels of transaminases. Gastrointestinal intolerance may occur. It does not produce iatrogenic paroxysmal intoxication. A low copper diet is recommended in all cases.

Most children who have isolated hepatic disease usually do well on treatment. Approximately 40–50% of those with neurological manifestations become asymptomatic. Patients with advanced liver disease or acute liver failure can benefit from liver transplantation, which is often practised in refractory disease (Dhawan et al. 2005).

Zinc therapy is important in young presymptomatic patients, pregnant patients, and as a maintenance after de-coppering treatment.

**MENKES DISEASE**

(Kinky Hair Disease, Steely Hair Disease, Trichopoliodystrophy)

Menkes disease is an uncommon, X-linked disease (incidence 1 in 50,000 births) characterised pathologically by multiple
focal involvement of the brain grey matter and by low serum copper and ceruloplasmin. Figures 9.29 and 9.30 the gene (MNK) is located at Xq13.3 and codes for a copper-transporting ATPase (ATPase7A). Deficiency of this protein results in lack of transport of copper to cellular organelles. There is a secondary deficit of several copper-dependent enzymes including cytochrome c oxidase and lysine oxidase, accounting for bone and connective tissue abnormalities. The expression of the disease can be extremely diverse even with the same mutation (Borm et al. 2004). Many mutations have been identified: in particular splicing mutations resulting in an incomplete gene with partial activity responsible for allelic variants, especially the occipital horn syndrome (Qi and Byers 1998).

**Pathology and pathophysiology**

Copper levels are low in the liver and brain but are elevated in intestinal mucosa and kidneys. Orally administered copper is poorly absorbed but intravenous copper produces a brisk rise of serum copper. The copper content of fibroblasts is markedly elevated. This suggests maldistribution of copper that becomes unavailable for the synthesis of copper-containing enzymes. DNA analysis can permit first trimester diagnosis if the mutation in the family has been identified (Tümer et al. 1994).

Defective activity of metalloenzymes produces diffuse disturbances that particularly affect arteries in the brain and elsewhere, and cause extensive focal degeneration of the grey matter with neuronal loss and gliosis. There is profound involvement of the cerebellar cortex (Robain et al. 1988) with loss of Purkinje cells. Remaining cells show abnormal dendritic and axonal swellings.

**Clinical manifestations of Menkes disease**

Clinical manifestations may be present from the neonatal period or after 2–3 months. Failure to thrive is the most striking feature. Seizures soon occur that can include infantile spasms (Bahi-Buisson et al. 2006; Bindu et al. 2007), and a profound deterioration with hypotonia becomes apparent. Hypothermia is an important clue although commonly unrecognized. The hair is sparse, brittle, and grey or silvery. Microscopic examination easily confirms the diagnosis by showing pili torti and occasionally trichorrhexis nodosa. The cherubic appearance of affected infants is striking. In the first few weeks of life the primary hair may be normal; however, even neonatal hair may have a special appearance (Gu et al. 2005). The skin is very loose.

Hydroureters and hydronephrosis are common. Generalised osteoporosis, metaphyseal spurring, diaphyseal periosteal reaction, scalloping of the posterior aspect of the vertebral bodies and multiple wormian bones are often present. Angiography shows elongated and tortuous arteries but is not routinely indicated. However, tortuosity of intracranial arteries is well demonstrated by imaging and aneurysms may develop. Neuroimaging techniques show diffuse brain atrophy, defective myelination and often subdural haematomas. In some cases, more focal abnormalities with areas of cortical atrophy and associated hypodensity are seen (Takahashi et al. 1993). The course is rapidly downhill and the mean age at death is 19 months.

Early diagnosis may be difficult to make firmly as low copper levels may occur normally in the neonatal period and this may delay the diagnosis, which is highly regrettable as copper-histidine therapy should be started early. A low urine homo-vanillic/vanillylmandelic acid ratio due to the
decreased activity of the copper-dependent enzyme dopamine beta-hydroxylase may be suggestive (Matsuo et al. 2005). Prenatal diagnosis can be done by genetic analysis (Gu et al. 2002).

Other early clues are a low birthweight and preterm birth, which are present in a third of cases, and the unusual colouration of the hair.

**Variants of Kinky Hair Disease**

Milder cases of the condition are known and may present with ataxia and mild intellectual disability (Kodama et al. 1999) and run a less malignant course. Other atypical cases have presented with hypotonia and hair anomalies but without seizures or hypothermia (Inagaki et al. 1988). The occipital horn syndrome features hyperelastic and bruiseable skin, hyperextensible joints and calcification at the junction of the neck muscles and occipital bones (Qi and Byers 1998). Abnormalities in copper metabolism are similar to those of Menkes disease, but less marked (Proud et al. 1996). There may be intellectual disability.

**Treatment of Menkes Disease**

Administration of copper-histidine, either by subcutaneous or intramuscular injection, not only corrects copper levels but results in clinical improvement, particularly if started as early as 35 weeks gestational age (Tümer et al. 1996) and not later than 10 days post-term. Munakata et al. (2005) have shown that the treatment improves some of the biochemical disturbances (increased lactate and decreased N-acetyl aspartic acid as shown by proton MRS). However, evaluation of results is still difficult. After the treatment is started, after the neonatal period, histidine copper has no more effect due to the blood–brain barrier and seizures will increase. Improvement with copper-histine is also dependent on the mutation, some genotypes having a partial copper transport capacity.

---

**DISORDERS OF PURINE AND PYRIMIDINE METABOLISM**

**PURINES**

Purines are essential building-stones for nucleic acids, but are also components of other important biological molecules such as ATP, GTP, cAMP, NADH and Acetyl-COA. The purine source is exogenous (meat) and endogenous de novo synthesis. This biosynthesis is in several steps. They are catabolised to uric acid and then excreted through the kidneys. The purines are synthesised through several steps and then degraded and excreted as uric acid.

There are three disorders in purine synthesis that lead to well characterised neurological disease; a few others are less well described and more rare.

---

**LESCH–NYHAN DISEASE**

**Pathophysiology**

Lesch–Nyhan disease is an X-linked deficiency of the purine salvage enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT). HGPRT catalyses the conversion of hypoxanthine to inosine monophosphate (IMP) and guanine to guanosine monophosphate (GMP), an important salvage pathway for the synthesis of purines. As a consequence of this enzymatic defect, hypoxanthine and guanine cannot be converted to the corresponding nucleotides IMP and GMP. Hypoxanthine is then catabolised to xanthine and uric acid and excreted. The increased
production of uric acid and the depletion of hypoxanthine, which acts as a feedback regulator of uric acid synthesis, leads to a markedly increased concentration of uric acid in all body fluids, hyperuricaemia and hyperuricosuria and its consequences (urolithiasis and gout). The mechanism of the neurological disease manifestations is still obscure and is unrelated to uric acid. They may result, at least in part, from a mixture of abnormal neurodevelopment and neurotransmitter abnormalities (Hyland et al. 2004). Failure of development of dopaminergic synaptic terminals has been demonstrated. The concentration of dopamine and the activity of enzymes involved in its synthesis are lessened, and this and other alterations in neurotransmitter balance within the basal ganglia are probably important.

There is a striking degree of genetic heterogeneity of HGPRT defects. Over 300 pathogenic mutations in the HGPRT gene located at Xq26–q27 are known (Jinnah et al. 2004), and the spectrum of severity is extremely wide (Puig et al. 2001). This can range from asymptomatic cases to the most severe classic syndrome, depending on the degree of residual enzyme activity and probably also other yet unknown modulating factors.

Genotype–phenotype studies indicate no clear relationship to specific mutations (Jinnah et al. 2004); however, mutations that produce a null enzyme are typically associated with the most severe phenotype.

**Clinical manifestations of Lesch–Nyhan disease**

The clinical manifestations are striking. They become apparent during the first year of life in the form of developmental delay and generalised hypotonia or dystonia. Patients are usually mistakenly diagnosed with quadriplegic or dystonic cerebral palsy. Abnormal movements usually appear between 6 months to 1 year of age. Dystonia is constant; choreoathetosis or ballismus are subsequently superimposed in 44–90% of patients (Jinnah et al. 2006) but are not progressive after the first few years (see also Chapter 19). Some degree of spasticity develops progressively. Ocular saccades are sometimes initiated by head movements or eye blinking, reflecting involvement of the basal ganglia. Seizures are uncommon but bouts of dystonic opisthotonus can occur and may resemble seizures.

Self-mutilation is the most striking feature and one that raises major problems. The most common behaviour is biting of the fingers, lips and tongue that appears usually between 2 and 4 years of age but sometimes later. This behaviour often results in severe lesions of the mouth or hands that are difficult to prevent. Head banging, extension of the arms while being wheeled through doorways or putting fingers in the wheel spokes, and eye poking come next in frequency (Robey et al. 2003). Affected children are variably intellectually disabled, usually mildly or moderately with global IQ scores between 60 and 70, but most suffer from attention deficit and difficulties of comprehension of complex or lengthy speech and in multistep reasoning. They are severely disturbed by their compulsion to self-mutilate and appear happier when maintained in restraints.

In late childhood or adolescence, haematuria, renal calculi and ultimately renal failure develop. Gouty arthritis can also be observed.

**Diagnosis and treatment of Lesch–Nyhan disease**

The diagnosis is suggested by elevated serum uric acid levels. However, determination of the ratio of uric acid to creatinine in a morning sample of urine is a better screening test. Enzymatic analysis of HGPRT in erythrocytes or fibroblasts confirms the diagnosis, followed by gene analysis. Asymptomatic carrier mothers can be identified.

Treatment with allopurinol is effective in relieving the symptoms due to high uric acid but has no impact on the neurological manifestations. Attempts at gene therapy are being pursued. Treatment of the neurological problem is mainly with behaviour modifiers and neurotransmitter therapy. Gabapentin has been reported to be efficacious in one patient. Deep brain stimulation has been tried with variable success.

**Partial deficits in hypoxanthine-guanine phosphoribosyltransferase and variants of Lesch–Nyhan disease**

Deficits in HGPRT less complete than those in the classic Lesch–Nyhan disease (<1.3% of normal activity) can produce various clinical pictures. Patients with an enzymatic activity level of more than 8.5% of normal have no neurological symptoms but may have uric acid-related problems. At intermediate range, a neurological picture similar to Lesch–Nyhan syndrome but without intellectual disability and self-mutilation may be observed (Puig et al. 2001). Other variants with mild intellectual disability, spasticity and skeletal malformations, choreoathetosis, developmental delay and deafness have been described. Although intelligence is normal in most cases, comparison of patients with partial HGPRT deficiency with normal individuals has shown intermediate levels between those of controls and those with the classic syndrome.

**Adenosylsuccinate lyase deficiency**

Jaeken and van den Berghe (1984) were the first to report on an autism syndrome with intellectual disability in association with the presence of large amounts of succinyladenosine (S-AMP) and succinylaminomidazole carboxamide riboside (SAICAR) in the CSF and urine.
Pathophysiology

Adenosylsuccinate lyase (ADSL) catalyses two steps in the synthesis of purine nucleotides. This leads to conversion of SAICAR into AICAR and the conversion of S-AMP into AMP. When ADSL is deficient SAICAR and S-AMP accumulate.

Clinical features

Most patients have been classified as type 1, combining psychomotor delay and autistic features, followed by epilepsy in childhood. Later, patients with neonatal intractable epileptic encephalopathy were described and even an earlier presentation is intrauterine growth impairment, microcephaly, fetal hypokinesia and absent fetal heart rate variability (Moucheh et al. 2007). In type 2 patients intellectual disability is less pronounced with a picture of autism, a behaviour resembling Angelman syndrome (Gitiaux et al. 2009 see also Chapter 5) or associated with seizures. This disorder should be thought of in infants with early-onset seizures and in children with autism spectrum disorder.

Genetics

ADSL (gene ADSL on 22q) deficiency is an autosomal recessive disorder. There is a common mutation R426H in type 1 and R303C in milder cases.

Diagnosis

This can be confirmed by the presence of succinylpurines in the CSF (SAICAR, S-Ado). Many gene mutations are known.

Treatment

Therapeutic trials have been performed with D-ribose and uridine, however results were not convincing (Jurecka et al. 2008).

Disorders of Pyrimidine Degradation

Defects of dihydro pyrimidine dehydrogenase (DPD) (van Gennip et al. 1994) and of dihydropyrimidinidase dehydrogenase (DHP) (Putman et al. 1997) have been reported to be associated with convulsions, intellectual disability or choreoathetosis, and sometimes dysmorphism.

Dihydropyrimidine dehydrogenase deficiency

Clinical features of dihydropyrimidine dehydrogenase deficiency (DPD) can be found in children with epilepsy and psychomotor delay, associated with hypertonia, growth delay, microcephaly and autistic features (van Gennip 1997). The second presentation is in adults who receive 5-fluorouracil, used in cancer treatment and resulting, in these patients, in highly enhanced toxicity with neutropenia, stomatitis, gastrointestinal perforations and neurological deterioration.

There is an increase of excretion of uracil. The diagnosis can be confirmed enzymatically or by gene sequencing. The infantile form is inherited as an autosomal recessive form; the adult form is seen in heterozygotes.

Dihydropyrimidinidase deficiency

Dihydropyrimidinidase deficiency (DHP) (Assmann et al. 1997, Kuilenburg 2010) leads to severe developmental delay, epilepsy, dysmorphic features or microcephaly. Some have no symptoms at all. Some patients also have cyclic vomiting, reflux or malabsorption.

Urinary dihydrouracil and dihydrothymine are elevated. The enzyme assay requires a liver biopsy. Mutation analysis of the DPYS gene is possible.

Beta-ureidopropionase deficiency

Beta-ureidopropionase (also called Beta-alanine synthase) deficiency, can result in severe dystonia, intellectual disability and a severe defect in myelination, cerebellar hypoplasia but is also seen in asymptomatic infants (Assmann et al. 2006).

There is an elevation of ureidopropionic acid and ureidoisobutyric acid in the urine.

Disorders of Creatine Synthesis and Transport

Creatine and phosphocreatine (PCr) are major components in energy storage and transmission. Creatine is mainly synthesised in the liver and the pancreas in a two-step mechanism from glycine, arginine and methionine and finally converted by non-enzymatic cyclisation to creatinine (Fig. 9.31). Humans maintain their creatine pool by biosynthesis and nutritional uptake of 1–2 g/day. Creatine is transported via the blood and at the cellular level by the Cr-transporter system (CrT).

Three diseases have been described in this pathway: arginine glycine amidinore transferase deficiency (AGAT), guanidino acetate methyl transferase deficiency (GAMT) and creatine transporter deficiency (CrT). They lead to absence of creatine and phosphocreatine in the brain.

Developmental delay, severe speech disturbances, intellectual disability and autistic behaviour are common, and usually recognised between 6–12 months and more clearly between 2–3 years of age.
GUANIDINOACETATE METHYLTRANSFERASE DEFICIENCY

CLINICAL FEATURES

The first patient with guanidinoacetate methyltransferase (GAMT) deficiency was reported by Stöckler et al. (1994). The child was normal at birth but became hypotonic, and developed extrapyramidal dystonic symptoms and severe psychomotor retardation. MRI at 12 months of age showed abnormal signals in the globus pallidus. Proton MRS revealed the absence of brain creatine and creatine phosphate signals, suggesting an inborn error of creatine synthesis. Deficient GAMT activity was confirmed in liver tissue.

Most patients have the severe phenotype with an extrapyramidal movement disorder and drug-resistant epilepsy. The onset of the seizures associated with a developmental regression usually occurs in the second and third year. Seizures include myoclonic, generalized tonic-clonic, partial complex seizures and drop-attacks (Mercimek-Mahmutoglu et al. 2006). Most children have no active speech. On MRI, there is delayed myelination and/or bilateral hyperintensity in the globus pallidus (Schulze 2003).

DIAGNOSIS

Pathognomonic laboratory findings in GAMT-deficiency consist of decreased concentrations of creatine and creatinine in blood, CSF and urine, while guanidinoacetate, the precursor of creatine, is elevated in the same fluids. The absence of a creatine PCr signal in brain MRS is almost diagnostic. Further biochemical and genetic studies allow the identification of the underlying defect.

GAMT-deficiency is an inherited autosomal disease; the gene maps to chromosome 19p13.3. Several mutations have been identified.

TREATMENT

Early treatment can be important. Creatine monohydrate 300–400mg/kg per day in total, given in 3–6 doses (Stickeler-Ipsiroglu et al. 2006) resulted in an improvement of the extrapyramidal signs and better control of the seizures.

Further guanidinoacetate (GAA) reduction by giving 800mg ornitine per kg per day in 3–6 doses and dietary arginine restriction requiring 0.4–0.7g natural protein per kg and a synthetic arginine-free mixture with essential amino acids gave some further improvement. A further reduction of GAA precursors can be obtained by adding sodium benzoate (100mg/kg/day) (Stockler-Ipsiroglu et al. 2006).

ARGININE GLYCINE AMIDINOTRANSFERASE DEFICIENCY

AGAT deficiency was first described in 2001 (Item et al. 2001).

CLINICAL FEATURES

Very few patients have been described. Most symptoms such as developmental delay, delayed speech and mild to moderate intellectual disability are nonspecific. No seizures have been reported.
Part IV Metabolic and Heredodegenerative Disorders

**Diagnosis**
Creatine in serum is normal, GAA slightly decreased and the excretion of GAA in urine extremely low. The enzymatic diagnosis of AGAT-deficiency can be made in fibroblasts and lymphoblasts and confirmed by gene sequencing (GATM) on chromosome 15q15.3.

**Treatment**
Treatment consists of creatine monohydrate 400mg/kg/day in total given in 3–6 doses (Stockler-Ipsioglu 2006), again with good results if treatment is started early.

**X-Linked Creatine Transporter Deficiency**
Several families have been described since the first patient in 2001 (Salomons 2001) (Fig. 9.32).

**Clinical Features**
This disorder features mild intellectual disability and severe delay in the expression of speech and language function in boys. Apart from mild hypotonia, motor functions are normal. Focal seizures, failure to thrive and behavioural abnormalities can be part of the clinical picture (Degrauw et al. 2002). The speech disorder is an expressive aphasia. Behaviour abnormalities have been described as aggressive with autistic features. Seizures are usually mild and infrequent (Fons et al. 2009). A variety of other organ manifestations such as megacolon, chronic constipation and gastrointestinal ulcers have been described. Females can have a mild cognitive delay and learning difficulties.

**Diagnosis**
Creatine concentrations in plasma and urine are elevated, while GAA is normal. The urinary creatine to creatinine ratio is increased, but can be normal in females. MRI is normal and MRS reveals reduced or almost complete absence of the creatine signal (Fig. 9.32). Mutations are found in the X-linked creatine transporter *SLC6A8* gene mapping to Xq28 (Salomons et al. 2003).

**Treatment**
There is not an efficient treatment (Stockler-Ipsioglu 2006). Adding L-arginine 400mg/kg/day and L-glycine 150mg/kg/day is still inconsistent in success. Seizures can usually be controlled with valproate or carbamazepine.

**Cerebrotendinous Xanthomatosis**
Cerebrotendinous xanthomatosis (CTX) is a rare inherited disorder of bile acid metabolism leading to the accumulation of cholestanol and cholesterol in most tissues including the CNS. It is responsible for xanthomas, early cataract, severe neurological deterioration and premature atherosclerosis. In spite of its rarity, a diagnosis is important because early treatment can halt and, in some, cases reverse the neurological impairment (Federico and Dotti 2003).
Cholestatic jaundice in infancy might be the first manifestation (Clayton 2002). This improves but subsequent symptoms appear: intellectual disability in the first decade and cataracts as early as 5 years. In the second decade, additional neurological signs appear with spastic paraparesis, peripheral neuropathy, ataxia and dysphasia. Psychiatric symptoms mimicking schizophrenia also occur (Berginer et al. 1988).

Tendon xanthomata can develop, from the second decade on. Premature coronary heart disease or atherosclerosis have been reported. Xanthomas may be absent in the early stages of the disorder or even never develop, and a few patients have had normal intelligence in spite of neurological impairment such as ataxia, paresis or peripheral neuropathy (Björkhem et al. 1987). In the late and final stage, neurological deterioration is severe, speech becomes difficult, and swallowing difficulties and sphincter incontinence develop. MRI studies of the brain and spinal cord have demonstrated cerebral, cerebellar and spinal cord atrophy (Bencze et al. 1990) and demyelination in the cerebrum, cerebellum, and brainstem (Federico and Dotti 2003) with increased signal intensity in the cerebellar white matter and dentate nucleus.

Results of neurophysiological studies are consistent with a demyelinating or mixed axonal and demyelinating peripheral neuropathy (Arpa et al. 1995). The biochemical diagnosis is made by the determination of excessive urinary excretion of bile alcohols and by the measurement of cholestanol/cholesterol ratio in serum (Björkhem et al. 1987; Arpa et al. 1995). The defect impairs the mitochondrial part of bile acid synthesis from cholesterol and results in the accumulation of cholestanol and cholesterol. The definitive diagnosis relies on the measurement of 7-alpha-hydroxylase in cultured fibroblasts.

Cerebrotendinous xanthomatosis is an autosomal recessive disorder resulting from a mutation of the CYP27A1 gene affecting the 27-hydroxylase mitochondrial enzyme activity.

Supplementation of the end-product of bile acid synthesis, chenodeoxycholic acid, decreases cholestanol accumulation and results in a clinical, radiological and neurophysiological improvement (Björkhem et al. 1987). Addition of simvastatin, an inhibitor of 3-hydroxy-3-methyl-glutaryl-CoA reductase, may further improve the therapeutic effects.

HYPOTONIA–CYSTINURIA SYNDROME

This syndrome resembles the Prader-Willi syndrome (PWS) clinically and is characterised by generalised severe hypotonia at birth, nephrolithiasis due to cystinuria, growth hormone deficiency, some facial dysmorphia and failure to thrive. Later, patients develop hyperphagia and rapid weight gain.

Cystinuria is found in by urinary amino acid analysis.

REFERENCES

It is caused by a homozygous contiguous deletion of one of two genes: SLC3A1 (mutations which cause cystinuria type I) or PREPL 2. The function of PREPL and how deletions of this gene cause this PWS-like disorder are still unclear. Larger deletions involving these two as well as neighbouring genes also exist and are associated with more severe and extended phenotypes (Regal et al. 2013).

## Leukodystrophies

### Demyelinating/Dysmyelinating Leukodystrophies
- Metachromatic Leukodystrophy
- Metachromatic Leukodystrophy Due to Saposin B Deficiency
- Multiple Sulphatase Deficiency
- Globoid Cell Leukodystrophy
  - Krabbe Disease
- X-Linked Adrenoleukodystrophy
  - Addison Disease and Cerebral Sclerosis, Melanodermic Leukodystrophy;
    - Siemerling-Creutzfeldt Disease, Bronzed Schilder Disease

### Other Peroxisomal Disorders
- Alexander Disease
- Giant Axonal Neuropathy 1
- Canavan Disease
  - Canavan-Van Bogaert-Bertrand Disease; Spongy Degeneration of CNS;
    - Aspartoacylase Deficiency
- Leukoencephalopathy with Vanishing White Matter
  - Vanishing White Matter Disease, Vanishing White Matter Leukodystrophy,
    - Childhood Ataxia with CNS Hypomyelinisation, Myelinopathia Centralis Diffusa
- Megalencephalic Leukoencephalopathy with Subcortical Cysts 1
  - Vacuolating Megalencephalic Leukoencephalopathy with Subcortical Cysts;
    - Leukoencephalopathy with Swelling and Cysts; Van Der Knaap Disease
- Megalencephalic Leukoencephalopathy with Subcortical Cysts 2
- Cystic Leukoencephalopathy without Megalencephaly
  - RNase T2-Deficient Leukoencephalopathy
- Leukoencephalopathy with Brainstem and Spinal Cord Involvement and Lactate Elevation
- Leukoencephalopathy with Thalamus and Brainstem Involvement and High Lactate
- Leukodystrophy with Calcification of the Basal Ganglia and Lymphocytosis of CSF
  - Aicardi–Goutières Syndrome
- Cereboretinal Microangiopathy with Calcifications and Cysts
  - Coats Plus Syndrome
- Sjögren-Larsson Syndrome
  - Fatty Aldehyde Dehydrogenase Deficiency
- Cerebrotendinous Xanthomatosis
  - Van Bogaert-Scherer-Epstein Disease
- L-2-Hydroxyglutaric Aciduria

Heredodegenerative Disorders

Victoria San Antonio Arce, Jaume Campistol Plana, Alexis Arzimanoglou and Robert Ouvrier

A significant proportion of genetically transmitted neurological diseases have not yet been linked with demonstrated metabolic errors, especially known enzymatic deficits. Many are characterised by early degeneration of one or more specific central nervous system (CNS) areas or systems. Some demonstrate morphological evidence of storage at the microscopic or ultramicroscopic level. A majority show only ‘degenerative’ lesions of the brain and in some cases of the peripheral nervous system. These disorders are caused by genetic abnormalities of structural or enzyme proteins. Many of these have been identified in the recent past; some of them are yet to be identified. These disorders are termed heredodegenerative CNS disorders. They share most of the clinical features of recognised metabolic diseases; in particular, they are progressive illnesses. A symptom-free interval and a loss of previously acquired skills are frequent but not constant features, especially in cases with congenital or early infantile onset when the progressive nature may be difficult to determine. This group is highly heterogeneous, including many disorders with no real link between them. The various conditions studied in this chapter will be grouped mainly according to gross pathological criteria; for example, on the system or part of the CNS that bears the brunt of the disease, although topographic delimitation is far from being always precise. Pathological location is relatively well correlated with the clinical features.

Heredodegenerative disorders can have their onset at any age, and age at onset is an important diagnostic clue. Because no specific biological disturbance is known for several of these conditions, their diagnosis rests on clinical grounds, especially careful history taking, family investigation and neurological examination, and on certain laboratory tests – radiological, neurophysiological, ophthalmological or biochemical. Brain biopsy that was used for the diagnosis of some heredodegenerative CNS disorders has been largely replaced, over the past two decades, by biopsies of peripheral tissues.

Study of this group of disorders has been revolutionised by the progress of molecular genetics and the use of linkage techniques. These permit identification of mutations within or close to the relevant gene or in the proteins they code, making reliable diagnosis possible. When the gene has been mapped and cloned, appropriate methods can be applied to help determine the abnormal gene product and, hopefully, understand the mechanisms of the disease and eventually prepare possible therapies. DNA studies may permit prenatal diagnosis, and, in some cases, preimplantation procedures. With direct study of the gene sequence, mutations or deletions can be detected, enabling precise determination of the genotype and consequently of the subtype and genetic origin of the disorder. Diagnosis by molecular genetic techniques has medical and ethical implications which have to be carefully considered. There is no doubt though that molecular genetic techniques have opened exciting new perspectives in the field of heredodegenerative diseases.

For convenience, a few diseases that are not progressive but have similar clinical presentations and are also of genetic origin will be included in this discussion.

**LEUKODYSTROPHIES**

The leukodystrophies comprise a group of genetic diseases that affect the white matter of the brain and, in a few disorders, also peripheral myelin. There is no classification available that covers all aspects of clinical presentation, morphological alterations, or metabolic and genetic characteristics. In a broad sense leukodystrophies are defined as genetic white matter brain disorders. They belong to a larger group of conditions that affect predominantly the white matter, termed leukoencephalopathies, which also include other hereditary disorders as well as acquired disorders involving the white matter. The leukoencephalopathies produce imaging features that can closely resemble those of the leukodystrophies proper and constitute a major differential diagnosis (Table 10.1).

Originally the classification of leukodystrophies was based on morphological characteristics; examples are globoid cell leukodystrophy (Krabbe disease), metachromatic leukodystrophy and sudanophilic leukodystrophy. This last term has more or less disappeared as a result of advances in understanding of the genetic aetiology of most leukodystrophies. The terms demyelination, dysmyelination and hypomyelination describe the possible pathophysiological aspects. Demyelination refers to the breakdown of structurally and biochemically normal
Pelizaeus–Merzbacher disease). Demyelination may occur in cates disturbance and delay in the formation of myelin (e.g. adrenoleukodystrophy); while hypomyelination indi- structurally and biochemically abnormal or unstable myelin tion, separate the disease from the so-called From the clinical point of view, the leukodystrophies are characterised clinically by the predominance of motor involvement, especially pyramidal and cerebellar signs, with some degree of cognitive deterioration and low incidence of seizures, myoclonus and paroxysmal electroencephalogram (EEG) abnormalities. From the imaging point of view, all share involvement of white matter, best demonstrated by mag- netic resonance imaging (MRI). Hyperintensity in the white matter in T2-weighted sequences is the MRI finding required for diagnosis of a leukodystrophy. T1-weighted sequences show hypointensity in the white matter in the demyelinating leukodystrophies and iso- or hyperintensity in the hypomy- elinating leukodystrophies. The MRI findings, especially the type and distribution of the white matter involvement and the eventual presence of associated features (e.g. cysts, calci- fication, grey matter involvement, brainstem involvement, spinal cord involvement), together with the age at onset and the clinical findings, are the most valuable information to sus- pect a specific leukodystrophy and to orientate the diagnostic procedure especially the performance of specific biochemical or molecular genetic testing (see Table 10.3). For practical purposes, in the present chapter we will use this classification to separate the demyelinating/dysmyelinating and hypomy- elinating leukodystrophies. The MRI features of white matter diseases have been reviewed by van der Knaap and Valk (2005) and more recently by Schiffmann and van der Knaap (2009), and magnetic resonance spectroscopic anomalies by Hanefeld et al. (2004).

Adults only.

myelin (e.g. in multiple sclerosis); dysmyelination denotes a structurally and biochemically abnormal or unstable myelin (e.g. adrenoleukodystrophy); while hypomyelination indicates disturbance and delay in the formation of myelin (e.g. Pelizaeus–Merzbacher disease). Demyelination may occur in all three conditions, usually involving oligodendrocytes and macrophages as the major cellular components. Studies in recent years have given evidence for the involvement of the extracellular matrix proteins in the stabilisation of the myelin membrane (e.g. alpha-sarcoglycanopathies). Axonopathies and disorders of neurofilaments may also play an important role in the maintenance of myelin. The role of astrocyte dysfunction has been discussed as a factor in demyelination (Seifert et al. 2006; Lanciotto et al. 2013). Despite all diagnostic efforts and progress in modern neurological, radiological, biochemical and genetic techniques, a substantial proportion of leukodystrophies in childhood remains unclassified and the pathogenesis of many disorders of cerebral white matter remains unsolved. While onset of leukodystrophies is usually in early childhood, the age spectrum ranges from prenatal/ congenital to adult-onset types in most entities. Leukodystrophies represent the classic type of white matter disorders. However, dysfunction of grey matter is increasingly recognised as a feature in many early-onset types. The classification of leukodystrophies as defined (Table 10.2) is primarily based on disturbances of cell organelles (lysosomes, peroxisomes, mito- chondria), structural elements (neurofilaments) and metabolic processes. Table 10.3 classifies the leukodystrophies according to the genetic defect. Leukodystrophies with an identified genetic cause may be inherited in an autosomal dominant manner, an autosomal recessive manner, or an X-linked recessive manner. Genetic counselling regarding risk to family members depends on accurate diagnosis, determination of the mode of inheritance and identification of the responsible mutation. Prenatal testing for pregnancies at risk is possible if the responsible mutation is known.

From the clinical point of view, the leukodystrophies are characterised clinically by the predominance of motor involvement, especially pyramidal and cerebellar signs, with some degree of cognitive deterioration and low incidence of seizures, myoclonus and paroxysmal electroencephalogram (EEG) abnormalities. From the imaging point of view, all share involvement of white matter, best demonstrated by magnetic resonance imaging (MRI). Hyperintensity in the white matter in T2-weighted sequences is the MRI finding required for diagnosis of a leukodystrophy. T1-weighted sequences show hypointensity in the white matter in the demyelinating leukodystrophies and iso- or hyperintensity in the hypomyelinating leukodystrophies. The MRI findings, especially the type and distribution of the white matter involvement and the eventual presence of associated features (e.g. cysts, calcification, grey matter involvement, brainstem involvement, spinal cord involvement), together with the age at onset and the clinical findings, are the most valuable information to suspect a specific leukodystrophy and to orientate the diagnostic procedure especially the performance of specific biochemical or molecular genetic testing (see Table 10.3). For practical purposes, in the present chapter we will use this classification to separate the demyelinating/dysmyelinating and hypomyelinating leukodystrophies. The MRI features of white matter diseases have been reviewed by van der Knaap and Valk (2005) and more recently by Schiffmann and van der Knaap (2009), and magnetic resonance spectroscopic anomalies by Hanefeld et al. (2004).

**DEMYELINATING/DYSMYELINATING LEUKODYSTROPHIES**

**METACHROMATIC LEUKODYSTROPHY**

Metachromatic leukodystrophy (MLD; MIM #250100) was first described by Scholz (1925) and Greenfield (1933). Scholz reported the genetic origin of the disease and separated it from disorders described under the term of diffuse sclerosis. The typical staining properties, showing metachromasia after staining with cresyl violet or toluidine blue in an acid solution, separate the disease from the so-called orthochromatic

or sudanophilic leukodystrophies. The staining appears to be specific for sulphatides, present not only in brain tissue but also in nerves and many somatic tissues like kidneys, liver, ovaries and also in urine. In addition to metachromasia, peripheral nerves may also show segmented demyelination. The detection of metachromatic material in urinary epithelial cells is still a useful diagnostic test.

MLD is an autosomal recessive disorder with an estimated prevalence of one in 40,000. It is caused by a deficiency of the lysosomal enzyme arylsulphatase A (ARSA). The deficiency of ARSA results in a storage of cerebroside sulphate (sulphatide). The genetic defect is localised on chromosome 22 (Polten et al. 1991). The accumulation of sulphatides leads to break down of central and peripheral myelin. Sulphatide concentration in affected tissue is increased and cerebroside concentration is decreased.

Besides the ARSA-alleles (frequency 0.5%) causing the late infantile, juvenile and adult-onset forms of MLD, another ARSA allele (frequency 7–15%) exists, which has been called ARSA pseudodeficiency (ARSA-PD) (Gieselmann et al. 1991). Ten to 20 per cent of individuals homozygous for this allele have a low ARSA activity but show no clinical symptoms and no sulphatiduria. Homozygosity for ARSA-PD is frequent in the general population; patients with neurological symptoms of other causes and ARSA-PD may therefore be misdiagnosed as having MLD. The pseudodeficiency allele

### Part IV

#### Metabolic and Hereditodegenerative Disorders

**Leukoencephalopathy with thalamus and brainstem involvement and high lactate (LTBL)**

- **Oxidative phosphorylation deficiency 12 (COXPD12)**
  - #614924 Autosomal recessive
  - EARS2 (16p12.2)
  - Lesions in deep cerebral white matter, including thalami and hypothalami, as well as in brainstem and cerebellum, with sparing of the periventricular region, and thin posterior part of corpus callosum, lactate elevation in MR spectroscopy

**Aicardi–Goutières syndrome**

- Leukodystrophy with calcification of the basal ganglia and lymphocytosis of CSF
  - See Table 10.5
  - See Table 10.5
  - See Table 10.5

**Cerebroretinal microangiopathy with calcifications and cysts (CRMCC)**

- Coats plus syndrome
  - #612199 Autosomal recessive
  - CTC1 (17p13)
  - Intracranial calcifications and cysts involving deep grey nuclei, brainstem, cerebral and cerebellar white matter, and dentate nuclei

**Sjögren-Larsson syndrome (SLS)**

- Fatty aldehyde dehydrogenase (FALDH) deficiency
  - #270200 Autosomal recessive
  - ALDH3A2 (17p11)
  - Congenital viral infection-like, acquired microcephaly, cutaneous lesions (chilblain-like) possible, neurological decline (motor and cognitive)

**Cerebrotendinous xanthomatosis (CTX)**

- Van Bogaert–Scherer–Epstein disease
  - #213700 Autosomal recessive
  - CYP27A1 (2q35)
  - Dysmyelination with posterior predominance, cerebellum, brainstem and spinal involvement, brain and cerebellar atrophy, non-calculizing lesions in basal ganglia, calcifications possible

**L-2-hydroxyglutaric aciduria**

- #236792 Autosomal recessive
  - L2HGDH (14q21)
  - Cerebral dysmyelination with subcortical predominance, cerebellar abnormalities in the dentate nucleus, cerebellar atrophy possible

Figure 10.1 Metachromatic leukodystrophy. T2-weighted image showing high signal from the periventricular white matter.

can be determined directly by DNA techniques. In addition, two non-allelic forms of MLD exist: MLD due to saposin B deficiency (MIM #249900) and multiple sulphatase deficiency or juvenile sulphatidosis (MIM #272200), a disorder that combines features of a mucopolysaccharidosis with those of metachromatic leukodystrophy (see Multiple Sulphatase Deficiency section).

Three clinical types of MLD can be distinguished according to age at onset: late infantile type (40%), juvenile type (40%) and adult type (20%). The late infantile form is the most homogeneous group, which presents between the ages of 6 months and 2 years. Children show delayed development or deterioration of walking, some being never able to walk alone. The gait is characterised by spasticity and ataxia. Ankle reflexes may be absent, contrasting with the presence of a bilateral Babinski sign. Later in the course of the illness, optic atrophy and more generalised spasticity dominate the clinical picture (MacFaul et al. 1982). The prognosis is poor, with death occurring before the age of 10 years.

The juvenile type varies in onset and may show symptoms as early as 4–6 years. Gait disorders combined with learning and behavioural problems can be observed. Motor signs include cerebellar and pyramidal dysfunction as well as signs of a peripheral neuropathy. Seizures and dementia are late manifestations. In adult cases, gait disorders, extra pyramidal symptoms and a psychiatric symptomatology dominate the clinical picture.

MLD should be suspected in all children with a progressive spastic–ataxic disorder and the paradoxical finding of a negative Achilles tendon reflex in the presence of exaggerated patellar tendon reflexes and Babinski sign. Fundi may show optic atrophy. The EEG is usually normal or may show some slow activity and epileptiform discharges late in the disease. The electroretinogram is preserved. Sensory and particularly motor nerve conduction velocities are decreased. In almost all cases there is an increased protein level in cerebrospinal fluid (CSF). In all three types, computed tomography (CT) and MRI show changes in the periventricular white matter with a frontal predominance (Fig. 10.1). U-fibres are spared, the corpus callosum is affected early during the disease, and pyramidal tracts may show signs of demyelination in juvenile and adult cases. The diagnosis is confirmed by measurement of ARSA and the demonstration of metachromatic material in urine.

No effective treatment is yet available. Bone marrow or haematopoietic stem cell transplantation has been tried with conflicting results. The supplementation of aryl-sulphatase A has been discussed (Matzner and Gieselmann 2005). Most recently cord blood transplant (Pierson et al. 2008) and lentiviral haematopoietic stem cell (HSC) gene therapy (Biffi et al. 2013) have been reported to stop disease progression in presymptomatic MLD cases.

METACHROMATIC LEUKODYSTROPHY DUE TO SAPOSIN B DEFICIENCY

Rare cases of MLD (MIM #249900) are caused by a mutation involving an activator protein (saposin B) that is encoded by the gene PSAP on chromosome 10q22.1 (Henseler et al. 1996; Wroble et al. 2000; Kuchar et al. 2009). The activator protein activates not only the hydrolysis of sulphatides by ARSA but also the hydrolysis of GM1-gangliosides. Deficiency of saposin B may result in a juvenile or rarely a late infantile phenotype of MLD but which histologically also showing storage of gangliosides. The diagnosis can be confirmed in fibroblast cultures: pathological sulphatide metabolism can be corrected by the activator protein (Inui et al. 1983).

MULTIPLE SULPHATASE DEFICIENCY

Mucosulfatidosis; Juvenile Sulfatidosis of Austin type

Multiple sulphatase deficiency (MSD; MIM #272200) is a rare autosomal recessive disorder, combining features of both MLD and mucopolysaccharidosis, caused by the absence of arylsulphatase A, B and C and mucopolysaccharide sulphatidase activity. It is caused by homozygous or compound heterozygous mutations in the sulphatase-modifying factor-1 gene (SUMF1) on chromosome 3p26 (Cosma et al. 2003; Dierks et al. 2003). As a result of the deficit, patients accumulate sulphatides and mucopolysaccharides in viscera and brain and there is an increased excretion of heparan sulphate in urine. Clinical manifestations include coarse features, short stature, hepatosplenomegaly combined with skeletal changes, progressive neurodevelopmental deterioration and peripheral neuropathy. There is no corneal clouding. Three subtypes (neonatal, early childhood and juvenile) can be distinguished. Children with the most frequently occurring early childhood form learn to walk but develop a progressive encephalopathy combined with a peripheral neuropathy and the described somatic features around the age of 2 years. Progressive deterioration leads to early death. The diagnosis can be suspected in patients with neurological symptoms combined with skeletal
dysplasia on X-ray and finally confirmed by the demonstration of arylsulphatase A, B and C deficiency. X-rays of the lumbar spine may show anterior beaking or ovoid vertebrae as in classic MPS disorders. Cranial MRI showing white matter changes similar to those in MLD.

**GLOBOID CELL LEUKODYSTROPHY**

**Krabbe Disease**

Globoid cell leukodystrophy (GLD; MIM #245200) is an autosomal recessive disorder caused by a deficiency of the lysosomal enzyme galactocerebroside-beta-galactosidase (galactocerebrosidase) (Suzuki et al. 1971). It is due to homozygous or compound heterozygous mutations in the galactosylceramidase (\(GALC\)) gene on chromosome 14q31.3 (Sakai et al. 1994). Galactocerebrosides are the most specific myelin lipids in the brain; their concentration reflects maturation. Three subtypes of GLD have been delineated: the most common infantile form, and rare juvenile and adult subtypes. The neuropathology of Krabbe disease is characterised by a paucity of oligodendrocytes, lack of myelin and proliferation of glial cells in affected areas with mononuclear epithelioid cells and clusters of large multinucleated globoid cells. Involvement of the peripheral nervous system is common but may be less pronounced than in MLD. The deficiency of galactocerebroside-beta-galactosidase results in accumulation of cerebrosides and psychosine (galactosyl sphingosine). Many symptoms observed in GLD are related to the increase of psychosine, which acts as a toxic substance (Suzuki 2003).

The most common infantile form presents initially with hypotonia before 6 months of age. In addition, extreme irritability, especially marked sound-induced startle and progressive stiffness, are characteristic early symptoms. Increased muscle tone and pyramidal tract signs are found on examination, and opisthotonic spasms with head retraction are often precipitated by external stimuli. Convulsions are frequent and may present as infantile spasms with atypical hypersrrhythmic EEG patterns. Absence of deep tendon reflexes frequently contrasts with the spasticity. Optic atrophy and blindness develop. The disease is rapidly progressive and death usually occurs before the age of 2 years. The clinical stages of Krabbe disease have been delineated by Hagberg et al. (1969).

In all infantile cases, high CSF protein (above 70mg/dL) is found and nerve conduction velocities are decreased. In late-onset forms of GLD, CSF protein may be normal. Hyperintensities in brainstem, cerebellum, internal capsule, thalamus and basal ganglia have been found on CT. MRI detects T1 hypointensity and T2 hyperintensity in cerebral and cerebellar white matter with periventricular and parieto-occipital predominance (Fig. 10.2). Magnetic resonance spectroscopy MRS reveals pronounced elevation of myo-inositol and choline-containing compounds in affected white matter, reflecting demyelination and glial proliferation, accompanied by a decrease of N-aspartyl acetate as a sign of neuro-axonal loss (Brockmann et al. 2003a).

The diagnosis of GLD is based on the characteristic clinical symptoms, raised CSF protein and MRI findings. In late-onset cases, symptoms are less characteristic and include walking difficulties, fading vision, and learning problems. In any leukodystrophy combined with a mild peripheral neuropathy, GLD must be suspected. The diagnosis is confirmed by measuring galacto-cerebroside-beta-galactosidase in white blood cells or fibroblasts. Molecular analysis may demonstrate one of the more than 60 mutations that have been described in association with Krabbe disease (Wenger et al. 1997; Tappino et al. 2010).

Treatment is symptomatic. High doses of benzodiazepines may be useful in relieving the extreme irritability and opisthotonus. Haematopoietic stem cell transplantation has been tried with doubtful results (Krivit et al. 1998). Transplantation of umbilical cord blood from unrelated donors has been found to restore normal blood levels of galacto-cerebrosidase and to stop the progression of the disease in presymptomatic patients (Escolar et al. 2005; Prasad et al. 2008).

**X-LINKED ADRENOLEUKODYSTROPHY**

**Addison Disease and Cerebral Sclerosis; Melanodermic Leukodystrophy; Siemerling-Creutzfeldt Disease; Bronzed Schilder Disease**

X-linked adrenoleukodystrophy (X-ALD; MIM #300100) is the most frequently occurring leukodystrophy in males,
with an estimated incidence of 1:20 000. The disorder was initially described as ‘encephalitis periaxialis diffusa’ by Schilder in 1913 and in a case report of ‘diffuse sclerosis’ combined with adrenal atrophy by Siemerling and Creutzfeldt in 1923. More than half a century later, the defect in peroxisomal beta-oxidation leading to characteristic excess of very long chain fatty acids in plasma, blood cells and altered fibroblasts was discovered (Igarashi et al. 1976; Moser et al. 1980). The gene for X-ALD, ABCD1 gene, has been mapped to Xq28 and found to encode a peroxisomal membrane protein of the ATP-binding cassette (ABC) transporter family (Moser et al. 1993). More than 200 mutations have been identified.

The transporter is necessary for transferring very long chain fatty acids (VLCFAs) or VLCFA-CoA into the peroxisomes, where they are metabolised. This process depends on a number of peroxisome biogenesis genes or peroxines (PEX). No correlation has been found between the nature of a mutation and the clinical phenotype (Powers and Moser 1998; Dubois-Dalcq et al. 1999).

A selective susceptibility of adrenal glands and neuronal tissue, with lesions especially involving the spinal cord and brain, is the morphological hallmark of X-ALD. In contrast to the adult adrenomyeloneuropathy (AMN), the childhood form of X-ALD is associated with an inflammatory reaction in the cerebral white matter. There is a confluent loss of myelin, usually symmetrical and most prominent in the parieto-occipital regions. U-fibres are relatively spared, but corpus callosum, the posterior part of the internal capsule, the corticospinal tract, the pons and the medulla are also involved.

Histological study reveals a loss of myelinated axons and oligodendrocytes, reactive astrocytosis and later cavitations and astrogliosis. The active edge of demyelination showing intensive perivascular inflammation and accumulation of lipophages. Perivascular cell collections contain macrophages and particularly lymphocytes. Hypertrophic GFAP-positive astrocytes and macrophages express cytokines like tumour necrosis factor alpha (TNF-alpha) and interleukin 1 (IL-1).

Three main phenotypes of X-ALD occur in males and three further subtypes are known (van Geel et al. 1994; Bezman and Moser 1998; Kirk et al. 1998; Ruiz et al. 1998; Bezman et al. 2001). Heterozygous female carriers of the mutated gene may be symptomatic, mainly in the following forms of AMN:

1. The cerebral childhood form (frequency 30–40%): onset by 3–10 years of age, rapidly progressive.
2. Adolescent ALD (4–7%): onset by age 11–21 years, slower progression.
3. Adult AMN (25–40%): onset by mean age 28 years (SD 9 years), spinal cord involvement.
4. Adult ALD (2–5%): marked by psychiatric symptoms and dementia.
5. Addison disease only (10–15%): onset before 7–8 years; most patients eventually develop AMN, the frequency of which varies with age.
6. Asymptomatic cases (5–15%): biochemical and genetic defect only.

The cerebral childhood form of ALD has an initial slowly progressing phase followed by rapid deterioration. Initial symptoms are difficulties at school, combined with behavioural disturbances. Impaired hearing or hearing loss may be an early symptom. Impaired vision, dementia, seizures, and difficulties in walking, speech and handwriting develop fast following the onset of first neurological symptoms. Once neurological symptoms become manifest, progression is rapid and an apparent vegetative state develops in a few years. Mean age at death was 9.4 years (SD 2.7 years, range 5.1–19 years) in a series of patients reported from the Kennedy Krieger Institute in the USA (Powers and Moser 1998).

Hyperpigmentation typical for Addison disease may be present before neuropsychological disturbances occur.

X-linked ALD must be excluded in every boy with adrenal insufficiency. The diagnosis is based on the demonstration of increased concentrations of VLCFA (c22:0, c24:0, c26:0) in plasma. Prenatal diagnosis is possible by measurements of VLCFA in cultured amniocytes and mutation analysis. The demonstration of cerebral demyelination by MRI is of great value and in many cases almost diagnostic. Cerebral demyelinating lesions usually start in the splenium of the corpus callosum and slowly progress symmetrically into the parieto-occipital white matter. Arcuate fibres are spared (Fig. 10.3). Using contrast agents the most severely affected area of the brain showing a rim of enhancement. The posterior limb of the internal capsule, pyramidal tract, pons and brainstem may also be involved. In about 10% of cases, demyelination may also start frontally with involvement of the anterior limb of the internal capsule. Symmetrical involvement of the cerebellar white matter is also possible. The differential diagnosis of X-ALD includes among others: brain tumour, other leukodystrophies, encephalitis, subacute sclerosing panencephalitis, multiple sclerosis and acute demyelinating encephalitis.

Adrenal insufficiency can be effectively corrected by hormone replacement, but substitution does not prevent or alter the neurological manifestations. A diet with unsaturated fatty acids is ineffective.
acids (Lorenzo’s oil) lowers the plasma levels of VLCFA in patients with X-ALD (Kolodny 1987). However, the clinical results are disappointing when given to symptomatic patients (Aubourg et al. 1993). A follow-up study of 49 asymptomatic patients with ALD treated with Lorenzo’s oil was able to show a reduced risk of developing MRI abnormalities (Moser et al. 2005). The most effective treatment so far has been the haematopoietic stem cell transplantation in the early stage of the disease (Shapiro et al. 2000; Peters et al. 2004). More recently, possible clinical benefits of lentiviral-mediated gene therapy of haematopoietic stem cells have been reported (Cartier et al. 2009).

**Chapter 10 Heredodegenerative Disorders**

**OTHER PEROXISOMAL DISORDERS**

Peroxisomal disorders can be classified into two main groups: (1) disorders of peroxisome biogenesis and (2) single peroxisomal enzyme deficiencies (see Chapter 9). A peroxisomal disorders classification according to genetic defects is shown in Table 10.4.

The peroxisome biogenesis disorders (PBDs) are a group of autosomal recessive disorders affecting the formation of functional peroxisomes. They can be caused by mutations in any of several genes, known as pexins (PEX), involved in peroxisome biogenesis (Ebberink et al. 2011). PBDs can be classified into four phenotypes. Three of them, Zellweger syndrome, neonatal adrenoleukodystrophy (NALD) and infantile Refsum disease (IRD), constitute a spectrum of overlapping features (Zellweger syndrome spectrum [ZSS]), with the most severe being the Zellweger syndrome and the least severe infantile Refsum disease. The fourth, rhizomelic chondrodysplasia punctata (RCDP1), constitutes a distinct PBD phenotype.

ZSS is characterised by multiple organ dysfunction, sensorineural hearing loss, pigmentary retinal degeneration, and psychomotor impairment. Zellweger syndrome, the most severe form, is characterised by neonatal onset with neuronal migration defects, dysmorphic craniofacial features, large fontanelle, severe hypotonia, neonatal seizures, skeletal abnormalities (patellar calcifications) and liver dysfunction, and is fatal in early life. NALD and IRF constitute milder forms resulting in a more varied initial presentation and natural history. Progressive sensorineural hearing loss, retinal dystrophy and developmental delay are seen in older children. MRI findings in ZSS include, in addition to dysmyelination, brain atrophy and neuronal migration defects resulting in polymicrogyria, pachygyria and heterotopias. Concerning diagnosis, measurement of plasma VLCFA levels is the most commonly used and most informative initial screen. Biochemical abnormalities should be confirmed in cultured fibroblasts or by mutation analysis.

RCDP1 is characterised by skeletal abnormalities with severe shortening of the proximal parts of the extremities, microcephaly, characteristic facial features, cataracts, severe intellectual disability and spasticity, most patients dying in the first decade of life. MRI findings may include supratentorial white matter abnormalities with parieto-occipital predominance. Biochemically, plasmalogen synthesis and phytanic acid alpha-oxidation are defective, while plasma VLCFA are normal.

The second group includes disorders in which the defect involves a single peroxisomal protein but the structure of the peroxisome is intact. Most of them are due to single defects in proteins involved in peroxisome fatty acid beta-oxidation. The paradigm of these disorders is X-ALD (MIM #300100; see X-linked Adrenoleukodystrophy section). Peroxisomal acyl-CoA oxidase deficiency, also called pseudoneonatal adrenoleukodystrophy (pseudo-NALD; MIM #264470), is a rare autosomal recessive neurodegenerative disorder caused by mutations in the ACOX1 gene (17q25.1) encoding peroxisomal straight-chain acyl-CoA oxidase (Ferdinandusse et al. 2007). To date, only 30–40 cases have been described. Clinical onset occurs in the neonatal period with characteristic facial features, hypotonia and seizures as dominant features. In the course of the disease, developmental delay, hypertonia with hyper-reflexia, neurosensory hearing loss and retinal dystrophy may occur. MRI showing atrophy and white matter abnormalities in the ponto-medullary corticospinal tracts and in the cerebellar and cerebral white matter. Diagnosis is based on the demonstration of increased serum VLCFA and markedly reduced acyl-CoA oxidase activity in fibroblasts, and can be confirmed by mutation analysis. Similar manifestations have been described in D-bifunctional protein deficiency (MIM #261515) caused by mutations in the HSD17B4 gene on chromosome 5q23.1 (van Grunsven et al. 1998). Alpha-methylacyl-CoA racemase (AMACR) deficiency (MIM #614307) is caused by homoyzogous mutations in the AMACR gene on chromosome 5p13.2 (Ferdinandusse et al. 2000). It is clinically characterised by learning disability and seizures that may be present since childhood, and later on visual impairment, sensorimotor neuropathy, spasticity and migraine. Brain MRI showing white matter involvement. Serum pristanic acid and C27 bile acid intermediates are increased. Sterol carrier protein 2 (SCPS) deficiency, also known as leukoencephalopathy with dystonia and motor neuropathy (MIM #613724), caused by homozygous mutation in the SCP2 gene on chromosome 1p32.3, has been described in one patient with juvenile clinical onset with torticollis and dystonic head tremor as well as slight cerebellar signs with intention tremor, nystagmus, hypomnesia, and azoospermia, accumulation of branched-chain pristanic acid in plasma and abnormal bile alcohol glucuronides excreted in urine, and leukencephalopathy and involvement of the thalamus and pons on MRI (Ferdinandusse et al. 2006).

Some disorders are due to single defects in proteins involved in ether-phospholipid biosynthesis. Rhizomelic chondrodysplasia punctata type 2 (RCDP2; MIM #222765), caused by homozygous or compound heterozygous mutations in the DHAPAT gene encoding the enzyme dihydroxyacetonephosphate acyltransferase on chromosome 1q42.2 (Ofman et al. 1998), and rhizomelic chondrodysplasia punctata type 3
Part IV  Metabolic and Heredodegenerative Disorders

(RCDP3; MIM #600121), caused by homozygous or compound heterozygous mutations in the gene AGPS encoding the enzyme alkylidihydroxyacetonephosphate (alkyl-DHAP) synthase on chromosome 2q31.2 (Wanders et al. 1994), are part of this group. RCDP2 and RCDP3 are clinically similar to RCDP1. However, plasmalogen levels are reduced but phytanic acid levels and the processing of 3-ketothiolase are normal.

|              | adrenoleukodystrophy; CCALD, cerebral childhood form of X-linked adrenoleukodystrophy; AdoALD, adolescent adrenoleukodystrophy; AAMN, adult adrenomyeloneuropathy; AALD, adult adrenoleukodystrophy; X-R, X-linked recessive; ACOX Def, peroxisomal acyl-CoA oxidase deficiency; PNALD, pseudoneonatal adrenoleukodystrophy; DBP Def, D-bifunctional protein deficiency; SCPx, sterol carrier protein 2 (SCPx) deficiency; AMACR Def, alpha-methylacyl-CoA racemase deficiency; RCDP, rhizomelic chondrodysplasia punctata; RD, classic/adult Refsum disease.

(RCDP3; MIM #600121), caused by homozygous or compound heterozygous mutations in the gene AGPS encoding the enzyme alkylidihydroxyacetonephosphate (alkyl-DHAP) synthase on chromosome 2q31.2 (Wanders et al. 1994), are part of this group. RCDP2 and RCDP3 are clinically similar to RCDP1. However, plasmalogen levels are reduced but phytanic acid levels and the processing of 3-ketothiolase are normal.
Lastly, there are single defects in proteins involved in fatty acid alpha-oxidation. Classic Refsum disease, also known as adult Refsum disease type 1 (MIM #266500) is the only known type in this group. It is caused by mutation in the gene \textit{PHBH/PAXH} encoding phytanoyl-CoA hydroxylase on chromosome 10p13 (Mihalik et al. 1997). Accumulation of phytanic acid leads to lesions essentially in retina, brain and peripheral nervous system. Clinical onset occurs usually in young adults, but its first signs may also appear during childhood, in the form of retinitis pigmentosa, and later on peripheral sensory–motor polyneuropathy, cerebellar ataxia and elevated protein levels in the CSF without an increase in the number of cells. Other features such as sensorineural hearing loss, anosmia, ichthyosis, skeletal abnormalities and cardiomyopathy may occur. Phytanic acid comes exclusively from food, a strict diet may reduce symptoms.

A phenotype clinically indistinguishable from that of classic Refsum disease, but with a different biochemical profile, is found in Refsum disease type 2 (MIM #614879), caused by mutations in the gene \textit{PEX7} on chromosome 6q23.

ALEXANDER DISEASE

Alexander disease (MIM #203450) is the first described disorder caused primarily by a dysfunction of astrocytes (Hanefeld 2004; Mignot et al. 2004). It was first described by Alexander in 1949 in an 18-month-old boy with macrocephaly. The neuropathological hallmark on examination was the presence of ‘rod-shaped fuscophil fibres’ in the white matter of his brain, which were later identified as Rosenthal fibres. Glial fibrillary acidic protein (GFAP) is present in high concentration in Rosenthal fibres and is therefore used as a histological marker. Heterozygous mutations, de novo in 95% of cases, of the gene \textit{GFAP} encoding glial fibrillary acidic protein, one of the major intermediate filament proteins of mature astrocytes, on chromosome 17q21 in patients with Alexander disease have subsequently been discovered to be the cause of this autosomal recessive disease (Brenner et al. 2001).

According to the clinical presentation three different types of Alexander disease can be distinguished: infantile, juvenile and adult cases. The most common infantile type belongs to the group of macrocephalic white matter diseases. Affected children are normocephalic at birth and develop a slowly progressive megalencephaly combined with symptoms of spasticity, irritability and epileptic seizures (Pridmore et al. 1993). Acute episodes of intracranial hypertension may be observed following mild head trauma. Death may occur before the age of 10 years. Apart from this infantile progressive type, Alexander disease has also been diagnosed in juvenile and adult patients. One peculiarity in the cases of older patients is the increasing involvement of brainstem and bulbar structures. Older patients are usually normocephalic. The disease has been reviewed by Mignot et al. (2004).

A more recent classification distinguishes Alexander disease type I, with onset in infancy with encephalopathy, epilepsy and failure to thrive and shorter survival (median 14 years), and Alexander disease type II, with onset throughout the lifespan (mean 21.64 years) with bulbar autonomic and motor signs and longer survival (median 25 years).

The diagnosis in classic cases of Alexander disease is based on the clinical presentation with macrocephaly, regression, seizures and the presence of bulbar symptoms in older patients. The EEG may show generalised slow activity and some focal discharges. The most important information is provided by cranial CT and MRI. Van der Knaap et al. (2001) described neuroradiological characteristics that are almost diagnostic for Alexander disease. These include extensive signal enhancement of cerebral white matter with frontal predominance, a periventricular rim with high signal on T1-weighted and a low signal on T2-weighted images, abnormalities in basal ganglia, thalami and brainstem, and contrast enhancement of particular grey and white matter structures. Atypical MRI features have also been described (van der Knaap et al. 2005; van der Knaap et al. 2006a). MRS reveals a strong elevation of myo-inositol and a decline of N-acetylaspartic acid (NAA) (unlike in Canavan disease), accompanied by accumulation of lactate in affected cerebral and cerebellar white matter. Myo-inositol was elevated in white matter as well as in grey matter and in basal ganglia (Fig. 10.4). The pattern reflects glial (astrocytic)
proliferation as well as active demyelination and neuro-axonal degeneration. Increased levels of GFAP in CSF in all three subtypes of Alexander disease were described by Kyllerman et al. (2005). The diagnosis is confirmed by molecular genetic analysis of the \textit{GFAP} gene. Only symptomatic treatment is available for Alexander disease.

**GIANT AXONAL NEUROPATHY 1**

Autosomal recessive giant axonal neuropathy or giant axonal neuropathy 1 (GAN1; MIM #256850) is a severe neurodegenerative disorder of childhood with polyneuropathy that affects both the peripheral and central nervous systems and is accompanied by characteristically kinky hair. Axonal loss and the presence of giant axonal swellings filled with neurofilaments on nerve biopsy are pathological hallmarks. Disorganisation of other members of the intermediate filament family of proteins is seen in other tissues such as keratine, which explains the characteristic kinky feature of hair. GAN1 is caused by homozygous or compound heterozygous mutations in the gene \textit{GAN} encoding gigaxonin, a protein involved in neurofilament architecture, on chromosome 16q23 (Bomont et al. 2000). Patients usually present with loss of intellectual capacity, epilepsy and cerebellar and pyramidal tract signs during early childhood. The disease progresses rapidly and children soon become bedridden and death occurs usually by late adolescence. However, phenotypic variability, even among patients with the same mutation, has been reported (Tazir et al. 2009), with age at onset ranging from birth to 7 years and variable presence of intellectual disability, spasticity and hair abnormalities. Brain MRI showing abnormalities of the cerebellum and brain white matter. Diagnosis can be made by mutational analysis. Genetic counselling is advised for parents of an affected child. Prenatal diagnosis can be proposed. There is no specific treatment.

**CANAVAN DISEASE**

Canavan-Van Bogaert-Bertrand Disease; Spongy Degeneration of CNS; Aspartoacylase Deficiency

Canavan disease (MIM #271900) was first described in 1931 under the designation \textit{Schilders Encephalitis periaxialis diffusa} and in 1949 was recognised by van Bogaert and Bertrand as a rare autosomal recessive disease entity including leukoencephalopathy and macrocephaly. In 1988 a deficiency of aspartoacylase (Matalon et al. 1989) leading to an increased concentration of NAA in urine and plasma was correlated with Canavan disease. The genetic defect is caused by mutations in the gene for aspartoacylase (\textit{ASPA}) located on chromosome 17p13.2 (Kaul et al. 1993). Canavan disease is also characterised by macrocephaly combined with hypotonia, irritability and feeding difficulties. Patients suffering from the most frequent infantile type develop spasticity and blindness, and death occurs before 3 years of age. A severe congenital form resembles a metabolic encephalopathy, while the very rare juvenile form has a normal head circumference and showing a more protracted course. Neuropathology is characterised by degeneration and rarefaction of neural tissue (status spongiosus).

The cranial CT showing diffuse symmetrical hypodensity of white matter; MRI reveals a centripetal pattern of demyelination starting in the U-fibres and progressing to the periventricular regions (Fig. 10.5). As one of the major metabolites detected by MRS, NAA showing an increased signal in the brain of patients with Canavan disease (Grod et al. 1990). The increased concentration of NAA in proton magnetic resonance spectra of the brain is almost diagnostic for the disease. The diagnosis is confirmed by the demonstration of increased concentrations of NAA in plasma and urine and a mutation in the gene of aspartoacylase.
Prenatal diagnosis is possible in cultured amniocytes. The course is progressive, although the rate of progression may be variable (Traeger and Rapin 1998). There is no known treatment.

LEUKOENCEPHALOPATHY WITH VANISHING WHITE MATTER

Vanishing White Matter Disease; Vanishing White Matter Leukodystrophy; Childhood Ataxia with CNS Hypomyelinisation; Myelinopathia Centralis Diffusa

This disorder, now called vanishing white matter disease or leukoencephalopathy with vanishing white matter (VWM; MIM #603896), represents one of the most prevalent inherited childhood white matter disorders (van der Knaap et al. 2006b). Following the description in earlier case reports, the disease was described in 1993 by Hanefeld et al. as diffuse white matter disease with unique features on MRI and proton MRS. These authors described three children, including male and female siblings, who developed ataxia following a mild head trauma and a nonspecific infection respectively. The third patient, a boy, became ataxic following mild head trauma. Ataxia persisted over three days. A CT taken at the time showed diffuse white matter changes. The boy made an initial recovery but became ataxic again following mild head traumas or nonspecific febrile illness. At the age of 4 years, he was referred with a spastic–ataxic gait, brisk reflexes, clonus and bilateral Babinski signs. During the following months and years he developed optic atrophy, swallowing difficulties and major seizures. He later died from bronchopneumonia. His sister followed almost the same clinical course. MRI in both siblings showed almost identical diffuse white matter abnormalities. The MRS done at the same time revealed a complete loss of all metabolites in affected white matter, while brain spectra of grey matter revealed only mild but definite decrease of NAA. The MRS appearance of white matter resembled CSF with a marked elevation of lactate (Fig. 10.6). Similar cases were described in large numbers during the following years (Schiffmann et al. 1994; van der Knaap et al. 1997). Leegwater et al. (2001a) and van der Knaap et al. (2002a) were able to demonstrate mutations in all five subunits of the eukaryotic translation initiation factor, eIF2B. Thus, VWM can be caused by homozygous or compound heterozygous mutations of EIF2B1 on chromosome 12q24, EIF2B2 on chromosome 14q24, EIF2B3 on chromosome 1p34, EIF2B4 on chromosome 2p23 or EIF2B5 on chromosome 3q27.

Further studies showed that early-onset variants including the Cree-leukoencephalopathy (Black et al. 1988) are caused by a mutation in eIF2B5 (Fogli et al. 2002a, b). This mutation has also been described in other cases with a severe, lethal ante- and perinatal onset of the leukoencephalopathy.

In addition other abnormalities are often present such as oligohydramnios, intrauterine growth retardation, cataract, pancreatitis, hepatosplenomegaly, hypoplasia of kidneys and ovarian dysgenesis (van der Knaap et al. 2003a). The combination of white matter disease with ovarian dysgenesis had already been described by Schiffmann et al. (1997). It has now become obvious that eIF2B disorders, as they are now called, show a wide spectrum of clinical manifestations, from the rare acute early-onset types, the classic VWM syndrome, to milder late-onset and adult cases (Fogli and Boespflug-Tanguy 2006; van der Knaap et al. 2006b).

Neuropathological investigations have demonstrated age-dependent abnormalities. Cystic cavitations are described in advanced cases. Microscopically there is a loss of myelin but no inflammatory reaction. Grey matter is generally spared but axonal loss in areas of cavitation is complete. Oligodendrocytes are severely affected, showing apoptosis in early-onset cases (Brück et al. 2001) and increased density of oligodendrocytes in long-standing cases (Rodríguez et al. 1999; Van Haren et al. 2004). A study of cell cultures from the brain of a boy who died at the age of 12 years showed in vitro a rapid generation of oligodendrocytes but a severely compromising reduction of GFAP-positive astrocytes. A deficiency of normal astrocyte...
function may, therefore, be involved in the pathogenesis of VWM.

The diagnosis in the classic type of VWM is based on the clinical presentation and course: normal early development during the first 2–3 years, followed by ataxia and spasticity, usually in the context of mild trauma or nonspecific febrile illness, rapid progression with loss of motor function, seizures and late cognitive deterioration. There are no signs of peripheral neuropathy. Alternatively, recovery, often only partial, may occur with later recurrences leading to progressive decline.

MRI showing diffuse white matter disease with a characteristic early involvement of the central tegmental tract. MRS confirms a loss of myelin, revealing a metabolic pattern, different from CSF only by the presence of lactate. The disease progresses to severe disability and most children with the classic phenotype die before the age of 20 years.

An elevation of glycine and a decreased concentration of asialotransferrin have been described as a possible marker of the disease (van der Knaap et al. 1999). However, MRI criteria, as formulated by van der Knaap, are primarily used for diagnosis (van der Knaap et al. 1998). In view of the wide phenotypic variability in eIF2B disorders the diagnosis has to be confirmed by genetic analysis. Prenatal diagnosis of eIF2B disorders is available. No treatment is known.

MEGALENCEPHALIC LEukoencephalopathy WITH SUBCORTICAL CYSTS 1

Vacuolating Megalencephalic Leukoencephalopathy with Subcortical Cysts; Leukoencephalopathy with Swelling and Cysts; Van Der Knaap Disease

Megalencephalic leukoencephalopathy with subcortical cysts 1 (MLC1; MIM #604004) was first described in 1995 by van der Knaap et al. as a ‘leukoencephalopathy with swelling and a discrepantly mild clinical course’ in eight children. Family studies suggested an autosomal recessive mode of inheritance; the MLC1 gene, coding for a transmembrane protein associated with Na,K-ATPase complex, was mapped to chromosome 22qter by Topçu et al. (2000) and identified by Leegwater et al. (2001b). The disease was characterised by megalencephaly and leukoencephalopathy, with onset during the first year of life and a slowly progressive neurological deterioration. Brain biopsy in one of the patients revealed a spongiform leukoencephalopathy with vacuolisation and splitting of the outer lamellae of the myelin sheaths (van der Knaap et al. 1995). Further cases with similar clinical presentation have been reported (Goutières et al. 1996; Singhal et al. 1996; Mejaski-Bosnjak et al. 1997; Topçu et al. 1998).

The clinical symptomatology consists of macrocephaly, ataxia, spasticity, seizures and mild intellectual deterioration. Remarkably, cognitive functions are well preserved in many patients up to adolescence. The EEG may show epileptiform activity, a photoconvulsive response and generalised slowing (Topçu et al. 1998). The MRI reveals extensive signal changes of hemispherical white matter early in the disease and the development of subcortical cysts predominantly in the temporal and parietal regions.

Mejaski-Bosnjak et al. (1997) reported the MRS features of an 8-year-old girl with a severe clinical course of MLC that had led to wheelchair dependency at age 5 years. Localised MRS of the affected white matter showed a loss of all metabolites, pointing to a complete disintegration of neuro-axonal and glial tissue (Fig. 10.7). Brockmann et al. (2003b) reported a 37-year-old woman cognitively normal with increasing gait disturbance caused by spasticity and ataxia. MRI showed enlargement of ventricles and subarachnoid spaces. Cerebral white matter was characterised by diffuse T2-hyperintensity with numerous subcortical cysts present.

Diagnosis is based on clinical findings, in particular megalencephaly, well-preserved cognitive function and characteristic MRI images. No treatment for the disease is available.

MEGALENCEPHALIC LEukoencephalopathy WITH SUBCORTICAL CYSTS 2

Megalencephalic leukoencephalopathy with subcortical cysts can also be caused by mutations in the HEPACAM gene, coding for a glial cell adhesion molecule, on chromosome 11q24.2 (Lopez-Hernandez et al. 2011). Two forms are known: megalencephalic leukoencephalopathy with subcortical cysts 2A (MLC2A, or remitting megalencephalic leukoencephalopathy with or without intellectual disability; MIM #613925), caused by homozygous or compound heterozygous mutations in the HEPACAM gene, and megalencephalic leukoencephalopathy with subcortical cysts 2B (MLC2B; MIM #613926), a similar, but less severe...
disorder that showing improvement of MRI changes with age, caused by heterozygous mutations in the HEPACAM gene.

MLC2A is an autosomal recessive disorder characterised by infantile-onset macrocephaly and later onset of motor deterioration, with ataxia and spasticity, seizures, and cognitive decline of variable severity. Brain MRI showing typical white matter abnormalities, including swelling of the cerebral white matter and subcortical cysts, in all stages of the disease.

MLC2B is an autosomal dominant disorder characterised by infantile onset of macrocephaly and mildly delayed motor development associated with white matter abnormalities on brain MRI that improve with age. About 40% of patients have intellectual disability.

**CYSTIC LEUKOENCEPHALOPATHY WITHOUT MEGALENCEPHALY**

**RNase T2-Deficient Leukencephalopathy**

Cystic leukencephalopathy without megalencephaly (MIM #612951) is caused by a homoyzogous or compound heterozygous mutation in the ribonuclease T2 RNASET2 gene on chromosome 6q27 (Henneke et al. 2009). About 30 cases have been reported to date. It is a non-progressive infantile-onset encephalopathy with normo- or micro-cephaly and severe psychomotor impairment, accompanied by seizures and sensorineural hearing impairment. Brain MRI showing bilateral anterior temporal lobe cystic lesions and enlarged inferior horns combined with multifocal brain white matter alterations. CT has shown intracranial calcifications in some children. The main differential diagnosis is congenital cytomegalovirus infection (Olivier et al. 1998; Gomes et al. 2001; Henneke et al. 2005; Henneke et al. 2009).

**LEUKOENCEPHALOPATHY WITH BRAINSTEM AND SPINAL CORD INVOLVEMENT AND LACTATE ELEVATION**

Leukencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL; MIM #614924), also known as combined oxidative phosphorylation deficiency 12 (COXPD12), is caused by homozygous or compound heterozygous mutations in the EARS2 gene, coding for the mitochondrial enzyme aspartyl-tRNA synthetase (DARS2) on chromosome 1q25.1 (Schepers et al. 2007).

About 30 cases have been reported to date, revealing a heterogeneous phenotype including adult-onset forms (Petzold et al. 2006), and one case presenting with exercise-induced episodic ataxia responding to acetazolamide (Synofzik et al. 2011).

**LEUKOENCEPHALOPATHY WITH THALAMUS AND BRAINSTEM INVOLVEMENT AND HIGH LACTATE**

Leukencephalopathy with thalamus and brainstem involvement and high lactate (LTBL; MIM #614924), also known as combined oxidative phosphorylation deficiency 12 (COXPD12), is caused by homozygous or compound heterozygous mutations in the EARS2 gene, coding for the mitochondrial glutamyl-tRNA synthetase 2, on chromosome 16p12.2 (Steenweg et al. 2012). Only few cases have been reported to date. Clinically there are two main phenotypes: the more severe phenotype is characterised by early onset after birth with hypotonia and lack of psychomotor development followed by a severe disease course with spastic tetraparesis, dystonia, visual impairment and seizures, resulting in marked disability; the milder phenotype is characterised by normal or mildly delayed early development with onset of regression later in the first year of life with spasticity, loss of milestones, and sometimes seizures and irritability, followed after age 2 years by clinical, biochemical and imaging improvement. Laboratory studies show intermittent increases of serum transaminases, increased alpha-fetoprotein, increased serum lactate, and muscle biopsy demonstrates cytochrome C oxidase (COX) deficiency. MRI showing T2-weighted hyperintensities of the deep cerebral white matter, including the thalami and hypothalami, as well as in the brainstem and cerebellum, with sparing of the periventricular region, and thin posterior part of the corpus callosum. MRS showing increased lactate in the cerebral white matter.

**LEUKODYSTROPHY WITH CALCIFICATION OF THE BASAL GANGLIA AND LYMPHOCYTOSIS OF CSF**

**Aicardi–Goutières Syndrome**

Aicardi–Goutières syndrome (AGS) is a genetically heterogeneous encephalopathy characterised in its most severe form by cerebral atrophy, leukodystrophy, intracranial calcifications, chronic CSF lymphocytosis, increased CSF interferon-alpha and negative serological investigations for common prenatal
infections. Aicardi and Goutières (1984) first reported eight cases in five families beginning in infancy, with calcification of the basal ganglia and chronic CSF lymphocytosis, leading rapidly to a vegetative state and early death. Lebon et al. (1988) described the intrathecal synthesis of interferon-alpha in patients with AGS which is also elevated in viral CNS infections and autoimmune disorders like systemic lupus erythematosus, suggesting a common pathogenic mechanism. Interferon-alpha may have a pathogenic role in AGS as indicated by the observation that astrocyte-specific chronic overproduction of interferon-alpha in transgenic mice recapitulates the neuropathological findings seen in AGS (Akwa et al. 1998).

The classic phenotype includes a very early onset in the first weeks or months of life so that deterioration, if any, is far from obvious. The clinical picture resembles an in utero viral infection. The general condition of the patient is poor. There is marked hypotonia interrupted by opisthotonic episodes, failure to develop, febrile episodes, and death in a state of decerebration within a few years, although some children survive for several years (Aicardi and Goutières 1984; Goutières et al. 1998). The two major diagnostic features are: (1) the presence of calcification of the basal nuclei, sometimes also of the periventricular white matter and the dentate nuclei, associated with hypodensities of the white matter and brain atrophy (Fig. 10.8); and (2) a persistent mild CSF lymphocytosis (10–80 cells per mm³) that is not constant and tends to decrease with time. Outside the nervous system, thrombocytopenia, hepatosplenomegaly and elevated hepatic transaminases along with intermittent fever may also erroneously suggest an infective process. Cutaneous lesions (chilblain-like) are present in about half the cases. Moderately elevated levels of interferon-alpha are present in CSF in most cases, at least in the first years of the disease (Lebon et al. 1988) and to a lesser extent in the blood. Similar cases have been reported as ‘Cree encephalitis’ from highly inbred Indian communities of Northern Quebec (Black et al. 1988).

Beside this classic form, a wide phenotypic spectrum has been recognised and most of the original criteria for diagnosis no longer apply: affected individuals may show later onset and may not have severe or progressive neurological dysfunction, calcification of the basal ganglia, or CSF lymphocytosis. The appearance of chilblains is an important clinical sign for correct diagnosis (see Stephenson 2008 for a review).

AGS is a genetically heterogeneous syndrome. To date seven different forms (AGS1–7; see Table 10.5) caused by mutations in different genes have been described with both recessive and dominant – with variable penetrance – inheritance patterns. AGS1 (MIM #225750) is caused by homozygous or compound heterozygous mutations in the TREX1 gene encoding a nuclear protein with 3′ exonuclease activity involved in DNA repair on chromosome 3p21 (Crow et al. 2006a). Cree encephalitis has been found to be allelic of AGS1. AGS1 has also been reported to be caused by heterozygous mutations in this gene (Haaxma et al. 2010). The same mutation in heterozygosity had previously been identified by Lee-Kirsch et al. (2007) in a family with chilblain lupus. AGS2 (MIM #610181) is

![Figure 10.8](image-url) Leukodystrophy with calcification of the basal ganglia (Aicardi–Goutières syndrome). (a) Axial MRI scan showing punctate calcification in the basal ganglia, low signal from the frontal lobes, and diffuse moderate atrophy of the brain. Note the presence of calcification in the white matter. (b) MRI scan of the basal ganglia: punctate calcifications are well shown as low-intensity signals.

| Table 10.5 Aicardi–Goutières syndrome classification according to genetic defects |
|---|---|---|---|
| Name | MIM no. | Mode of inheritance | Gene (chromosome) |
| AGS1 | #225750 | AR/AD | TREX1 (3p21) |
| AGS2 | #610181 | AR | RNASEH2B (13q14) |
| AGS3 | #610329 | AR | RNASEH2C (11q13.1) |
| AGS4 | #610333 | AR | RNASEH2A (19p13.2) |
| AGS5 | #612952 | AR | SAMHD1 (20q11.2) |
| AGS6 | #615010 | AR/AD | ADAR (1q21.3) |
| AGS7 | #615846 | AD | IFIH1 (2q24.2) |

AGS, Aicardi–Goutières syndrome; AR, autosomal recessive; AD, autosomal dominant.
caused by homozygous or compound heterozygous mutations in the \textit{RNASEH2B} gene encoding the non-catalytic subunit B of ribonuclease H2 involved in DNA replication on chromosome 13q14 (Ali et al. 2006; Crow et al. 2006b). AGS3 (MIM #610329) is caused by homozygous mutations in the \textit{RNASEH2C} gene encoding the non-catalytic subunit C of ribonuclease H2 on chromosome 11q13.1 (Crow et al. 2006a). AGS4 (MIM #610333) is caused by homozygous or compound heterozygous mutations in the \textit{RNASEH2A} gene encoding the catalytic subunit A of ribonuclease H2 on chromosome 19p13.2 (Crow et al. 2006b); AGS5 (MIM #612952) is caused by homozygous or compound heterozygous mutations in the \textit{SAMHD1} gene encoding a protein involved in the immune response to viral infection on chromosome 20q11.2 (Rice et al. 2009); AGS6 (MIM #615010) can be caused by homozygous, compound heterozygous or heterozygous mutations in the \textit{ADAR} gene encoding an enzyme involved in RNA editing on chromosome 1q21.3 (Rice et al. 2012). AGS7 (MIM #615846) is caused by heterozygous mutations in the \textit{IFIH1} gene coding for a putative RNA helicase on chromosome 2q24.2 (Rice et al. 2014).

Rice et al. (2007) analysed clinical data from 123 mutation-positive patients. Two clinical presentations could be delineated: a more severe early-onset neonatal form, with high mortality, highly reminiscent of congenital 

CEREBRORETINAL MICRO AN GIOPATHY WITH CALCIFICATIONS AND CYSTS

Coats Plus Syndrome

Cerebroretinal microangiopathy with calcifications and cysts (CRMCC; MIM #612199), also known as Coats plus syndrome, is an autosomal recessive infantile or early childhood onset disorder characterised by progressive extensive intracranial calcifications, leukodystrophy, and brain cysts, resulting in ataxia, spasticity, dystonia, seizures, and variable cognitive decline. Patients also have bilateral retinal telangiectasias and exudates (Coats disease) as well as extra-neurological manifestations, including poor growth, hair, skin and nail changes, gastrointestinal telangiectasias with risk of haemorrhage, skeletal abnormalities with osteopenia and sclerosis with increased fractures, and bone marrow suppression with anaemia and thrombocytopenia. A primary obliterator cerebral angiopathy involving small vessels, leading to calcifications, slow necrosis, cyst formation, and secondary white matter abnormalities has been postulated. Brain MRI showing progressive intracerebral calcifications involving deep grey nuclei, brainstem, cerebral and cerebellar white matter, and dentate nuclei, accompanied by diffuse white matter signal abnormality. About 30 cases have been reported to date. CRMCC is caused by compound heterozygous mutations in the \textit{CTCI} gene encoding a component of the CST complex, involved in the protection of telomeres from degradation, on chromosome 17p13 (Anderson et al. 2012; Polvi et al. 2012).

Another disorder called leukoencephalopathy, brain calcifications, and cysts (LCC; MIM #614561), also known as Labrune syndrome (Labrune et al. 1996; see Other Demyelinating/Dysmyelinating Leukodystrophies section), has similar neurological features to CRMCC in the absence of extra-neurological manifestations. However, mutations in the \textit{CTCI} gene have not been found in patients with Labrune syndrome, suggesting that the two disorders are not allelic (Anderson et al. 2012; Polvi et al. 2012).

SJÖGREN-LARSSON SYNDROME

Fatty Aldehyde Dehydrogenase Deficiency

Sjögren-Larsson syndrome (SLS; MIM #270200) is an autosomal recessive, early childhood onset disorder caused by an inborn error of lipid metabolism and characterised by congenital ichthyosis, intellectual disability, spasticity, macular dys trophy and leukoencephalopathy (for review see Fuijkschot et al. 2012). It is caused by homozygous or compound heterozygous mutations in the \textit{ALDH3A2} gene, which encodes fatty aldehyde dehydrogenase (FALDH), an enzyme that catalyses the oxidation of fatty aldehydes to fatty acids, on chromosome 17p11. Prevalence is estimated at 1/250 000 worldwide, but the syndrome is more common in Sweden due to a founder effect (Jagell et al. 1981).

Mild to moderate ichthyosis is usually present at birth and progresses during infancy. Neurological signs appear during infancy and consist of spastic diplegia or, less frequently, spastic tetraplegia. Approximately one-half of patients are non-ambulatory. Seizures occur in about 40% of cases. Intellectual disability varies from mild to severe, although rare patients with normal intellect have been reported. Ophthalmological involvement is often present and is characterised by retinal crystalline inclusions (so-called glistening white dots) surrounding the fovea. Brain MRI showing hypomyelination and a variable degree of periventricular dysmyelination and ventricular enlargement, and 1H-MR-spectroscopy reveals a characteristic abnormal lipid peak in periventricular white matter (van Domburg et al. 1999). In early infancy, before the onset of spasticity, differential diagnosis includes other forms of congenital ichthyosis. Once neurological symptoms appear later in infancy, differential diagnosis includes other neuro-ichthyotic syndromes such as neutral lipid storage disease (Chanarin-Dorfman syndrome), multiple sulphatase deficiency and Refsum disease.

SLS is diagnosed by measuring FALDH or fatty alcohol oxidoreductase (FAO) activity in cultured fibroblasts from skin biopsies. Identification of abnormal urinary excretion of leukotriene B4 and its metabolites may also be useful. Diagnosis can be confirmed by demonstration of \textit{ALDH3A2}}
gene mutations. Prenatal diagnosis is possible, by measuring the conversion of phytol into phytanic acid in chorionic villus biopsy samples, or by mutation analysis of the sample. Treatment should be multidisciplinary including neurologists, dermatologists, ophthalmologists, orthopaedic surgeons and physiotherapists. Limited clinical improvement has been shown using special diets with reduced fatty intake and supplementation with both n-3 and n-6 fatty acids to obtain a linoleic/linolenic acid ratio of 6, when tried early in the disease. Therapeutic trials with zileuton, a 5-lipoxygenase inhibitor and gene therapy are being tried.

CEREBROTENDINOUS XANTHOMATOSIS
Van Bogaert-Scherer-Epstein Disease
Cerebrotendinous xanthomatosis (CTX; MIM #213700) is an inherited lipid storage disease caused by homozygous or compound heterozygous mutations in the CYP27A1 gene coding for the bile acid biosynthetic enzyme sterol 27-hydroxylase on chromosome 2q35. Clinically it is characterised by beginning in late childhood or early adolescence with progressive neurological dysfunction including cerebellar ataxia, spinal cord involvement and cognitive decline, tendon xanthomas, premature atherosclerosis and cataracts. The presence of chronic diarrhoea and a history of prolonged neonatal cholestatic jaundice support the diagnosis (Mignatti et al. 2014). Large deposits of cholesterol and cholestanol are found in virtually every tissue, particularly the Achilles tendons, brain and lungs. The diagnosis can be made by demonstrating high serum levels of cholestanol. Dotti et al. (1994) described the CT and MRI findings in brain and spinal cord of ten patients aged 35 years or older with cerebrotendinous xanthomatosis. All of them had cerebral and/or cerebellar atrophy, and the majority had focal lesions distributed through the brain, cerebellum, brainstem or basal nuclei. More recently, Lionnet et al. (2014) described the clinical and paraclinical findings in 15 adult patients, with 73% beginning in childhood. Brain MRI was abnormal in all cases and showed images of periventricular leukodystrophy in 73% with predominant posterior brain involvement in 60%, T2-weighted hyperintensity of the dentate nuclei in 47%, hyperintensity of the cortico-spinal tracts in 53% and cerebellar atrophy in 33%. Oral therapy with chenodeoxycholic acid has been shown to arrest the progression of the disease but not to reverse the clinical manifestations. Thus early diagnosis is essential.

L-2-HYDROXYGLUTARIC ACIDURIA
L-2-hydroxyglutaric aciduria (MIM #236792) is an autosomal recessive early childhood onset neurological disorder caused by homozygous mutations in the L2HGDH gene encoding L-2-hydroxyglutarate dehydrogenase, a FAD-dependent mitochondrial enzyme that oxidises L-2-hydroxyglutarate to alphaketoglutarate, on chromosome 14q21 (Rzem et al. 2004; Topçu et al. 2004). About 150 cases have been reported to date. Clinical onset is often insidious in the first year of life. Presenting symptoms include psychomotor retardation and epilepsy. The disease slowly progresses, with cognitive decline, spasticity and cerebellar and extrapyramidal signs leading to loss of independent walking. Most reported patients had macrocephaly. An increased incidence of brain tumours has been reported (Aghili et al. 2009). Brain MRI showing subcortical white matter signal abnormalities, cerebellar atrophy, and signal changes in the putamina and dentate nuclei. Urinary organic acid screening reveals a massive increase of 2-hydroxyglutaric acid, and subsequent chiral differentiation is needed to establish the biochemical diagnosis of L-2-hydroxyglutaric aciduria. Demonstration of L2HGDH gene mutations allows diagnostic confirmation. Prenatal diagnosis can be performed by mutational analysis and by the measurement of L-2-hydroxyglutaric acid in amniotic fluid. No specific treatment exists. Prognosis is poor but most patients reach adulthood.

OTHER DEMYELINATING/DYSMYELINATING LEUKODYSTROPHIES
Leukodystrophy with palmo-plantar keratoderma is an autosomal recessive disorder described by Lossos et al. (1995) in four siblings with early childhood onset palmpoplantar keratoderma followed in adulthood by a progressive tetrapyrimald syndrome and cognitive impairment. Investigation disclosed cerebral white matter involvement on MRI and an arylsulphatase A pseudodeficiency carrier state, which was also identified in clinically unaffected family members. The skin content of collagen and total protein was higher in the affected patients. The authors suggested that an extracellular matrix abnormality may be involved in the pathogenesis of this disorder. Further cases have not been reported to date.

Skin abnormalities were also present in dermatoleukodystrophy (MIM #221790) described by Matsuyama et al. (1978) in a Japanese brother and sister born with thickened wrinkled skin resulting in a progeroid appearance who died in the third year of life from a progressive cerebral disease with cognitive and motor impairment. Postmortem neuropathologic studies showed a leukodystrophy with multiple axonal spheroids. Ultrastructurally, the spheroids contained granules resembling ceroid-lipofuscin bodies. Similar granules were found in degenerating oligodendrocytes and in Schwann cells. The skin showed hypercellularity and sclerosis. Further cases have not been reported to date.

A rare type of prenatal autosomal recessive leukodystrophy known as the Wiedemann–Rautenstrauch syndrome or neonatal progeroid syndrome (MIM #264090) has been reported, with progeroid features in association with demyelination of early onset (Martin et al. 1984). About 30 cases have been reported to date.

Cutaneous angiomatosis and pigmentation abnormalities were described in rare cases of familial non-calcifying
cortico-meningeal angiomatosis with progressive demyelination reported by Divry and Van Bogaert (1946).

A diffuse cerebral microangiopathy is thought to be responsible for diffuse dymyelination, calcification in brain and cerebellum and cyst formation resulting in spasticity, dystonia, seizures and cognitive decline in three unrelated children reported by Labrune et al. (1996) (Fig 10.9). The Labrune syndrome, also known as leukoencephalopathy, brain calcifications and cysts (LCC; MIM #614561), has similar features to ‘Coats plus syndrome’ or cereboretinal microangiopathy with calcifications and cysts (CRMCC; MIM #612199; see Cereboretinal Microangiopathy with Calcifications and Cysts (Coats Plus Syndrome) section above) in the absence of extra-neurological manifestations.

Leukoencephalopathy with metaphasic chondrodysplasia (LKMCD; MIM #300660) has been described by Neubauer et al. (2006) in four males of a three-generation German family with childhood onset slowly progressive leukoencephalopathy with tremor, ataxia, optic atrophy and spastic tetraparesis, associated with metaphasic chondrodysplasia with broad wrists and knees. Brain MRI showed diffuse cerebral demyelination. Radiography showed areas of marked radiolucency in the distal metaphyses of radius and cubitus. Brain MRI showed areas of marked radiolucency in the distal metaphyses of radius and cubitus. Postmortem examination of one case showed cerebral atrophy, a hypoplastic corpus callosum, thin optic nerves, and atrophic pyramidal tracts. Astrocytes were markedly increased. Bone mineralisation was diffusely decreased. Inheritance was consistent with an X-linked recessive pattern and linkage analysis of the X chromosome identified a 14-cM candidate region on Xq25-q27.

Progressive cavitating leukoencephalopathy was clinically characterised by Naidu et al. (2005) in 19 patients from 16 families with a neurodegenerative syndrome characterised by acute onset of irritability or neurological deficits between 2 months and 3.5 years of age, followed by steady or intermittent clinical deterioration leading to generalised spasticity, dementia, vegetative state and death in childhood or early adolescence, and patchy leukoencephalopathy with cavities, and vascular permeability in actively affected regions on brain MRI. Early lesions affected corpus callosum and centrum semiovale, with or without cerebellar or cord involvement, and after repeated episodes, lesions coalesced resulting in large cystic regions in brain or spinal cord. Grey matter was spared until late in the course. Partial clinical or MRI recovery may occur after episodes. Elevated levels of lactate in brain, blood and CSF, abnormal urine organic acids and changes in muscle respiratory chain enzymes were present. Pathological studies showed severe loss of myelin sparing U-fibres, axonal disruption, and cavitory lesions without inflammation. Familial occurrence and consanguinity suggested autosomal recessive inheritance. Ferreira et al. (2011) reported two siblings with progressive cavitating leukoencephalopathy associated with respiratory chain complex I deficiency and a novel mutation in NADH dehydrogenase (ubiquinone) Fe-S protein 1 (NDUFS1) gene, encoding the largest subunit of complex I, on chromosome 22q33-q34.

Other hereditary disorders, both autosomal recessive such as the adult polyglucosan body disease (MIM #263570) and dominant such as the autosomal dominant adult-onset demyelinating leukodystrophy (ADLD; MIM #169500) and the hereditary diffuse leukoencephalopathy with spheroids (HDLS; MIM #221820) cause progressive nervous system involvement with demyelination/dysmyelination but with adult-onset so they will not be discussed in detail in this chapter. Only one case of HDLS, also known as van Bogaert–Nyssen disease, hereditary diffuse leukoencephalopathy with axonal spheroids and pigmented glia or pigmented type of orthochromatic leukodystrophy, with childhood onset has been reported (Seiser et al. 1990).

**HYPOMYELINATING LEUKODYSTROPHIES**

The term hypomyelinating leukodystrophies (Schiffmann et al. 1994; Schiffmann and van der Knaap 2009) refers to inherited white matter disorders in which abnormalities in myelin development occur rather than destruction. The paucity of myelin development due to several genetic causes is thus the primary feature in hypomyelinating leukodystrophies. However, we will also include in this chapter some inherited white matter disorders with hypomyelination, in which the hypomyelination is thought to be secondary to neuronal disease, such as hypomyelinating leukodystrophy-3 (HLD3; MIM #260600), mitochondrial HSP60 chaperonopathy or hypomyelinating leukodystrophy-4 (HLD4; MIM #612233) and global cerebral hypomyelination or AGC1 deficiency (MIM #612949). In these cases, besides hypomyelination there are often prominent signs of grey matter involvement, such as early and severe brain atrophy with microcephaly, early-onset epilepsy and severe intellectual disability. Advances in genetics have led to the delineation of many of these disorders in recent years. Nonetheless, almost half of the patients with hypomyelination remain without genetic diagnosis. Most of these disorders have no specific treatment at present.
However, emerging research in oligodendrocyte biology and neuroradiology may result in the possibility of clinical trials of both pharmacological and cell-based therapies in the near future (Pouwels et al. 2014).

**PELIZAEUS–MERZBACHER DISEASE**

Pelizaeus–Merzbacher disease (PMD; MIM #312080) is an X-linked recessive hypomyelinating leukodystrophy (HLD1) in which myelin is not formed properly in the CNS, clinically characterised by early developmental impairment, nystagmus, hypotonia, choreoathetosis, and later on ataxia and spasticity. The classic form of PMD was first described by Pelizaeus (1885). Merzbacher (1910) described the neuropathology of the original family examined by Pelizaeus and conceived the disorder to be the result of a congenital aplasia of myelin sheaths. Much later biochemical analysis of cerebral white matter revealed a pattern consistent with that found in fetal myelin including a reduction of the proteolipid protein (PLP). Seitelberger added a congenital variant (type II). According to severity a transitional type III has also been defined.

The neuropathology of classic PMD (type I) is described as patchy hypo- and dysmyelination (so-called tigroid pattern), whereas type II exhibits almost total absence of myelin (Seitelberger 1995).

Deletions, duplications and mutations of the PLP1 gene on chromosome Xq22 give rise to the disorder. Duplications of the PLP1 gene, found in up to 60% of cases, are the major cause of PMD, whereas point mutations are less frequent (Sistermans et al. 1998). PLP1 codes additionally for DM20, another protein in the CNS.

Wolf et al. (2005) reported five unrelated patients with an atypically severe form of PMD who had three, and in one case, five copies of the PLP1 gene demonstrating that severe clinical symptoms are associated with increased PLP1 gene dosage. Regis et al. (2008) found no association between clinical disease severity and the extent of the duplicated segment among five unrelated PMD patients with PLP1 duplications.

Spastic paraplegia-2 (SPG2; MIM #312920) is an allelic disorder, and there is a clinical continuum between SPG2 and the milder forms of PMD.

Clinical and radiological criteria for the diagnosis of the classic form of PMD have been published (Bouloche and Aicardi 1986). They include the occurrence in a male patient of delayed motor development before 3 years of age (most often from a few months of age) and ophthalmological and neurological signs. Nystagmus is often the first detected manifestation. Hypotonia, choreoathetosis, and later on ataxia and spasticity develop progressively. Most patients show slow improvement until the age of 10–12 years. The majority of patients learn to sit; some are able to walk with aid but rarely independently. A minority develop active language. Most patients reach a plateau in development followed by a slow regression with dystonia, increasing ataxia, spasticity and the development of optic atrophy.

The congenital type II (Haenggeli et al. 1989) showing a more severe course with limited development before deterioration, even though its onset may not be much earlier than in the classic type. The five patients described by Wolf et al. (2005) developed severe symptoms before the age of 3 months with hypotonia, nystagmus, stridor and seizures. Two died at 7 and 9 months respectively; three suffered from severe epilepsy.

An array of clinical, electrophysiological and neuroradiological signs leads to the diagnosis. Early developmental impairment, nystagmus, muscular hypotonia and choreiform movements are characteristic clinical symptoms. Nystagmus may disappear before the age of 2 years. Disturbance of cerebral conduction of auditory and/or visual evoked potentials and a diffuse hyperintensity of the white matter on T2-weighted MRI are almost diagnostic for PMD. In the classic form an arrest of myelination in an early stage of development is shown in combination with progressive abnormalities of the unmyelinated white matter and possibly a slow degradation of some myelin. In the connatal form a complete absence of myelin in the brain is demonstrated (van der Knaap and Valk 1989). High signal intensity is seen in all unmyelinated white matter structures on T2-weighted images (Fig. 10.10), and low signal intensity on T1-weighted images. However, CT may be normal or show only some atrophy. MRS reveals a metabolic pattern of white matter similar to grey matter with increased concentrations of NAA, glutamine, myo-inositol, creatine and phosphocreatine, while the concentration of the choline-containing component is reduced. The proton MRS profile of PMD therefore differs from the pattern commonly observed in other leukodystrophies (Hanefeld et al. 2005).

To date, only symptomatic treatment is available for PMD. However, a phase I clinical study of allogenic neural stem cell transplantation in four patients with congenital PMD have showed the safety of the procedure and MRI changes in the region of the transplant suggestive of engraftment and consistent with the possibility of myelin formation, and encourages later phase II/III testing to prove efficacy of this approach (Gupta et al. 2012).

**Pelizaeus–Merzbacher-Like Disease**

The PMD phenotype has frequently been observed in patients without mutations or duplications of the PLP1 gene and these cases were classified as PMD-like disease (PMLD).

Uhlenberg et al. (2004) studied six families with PMLD, and in one Turkish consanguineous family and two German nonconsanguineous families, they identified five different mutations in the GJC2/GJA12 gene, encoding the gap junction protein alpha 12 (connexin 46.6), on chromosome 1q41. In the other three affected families, no GJC2/GJA12 mutations were found, suggesting that other atypical forms with a similar clinical presentation probably belong to other disorders. PMLD due to GJC2/GJA12 mutations, also known as PMLD1 or HLD2 (MIM #608804), is inherited as an autosomal recessive trait and, in addition to the PMD-like clinical picture, the patients also show signs of a peripheral
neuropathy and sporadic seizures. Henneke et al. (2008) identified GJA12 mutations in only 7.7% of 182 families with a PMD-like phenotype, and concluded that GJA12 mutations are a rare cause for a PMD-like disorder.

Feinstein et al. (2010) reported seven individuals from an extended consanguineous Israeli Bedouin family with an autosomal recessive form of connatal Pelizaeus–Merzbacher disease due to a homozygous mutation in the AIMP1 gene, encoding a cytokine involved in inflammatory processes, on chromosome 4q24. This form has been called hypomyelinating leukodystrophy-3 (HLD3; MIM #260600). However, Boespflug-Tanguy et al. (2011) replied that the patients described by Feinstein et al. did not present the core clinical and neuroradiological symptoms that define a hypomyelinating leukodystrophy, corresponding to a primary CNS myelin formation defect, but with features of white matter involvement secondary to neuronal involvement, and consequently should not be considered as a PMLD.

Magen et al. (2008) reported a large consanguineous Israeli Bedouin family with an autosomal recessive form of severe hypomyelinating leukoencephalopathy due to a mutation in the HSPD1 gene, encoding a mitochondrial chaperonin, on chromosome 2q33.1. There was a range of phenotypic heterogeneity, with onset between birth and age 3 months and death within the first two decades of life. Patients with more severe forms suffered from apneic spells during acute febrile illnesses and died before the age of 2 years. Patients who survived beyond the age of 2 years developed progressive limb spasticity and contractures. Plasma lactate levels were sometimes increased during encephalopathic episodes but there was no evidence of ragged red fibres on muscle biopsies. MRI showed no evidence of normal myelination and in more severe cases some degree of atrophy of cortex and brainstem. This disorder due to mutations in the HSPD1 gene has been called mitochondrial HSP60 chaperonopathy, MitCHAP60 disease or hypomyelinating leukodystrophy-4 (HLD4; MIM #612233), although signs of prominent grey matter involvement are present. Autosomal dominant hereditary ataxic paraplegia-13 (SPG13; MIM #605280) is an allelic disorder.

**HYPOMYELINATION AND CONGENITAL CATARACTS**

Hypomyelinating leukodystrophy-5 (HLD5), also known as hypomyelination and congenital cataracts (HCC; MIM #610532), is caused by a homozygous mutation in the FAM126A gene, coding the membrane protein hyccin, on chromosome 7p15.3 (Zara et al. 2006).

Clinically HCC/HLD5 is characterised by cataracts mostly at birth or in the first 2 months of life, developmental delay by the end of the first year of life, with delayed standing and walking, and later on slowly progressive pyramidal and cerebellar dysfunction, and mild to moderate intellectual disability. Brain MRI showing diffuse cerebral hypomyelination. There is often peripheral nervous system involvement with a sensorimotor demyelinating neuropathy. Some patients have seizures. There is a certain clinical variability as some patients may have a somewhat milder disease course, with onset of cataracts in infancy or later and some ability to walk in childhood (Ugur and Tolu 2008; Biancheri et al. 2011).

**HYPOMYELINATION WITH ATROPHY OF BASAL GANGLIA AND CEREBELLUM**

Hypomyelinating leukodystrophy-6 (HLD6), also known as hypomyelination with atrophy of basal ganglia and cerebellum (HABC; MIM #612438), is caused by mutations in the TUBB4A gene, encoding a beta tubulin family involved in the formation of microtubules, on chromosome 19p13.

It was first described by van der Knaap et al. (2002b) in seven unrelated patients with neurological impairment associated with a distinct brain MRI pattern characterised by hypomyelination and atrophy of the basal ganglia and cerebellum that develop over time. Clinical features included onset at 1–3 years of delayed motor development, with difficulty or absent walking and later deterioration of motor skills with spasticity and extrapyramidal signs such as rigidity, dystonia and choreoathetosis. Most patients showed mild intellectual disability. Two patients were more severely affected with onset at age 2 months, poor vision with optic atrophy, poor motor development, seizures and intellectual disability. Brain MRI showed a homogeneous picture, with diffuse myelin deficiency, atrophy of the cerebellar vermis, and small or absent putamen, with variable progression in serial studies.

HABC/HLD6 is mostly due to de novo heterozygous mutations and occurs sporadically. Two sibs with the disorder, however, have been reported who inherited the mutation from their unaffected mother, who was found to be somatic-mosaic for the mutation (Simons et al. 2013).
POLYMERASE III-RELATED HYPOMYELINATING LEUKODYSTROPHIES

In recent years, mutations in genes coding for the RNA polymerase III (Pol III) subunits POLR3A and POLR3B have been shown to be a major cause of childhood-onset hypomyelinating leukodystrophies with prominent cerebellar dysfunction, oligodontia, and hypogonadotropic hypogonadism. POLR3A is the largest of the 17 subunits that constitute Pol III. It forms, together with POLR3B, the second largest subunit, the catalytic centre of the enzyme. Pol III transcribes small untranslated RNAs involved in the regulation of essential cellular processes, including transcription, RNA processing, and translation. These conditions have been referred to as Pol III-related hypomyelinating leukodystrophies, and it has been suggested that mutations in genes coding for other Pol III subunits, and possibly in genes coding for proteins interacting with Pol III, could be responsible for cases of genetically uncharacterised hypomyelinating leukodystrophies (Tétreault et al. 2011).

HYPOMYELINATING LEUKODYSTROPHY 7 WITH OR WITHOUT OLIGODONTIA AND/OR HYPOGONADOTROPIC HYPOGONADISM

Bernard et al. (2011) demonstrated that the majority of previously reported cases affected by tremor-ataxia with central hypomyelination (TACH), hypomyelination, hypodontia and hypogonadotropic hypogonadism (4H syndrome) and leukodystrophy with oligodontia were caused by homozygous or compound heterozygous mutations in the POLR3A gene on chromosome 10q22.3.

Also called hypomyelinating leukoencephalopathy with ataxia and delayed dentition; ataxia, delayed dentition and hypomyelination (ADDH); hypomyelinating leukoencephalopathy with hypodontia and hypogonadotropic hypogonadism (4H syndrome), the hypomyelinating leukodystrophy 7 (HLD7; MIM #607694) is clinically characterised by childhood onset of progressive motor decline with prominent cerebellar signs combined with a variable degree of pyramidal signs that may seem to be almost stable for several years. There is mild intellectual disability and/or slowly progressive cognitive decline. High-level myopia has been reported in some patients. Other features may include hypodontia or oligodontia and hypogonadotropic hypogonadism. Brain MRI showing diffuse hypomyelination, cerebellar atrophy and a thin corpus callosum.

To date about 30 patients have been reported. Clinical variability has been demonstrated. Timmons et al. (2006) reported four unrelated patients with delayed tooth eruption and hypodontia of permanent teeth, otherwise asymptomatic until age 7 (in one case) or 12 years (in three cases), when progressive hypomyelination and dysmyelination resulted in ataxia, dysmetria, spasticity, dysarthria and mild cognitive impairment. All four had hypogonadotropic hypogonadism. Sural nerve biopsy showed loss of normal myelin periodicity. However, peripheral nerve abnormalities have not been further reported. On the other hand, Bernard et al. (2010) reported seven patients from five families with a similar form in very early childhood, with average age at onset of 2.5 years, becoming wheelchair-bound by later childhood. Only two of seven patients had hypodontia, one had hypogonadotropic hypogonadism and none had peripheral nerve abnormalities.

HYPOMYELINATING LEUKODYSTROPHY 8 WITH OR WITHOUT OLIGODONTIA AND/OR HYPOGONADOTROPIC HYPOGONADISM

Saitsu et al. (2011) and Tétreault et al. (2011) found compound heterozygous mutations in the POLR3B gene on chromosome 12q23 respectively in three patients from two unrelated nonconsanguineous Japanese families and in three unrelated European patients who had a phenotype consistent with 4H syndrome but who did not have mutations in the POLR3A gene.

This entity has been called hypomyelinating leukodystrophy 8 (HLD8; MIM #614381) and clinically is similar to HLD7. About 15 cases have been reported to date (Saitsu et al. 2011; Daoud et al. 2013). In the MRI, though, both HLD7 and HLD8 show diffuse hypomyelination, cerebellar atrophy and a thin corpus callosum. Takanashi et al. (2014) have recently described different MRI patterns: patients with POLR3B mutations show smaller cerebellar structures, especially vermis, and milder hypomyelination than those in POLR3A mutations.

ALLAN-HERNDON-DUDLEY SYNDROME

Allan-Herndon-Dudley syndrome (AHDS; MIM # 300523), also known as monocarboxylate transporter 8 deficiency, triiodothyronine (T3) resistance or X-linked intellectual disability with hypotonia, is caused by mutations in the SLC16A2 gene on chromosome Xq13, encoding the monocarboxylate transporter-8, a protein involved in the cellular importation of thyroid hormone.

The first clinical description was made by Allan et al. (1944) in 24 males in six generations of a family. Affected males had hypotonia from birth, severe motor developmental delay and generalised muscular atrophy, joint contractures and hyporeflexia as adults. Stevenson et al. (1990) restudied the same family with five additional affected males in two generations, and completed the phenotypic description by reporting severe intellectual disability, dysarthria, ataxia, atetoid movements, generalised weakness with muscular atrophy, long face with bitemporal narrowing large, simple ears, and spastic paraplegia with hyper-reflexia, clonus, Babinski reflexes and joint contractures. An X-linked recessive pattern of inheritance was suggested.
Dumitrescu et al. (2004) found mutations in the SLC16A2 gene in two unrelated families in which males showed the typical clinical picture of AHDS. Rotatory nystagmus, impaired gaze and hearing loss were also reported. Serum thyroxine (T4) was decreased, TSH was normal to mildly increased, and serum T3 was increased. Free T4 was also decreased or at the lower limits of normal. Heterozygous females had a milder thyroid phenotype without neurological deficits.

Vaurs-Barriére et al. (2009) identified mutations in the SLC16A2 gene in 11% of 53 families in which a male was affected with a hypomyelinating leukodystrophy with a Pelizaeus–Merzbacher-like phenotype of unknown aetiology. MRI showed hypomyelination affecting early myelinated areas before age 2 years, although, unlike PMD, it appeared to improve with age, without associated neurological improvement. The authors concluded that males with a Pelizaeus–Merzbacher-like phenotype should be screened for SLC16A2 mutations.

18q–SYNDROME
18q–syndrome (MIM #601808) is an autosomal dominant disorder caused by a terminal macrodeletion on chromosome 18q23 that includes the MBP gene, coding for the myelin basic protein, a major constituent of the myelin sheath formed by oligodendrocytes and Schwann cells in the nervous system. Direct transmission of the deletion from mother to child has been reported. Hence, affected females, being fertile, should have genetic counselling (Chen et al. 2006). The clinical presentation is variable including generalised dysmorphic signs like microcephaly, high or cleft palate, narrow ear canals, clinodactyly, congenital heart disease and short stature. Cognitive retardation may be combined with hypotonia, choreoathetosis, poor co-ordination, nystagmus and seizures. Behavioural problems can be prominent. MRI showing diffuse hyperintensity throughout the cerebral white matter in T2-weighted images consistent with hypomyelination (Linnankivi et al. 2006). Interestingly, a recent study with MRS has shown increased concentrations of creatine, myo-inositol and choline with a normal N-acetylaspartate one, suggesting reactive astrocytic gliosis and accelerated myelin turnover as the cause of white matter abnormalities in 18q syndrome (Tada and Takanashi 2014), which is consistent with recent pathological reports (Tanaka et al. 2012).

OCULODENTODIGITAL DYSPLASIA
Autosomal dominant oculodentodigital dysplasia (ODDD; MIM #164200) is caused by heterozygous mutation in the gap junction protein alpha 1 (GJA1) or connexin-43 gene on chromosome 6q22.31. Clinically it is characterised by facial dysmorphism and variable involvement of the eyes, dentition and fingers. Characteristic facial features include a narrow, pinched nose with hypoplastic alae nasi, prominent columella and thin antverted nares together with a narrow nasal bridge, and prominent epicantalic folds giving the impression of hypertelorism. Eye findings include microphthalmia and microcornea. The teeth are usually small and carious. The characteristic digital malformation is complete syndactyly of the fourth and fifth fingers. Associated lymphedema has also been reported. Neurological features include progressive spasticity, bladder and bowel dysfunction, visual and hearing loss, ataxia and nystagmus. Cognitive impairment has been described in some patients. Diffuse, abnormally high signal intensity in T2-weighted images in the subcortical white matter bilaterally, as well as basal ganglia changes, are seen on MRI (Loddenkemper et al. 2002).

A rare and more severe autosomal recessive form of ODDD (MIM #257850) is also caused by mutations in the GJA1 gene (Richardson et al. 2006).

FREE SIALIC ACID STORAGE DISORDERS AND SALLA DISEASE
Free sialic acid storage diseases are autosomal recessive lysosomal storage diseases that may present as a severe infantile form (infantile sialic storage disease, ISSD) or as a slowly progressive form that is prevalent in Finland (Salla disease).

Salla disease (SD; MIM #604369), also known as Finnish type of sialuria, was first described in Finland by Aula et al. (1979). The name Salla refers to the birthplace of the first described patients. The efflux of sialic acid from lysosomes is disturbed by a transporter defect. The related gene SLC17A5 (also called AST, acidic sugar transporter) is located on chromosome 6q13 (Haataja et al. 1994).

Symptoms appear at 6–18 months of age in the form of hypotonia, ataxia, athetosis and transient nystagmus. Later, slow progression occurs and spastic symptoms, growth retardation and dysmorphic, gargoyle-like features develop. However, most patients reach adulthood. Cognitive development and speech are affected, most patients using only single words or short sentences. An unusually severe form of Salla disease has been described by Haataja et al. (1994); patients were had severe intellectual disability, either not responsive to the environment or responding only with facial gestures. Milder variants and single patients living outside Finland have also been diagnosed (Varho et al. 2002). Growth retardation becomes obvious, with varying endocrine abnormalities. Coarse facial features resemble storage diseases involving the skeletal system. X-ray of the lumbar spine may demonstrate ovoid-shaped vertebral bodies on lateral views. MRI in Salla disease showing generalised deficiency of myelin with a thin corpus callosum. Later, atrophy becomes evident that may especially affect the cerebellum. As in other mucolipidoses, the EEG showing slow voltage traces. Motor and sensory nerve conduction velocities are reduced. The increased excretion of sialic acid in urine is used for diagnosis. Confirmation requires the demonstration of storage of free sialic acid in fibroblasts. No causal treatment is available for patients with Salla disease.

Infantile sialic storage disease (ISSD; MIM #269920), also called infantile sialuria or n-acetylneuraminic acid (NANA)
storage disease is an allelic more severe form of the disorder. Unlike Salla disease, ISSD has no particular ethnic prevalence. It has earlier onset, in utero (with fetal hydrops and ascites) or at birth (with hyponatremia, severe visceral involvement, hepatosplenomegaly often associated with ascites, coarse facies, dysostosis multiplex, severe psychomotor retardation and seizures), and is fatal in early childhood.

**FUCOSIDOSIS**

Fucosidosis (MIM #230000) is an autosomal recessive lysosomal storage disease caused by defective alpha-L-fucosidase with accumulation of fucosylated glycoconjugates (e.g. glycoproteins and glycolipids) in tissues and urine. It is caused by homozygous or compound heterozygous mutations in the FUC1 gene encoding the lysosomal enzyme on chromosome 1p36. Clinical features include coarse facial features, visceromegaly, dysostosis multiplex, progressive psychomotor retardation, ocular abnormalities, hearing loss and, with age, angiokeratoma.

Van Hoof and Hers (1968) found the deficiency of alpha-fucosidase activity in the liver of patients with a Hurler-like disorder described by Durand et al. (1969). Based on age at onset, severity of symptoms and length of survival, two different types were proposed: Type 1, a more severe form characterised by onset at about 6 months of age with rapid progression and death within the first decade of life, and Type 2, characterised by milder signs and slower progression with survival into adulthood and with the development of angiokeratoma corporis diffusum. Intermediate cases have been described and an intermediate third type was discussed. Willems et al. (1991) reviewed the literature on 77 patients with fucosidosis and suggested that the distinction between these types did not reflect true genetic heterogeneity, but rather that there seemed to exist a continuous clinical spectrum. The diagnosis of fucosidosis is made by finding the typical chromatographic profile of urinary oligosaccharides. Results are confirmed by measuring the alpha-L-fucosidase activity in leucocytes. Very low to negligible residual enzyme activity is found in patients of all types. Brain MRI showing diffuse hypomyelination, a thin corpus callosum, T1-hyperintensity and T2-hypointensity of the globus pallidus and cerebellar atrophy. Concerning treatment, bone marrow transplantation has been tried in some patients with fucosidosis (Vellodi et al. 1995; Miano et al. 2001). Although progressive increase in alpha-L-fucosidase levels and concomitant improvement in myelination on MRI was observed, there was no clinical improvement in psychomotor development.

**PERIPHERAL NEUROPATHY, CENTRAL HYPOMYELINATION, WAARDENBURG SYNDROME AND HIRSCHSPRUNG DISEASE**

The association of peripheral neuropathy, central hypomyelination, Waardenburg syndrome and Hirschprung disease (PCWH; MIM #609136), also called the neurological variant of Waardenburg-Shah syndrome, is caused by heterozygous mutations in the SOX10 gene, encoding a member of the SOX (SRY-related HMG-box) family of transcription factors involved in the regulation of neural crest and peripheral nervous system development, on chromosome 22q13.1. Waardenburg syndrome type 2E and 4C are allelic disorders.

The first case was reported by Inoue et al. (1999) in an 11-year-old Japanese girl with Waardenburg-Shah syndrome and neurological abnormalities, including a severe hypomyelinating leukodystrophy suggestive of PMD and a peripheral neuropathy consistent with Charcot–Marie–Tooth disease type I. Touraine et al. (2000) reported three unrelated European patients and contributed to the delineation of the clinical picture. Together with the clinical features of Waardenburg syndrome (pigmentary abnormalities of the hair, skin and eyes; congenital sensorineural hearing loss; and ‘dystopia canthorum’) and Hirschsprung disease (congenital absence of intrinsic ganglion cells in the myenteric and submucosal plexuses of the gastrointestinal tract), patients show early neurological signs with severe hyponatremia and developmental delay, nystagmus, and later on, progressive development of cerebellar ataxia, spasticity, demyelinating sensorimotor peripheral neuropathy and severe intellectual disability. Reduced production of tears, saliva and sweat develop progressively and growth failure is observed in surviving patients. Electrophysiological studies show reduced nerve conduction velocities and absent auditory brainstem responses. Brain MRI showing diffuse hypomyelination. Other MRI findings may be bilateral temporal bone abnormalities, agenesis of the cochlear nerve, agenesis of the olfactory bulbs and hypoplasia or agenesis of the lacrimal and parotid glands (Elmaleh-Berges et al. 2013).

**NUCLEOTIDE EXCISION–DNA REPAIR SYNDROMES**

Xeroderma pigmentosum (XP), Cockayne syndrome (CS) and trichothiodystrophy (TTD) are rare DNA repair syndromes with photosensitivity of the skin, hair and skin abnormalities, short stature, microcephaly, intellectual disability and various neurological abnormalities. An overlap between xeroderma pigmentosum and TTD, as well as between xeroderma pigmentosum and Cockayne syndrome, may be observed clinically and has also been demonstrated by complementation analysis of cell fusions. Hereditary mutations in the repair and transcription factor DFIH4 are associated with all three syndromes. White matter abnormalities are restricted mainly to Cockayne syndrome and TTD.

**COCKAYNE SYNDROME**

Cockayne syndrome is a rare but clinically characteristic disorder first described in 1936 as ‘dwarfism with retinal atrophy and deafness’. It follows an autosomal recessive inheritance.
Mutations in two major genes have been described: the gene \(ERCC8\) encoding the group 8 excision-repair cross-complementing protein on chromosome 5q11 (CSA; MIM #216400) (Henning et al. 1995); and the gene \(ERCC6\) encoding the group 6 excision-repair cross-complementing protein on chromosome 10q11 (CSB; MIM #133540) (Mallery et al. 1998), accounting for approximately 80% of Cockayne syndrome cases (Licht et al. 2003). From a clinical view, Nance and Berry (1992) reviewed 140 cases and distinguished three clinically different types of the disease: (1) classic Cockayne syndrome (the majority); (2) early-onset severe, rapidly progressive type Cockayne syndrome II, with clinical manifestations from birth and shorter survival; and (3) mild, late-onset, slowly progressive form. Mallery et al. (1998) found no correlation between genotype and phenotype among 16 patients with Cockayne syndrome of varying severities. Besides CSA and CSB, mixed forms associating features of Cockayne syndrome and xeroderma pigmentosum exist: XPG/CS (MIM #278780) caused by mutation in the \(ERCC3\) gene on chromosome 13q33; XPB/CS (MIM #610651), caused by mutation in the \(ERCC3\) gene on chromosome 2q21; and XPF/CS; MIM #278760, caused by mutation in the \(ERCC4\) gene on chromosome 16p13. Rapin et al. (2000) reviewed the clinical and molecular features of Cockayne syndrome, xeroderma pigmentosum and the xeroderma pigmentosum – Cockayne syndrome complex.

Affected children show characteristic cachiectic dwarfism, and a progeroid facial appearance with prominent chin and nose and large ears. The enophthalmia (sunken eyes) is due to the lack of subcutaneous orbital fat. Decreased height and weight, microcephaly, hearing loss, pigmentary retinopathy, dental caries and cataracts develop. Patients walk with a characteristic stoop, and develop pyramidal and cerebellar symptoms (Rapin et al. 2000). In contrast to other disorders of DNA repair, cancer has not been reported as a feature of classic Cockayne syndrome.

A peripheral neuropathy with reduced nerve conduction velocity and segmental demyelination in teased sural nerve preparations has been reported (Moosa and Dubowitz 1970). In an analysis of 13 cases, Pasquier et al. (2006) found a wide clinical variability of symptoms including conjunctival telangiectasia and skeletal dysplasia with flat vertebral bodies. Neuropathology described thickened leptomeninges, features of a calcifying vasculopathy, cerebral and cerebellar atrophy and lack of myelin with a tigroid pattern due to preserved islands of myelin. Calcium deposits may be found in the basal ganglia and dentate nuclei as well as in the white matter and cortex of the brain.

CT and MRI show calcifications of basal ganglia, white matter abnormalities (hypomyelination) and cerebellar atrophy (Adachi et al. 2006). CSF may show high lactate levels. Abnormal excretion of organic acids has also been observed. The diagnosis is based on the hypersensitivity to UV light of cultured cells (Lehmann et al. 1993). Prenatal diagnosis of Cockayne syndrome is possible (Kleijer et al. 2006). No treatment is available, the management is symptomatic.

**TRICHOThIODystrophy with Photosensitivity**

Trichothiodystrophy with photosensitivity (TTDP; MIM #601675) is an autosomal recessive disorder that may be caused by mutations in at least two genes that encode the two helicase subunits of transcription/repair vector TFIH: \(ERCC2/XPD\) gene on chromosome 19q13 (Frederick et al. 1994), accounting for the majority of patients; and \(ERCC3/XPB\) gene on chromosome 2q14 (Weeda et al. 1991). Besides these two groups, an exceptional trichothiodystrophy complementation group designated TTDA is caused by mutations in gene GTF2H5 coding for the tenth subunit of TFIH, TFB5, on chromosome 6q25 (Giglia-Mari et al. 2004).

Hashimoto and Egly (2009) reviewed the clinical features and genetics of trichothiodystrophies. TTDP is clinically characterised by (sulphur-deficient) brittle and fragile hair, often combined with ichthyosis and nail abnormalities. The abnormalities are usually obvious at birth, with variable clinical expression. Many patients die at a young age, most commonly due to infectious diseases. About half of the patients with TTD exhibit marked photosensitivity, due to abnormalities in excision repair of ultraviolet-damaged DNA. However, as in Cockayne syndrome, cancer is rare. Brain MRI showing a lack of myelination in supratentorial white matter with periventricular predominance and homogeneous involvement of the corpus callosum. The hair showing the characteristic ‘tiger-tail banding’ pattern with polarising microscopy, and contains decreased high-sulphur matrix proteins. The DNA excision repair defect can be demonstrated in fibroblasts.

Non-photosensitive trichothiodystrophy (TTDN; MIM #234050) is a distinct disorder without photosensitivity caused by mutations in the \(MPLKIP/TTDN1\) gene on chromosome 7p14 (Nakabayashi et al. 2005). The encoded protein is thought to be involved in regulating mitosis and not in nucleotide excision repair.

**MULTISYNTHETASE-RELATED HYpOMYELINATION LEUKODYSTROPHIES**

**DARS-Related Hypomyelination/ Hypomyelination with Brainstem and Spinal Cord Involvement and Leg Spasticity**

Hypomyelination with brainstem and spinal cord involvement and leg spasticity (HBSL; MIM #615281) is a recently described autosomal recessive leukoencephalopathy caused by homozygous or compound heterozygous mutations in the \(DARS\) gene on chromosome 4q21.3 (Taft et al. 2013). The gene \(DARS\) encoding the cytoplasmatic enzyme aspartyl-tRNA synthetase, a member of a multi-enzyme complex aminoacyl-tRNA synthetase (multisynthetase), that functions in mediating the attachment of amino acids to their cognate tRNAs.
Taft et al. (2013) reported ten patients from seven unrelated families from all over the world with severe lower limb spasticity associated with leukoencephalopathy. Most patients presented after normal early psychomotor development, between 4 and 12 months of age, with progressive motor dysfunction, mainly spasticity predominant in the lower limbs, as well as axial hypotonia and loss of motor milestones. None achieved independent walking. Four patients showed mild intellectual disability. Other features included nystagmus and pallor of the optic discs. Brain MRI showed extensive white matter abnormalities involving the supratentorial white matter, brainstem, cerebellar peduncles, and dorsal columns and lateral corticospinal tracts of the spinal cord. The authors noted the phenotypic similarities to the leukoencephalopathy with brainstem and spinal cord involvement and lactate elevation (LBSL; MIM #611105), which is caused by mutations in the DARS2 gene, coding for the mitochondrial enzyme aspartyl-tRNA synthetase 2 (see the Leukoencephalopathy with Brainstem and Spinal Cord Involvement and Lactate Elevation section).

**RARS-Related Hypomyelination**

By performing whole exome sequencing, Wolf et al. (2014) have recently found mutations in the RARS gene in four patients of three families with hypomyelination. The gene RARS, on chromosome 5q35, encodes the cytoplasmic enzyme arginyl-tRNA synthetase for arginine, which is also a component of the multi-enzyme aminoacyl-tRNA synthetase (multisynthetase) complex, like aspartyl-tRNA synthetase, deficiency of which causes HBSL (MIM #615281; see the DARS-Related Hypomyelination/Hypomyelination with Brainstem and Spinal Cord Involvement and Leg Spasticity section).

Clinically, three of the patients showed a similar picture, presenting around the age of 5–12 months with severe spasticity predominant in the lower limbs, nystagmus, mild ataxia and mild intellectual disability. The fourth patient had a much more severe form with earlier onset and with, in addition, a low level of cognition and lack of visual contact paralleling the early severe atrophy present at brain imaging. None of the patients had clinical evidence of peripheral neuropathy. CSF lactate was normal or only slightly elevated in the more severely affected patient. Brain MRI showed severe lack of myelin in the supratentorial white matter in all four patients. Proton MRS of the white matter showed low choline in all four patients and low N-acetylaspartate and elevated lactate in the more severely affected patient.

With the exception of the more severely affected patient, clinical presentation of patients with RARS-related hypomyelination was very similar to HBSL, especially concerning the severe spasticity. Imaging abnormalities are comparable in both entities regarding supratentorial signal abnormalities. Patients with mutations in the RARS gene, however, did not show the brainstem and spinal cord signal abnormalities typical of HBSL. The authors suggested that it is probable that defects in the multisynthetase complex play an important role in the pathogenesis of hypomyelination.

**GLOBAL CEREBRAL HYPOMYELINATION**

Global cerebral hypomyelination (MIM #612949), also called aspartate-glutamate carrier 1 (AGC1) deficiency, is caused by mutations in the SLC25A12 gene on chromosome 2q31.1, which encodes the AGC1 protein, also known as aralar, a calcium-binding mitochondrial carrier protein involved in the exchange of aspartate for glutamate across the inner mitochondrial membrane.

Only a few cases have been described to date. Wibom et al. (2009) reported the first case in a girl with delayed development from age 5 months with hypotonia, seizures and episodic apnea from 7 months and, later on, severe psychomotor retardation and spasticity. Plasma lactate was increased. Brain MRI showed a global lack of myelination in the cerebral hemispheres and decreased supratentorial volume. The cerebellum, brainstem, and thalami were essentially normal. There was no apparent lesion in the grey matter. MRS showed decreased NAA. Wolf and van der Knaap (2009) commented, and the authors agreed, that the patient described had a primary defect in the cortical grey matter, rather than a leukoencephalopathy. The reduced peak of NAA found on spectroscopy indicates neuronal degeneration, and impaired formation of myelin can be secondary to neuronal dysfunction.

**DEAFNESS, DYSTONIA AND CEREBRAL HYPOMYELINATION**

Deafness, dystonia, and cerebral hypomyelination (DDCH; MIM #300475) is caused by hemizygous mutations in the BCAP31 gene, encoding a member of the B-cell receptor associated protein 31 superfamily involved in the anterograde transport of membrane proteins from the endoplasmic reticulum to the Golgi, on chromosome Xq28. DDCH is an X-linked recessive disorder characterised by severe psychomotor development delay, dysmorphic facial features, sensorineural deafness, dystonia, pyramidal signs, increased liver enzymes during febrile illness and hypomyelination on brain imaging with variable cerebral or cerebellar atrophy (Cacciagli et al. 2013).

The gene BCAP31 is a neighbour of the gene ABCD1, responsible for X-linked adrenoleukodystrophy (X-ALD; MIM #300100; see X-linked Adrenoleukodystrophy section). Microdeletions including both genes give rise to the contiguous ABCD1/DXS1375E(BCAP31) deletion syndrome (CADDs), a disorder with neonatal onset and liver disease, unlike the classic X-ALD due to ABCD1 mutations (Corzo et al. 2002).
A few degenerative disorders involve most parts of both the cerebrum and cerebellum or brainstem structures, without any evidence of storage or specific lesion. They are of proven or likely genetic origin but their mechanism is undetermined. The peripheral nervous system is also affected in the two main conditions of this group, neuro-axonal dystrophy (NAD) and neuronal intranuclear inclusion disease.

**NEURO-AXONAL DYSTROPHY (SEITELBERGER DISEASE)**

This disease is now included in the group of diseases called neurodegeneration with brain iron accumulation (NBIA) characterised by iron accumulation in the basal ganglia. A number of autosomal recessive NBIA syndromes can present in childhood, most commonly pantothenate kinase-associated neurodegeneration (NBIA1 or PKAN, due to mutations in the PANK2 gene; see Chapter 19) and phospholipase A2 group A-associated neurodegeneration (NBIA2 or PLAN, associated with genetic defects in PLA2G6). PLAN comprises a heterogeneous group of autosomal recessive neurodegenerative disorders associated with genetic defects in the PLA2G6 gene (Khateeb et al. 2006; Morgan et al. 2006). PLA2G6 encodes a calcium-independent phospholipase A2 enzyme, which is involved in phospholipid remodelling and is thought to be integral to maintaining cell membrane homeostasis (Tanaka et al. 2004; Balsinde and Balboa 2005). Alteration or loss of function of this protein may result in the axonal pathology of both the central and peripheral nervous system and brain iron accumulation observed in these conditions. The phenotypic spectrum of PLA2G6-related disorders is ever expanding. The classic infantile neuro-axonal dystrophy (INAD; MIM #256600) is a form of PLAN presenting in infancy (infantile PLAN). It accounts for the majority of PLAN cases and the PLA2G6 mutation detection rate is particularly high (80–90%) in children with the classic INAD phenotype (Crompton et al. 2010). Allelic disorders are childhood PLAN or atypical NAD including Karak syndrome (MIM #610217) and adult-onset PLAN or early-onset dystonia-parkinsonism (MIM #612953) (Morgan et al. 2006; Kurian et al. 2008; Paisan-Ruiz et al. 2009).

Pathological findings in INAD include the presence of axonal swellings, known as spheroids, formed by branched tubular structures and bundles of filaments with mitochondria in nerve fibres, especially at presynaptic endings. The spheroids are widespread throughout the CNS and are especially numerous in the posterior horns of the spinal cord, Goll and Burbach nuclei, and pallidum, which also contain excess ferric pigment and fat. They are also present in the peripheral nerves, which has been the basis for the diagnosis by peripheral biopsy. Smaller bodies with a similar ultrastructure (eosinophilic bodies) are found in the cortex. There is associated diffuse gliosis of the white matter of the centrum semiovale and degeneration of several long tracts of certain systems (e.g. pyramidal, spinocerebellar) (Aicardi and Castelein 1979). A disturbance of retrograde axonal transport may be the cause of the disease.

Clinical onset is usually between 6 months and 2 years of age, median age 14 months (Aicardi and Castelein 1979; Nardocci et al. 1999b; Gregory et al. 2008; Kurian et al. 2008), often with axial hypotonia or difficulties of ambulation. In some cases, an intercurrent illness can precede symptom presentation, thus mimicking the clinical presentation of a metabolic disorder (Kurian et al. 2008). Progress stops and, after a period of stagnation of weeks to months, frank deterioration appears. Rapidly, there is hypotonia so marked as to suggest the diagnosis of a neuromuscular disease (Aicardi and Castelein 1979). However, pyramidal tract signs appear early even though deep tendon reflexes may be weak or absent. The disease progresses to severe dementia accompanied by increasing spasticity that evolves into decorticate rigidity. Optic atrophy with nystagmus is present in 70% of cases by 3 years of age, and may be reported in the early stages of the disease (Kurian et al. 2008). The majority of children develop spinal deformities such as kyphoscoliosis and limb contractures. Bulbar dysfunction is normally evident in most children by 5 years of age (Kurian et al. 2008). Extrapyramidal features such as dystonia are also reported, more commonly towards the end of the first decade. Epileptic seizures are unusual and frequently a later feature in the disease course (Barontini and Papini 1981) although in certain populations epileptic seizures may be evident at an earlier stage (Wu et al. 2009). Death occurs by 5–10 years, mean age 9 years, and is usually secondary to cardiorespiratory complications, infection, malnutrition and, rarely, status dystonicus (Kurian et al. 2008; Gregory et al. 2008). The CSF is normal and no specific biochemical marker is known. CT and MRI usually show cerebellar atrophy but no abnormality of density of the white matter. Cerebellar atrophy is a universal feature and often the earliest sign on MRI. Increased T2 signal in the cerebellar cortex and low water diffusion are suggestive (Nardocci et al. 1999a; Sener 2004) and usually increase in severity with age, but not all children have this feature. Cerebellar hypoperfusion has been demonstrated by functional imaging (Kobor et al. 2005). Many children (40–50%) also have evidence of brain iron accumulation (Gregory et al. 2008; Kurian et al. 2008) with increased iron deposition in the globi pallidi (particularly in the medial aspect of the globus pallidus), dentate nuclei, and substantia nigra, which also appears to become increasingly severe with age. High T2 signal and atrophy of the cerebral white matter have also been reported (Kurian et al. 2008). A neurophysiological syndrome, very suggestive of NAD, is virtually constant. It includes: (1) typical electromyography
(EMG) signs of denervation, especially in distal muscles, with normal sensory and motor conduction velocities; (2) high-amplitude, fast (18–24 Hz) activity in waking and sleep EEG after 18–30 months of age; (3) absent or abnormal visual and somesthetic evoked potentials after at least a few months course. Pathological confirmation of the diagnosis can be obtained from peripheral biopsies, especially of the skin or conjunctiva (Fig. 10.11) but also rectal mucosa, sural nerve and muscle. Brain biopsy is long since unjustified. The presence of axonal swelling and spheroid body formation is not specific, as they can also be found in other forms of NBIA. In recent years, the availability of molecular genetic testing has eliminated the need for invasive biopsy in the majority of cases.

Childhood-onset PLAN or atypical NAD is much rarer than INAD and includes the condition previously described as Karak syndrome (Mubaidin et al. 2003). It has a later clinical onset, from 18 months to 6.5 years, mean age 4 years and 3 months, usually with subtle gait abnormalities, dyspraxia, and speech regression, and the progression is slower (Morgan et al. 2006; Gregory et al. 2008; Gregory et al. 2009). Over time, many signs of INAD such as optic atrophy, nystagmus, tetraparesis and seizures appear; however, signs of adolescent or adult NBIA phenotypes such as extrapyramidal features and neuropsychiatric disturbances become major features later in the disease course. The lifespan of atypical NAD is not currently determined. Brain iron accumulation is a consistent universal feature, involving both globus pallidus and substantia nigra. Cerebellar atrophy may also be present. Fast rhythms of EEG have not been reported. Visually evoked potentials may be delayed with reduced amplitude. EMG, nerve conduction studies, and electroretinogram are reported to be normal. Histopathological findings are identical to those described for INAD.

In a significant proportion of children with NBIA there is currently no known genetic diagnosis (Gregory et al. 2009). This group display marked clinical heterogeneity, with age at presentation that varies greatly from symptom onset in infancy (often with rapid disease progression) to initial presentation in the third to fifth decade (often associated with slower disease progression), and diverse clinical signs including pyramidal, extrapyramidal, and ophthalmological features. Evidence of iron accumulation in the globus pallidus and substantia nigra is seen on brain MRI.

The differential diagnosis of INAD includes a large number of disorders, among which infantile metachromatic leukodystrophy may have a very similar presentation; also the pantothenate kinase 2 (PANK2)-associated neurodegeneration (formerly Hallervorden–Spatz disease) (see Chapter 19), accounting for approximately 50% of childhood NBIA disorders. It is clinically different as it presents mostly with extrapyramidal features, and is also genetically distinct by molecular study.

Only supportive treatment is available for any form of NAD. Genetic counselling and prenatal diagnosis is now possible in cases with identification of the causative gene.

## DISORDERS INVOLVING PREDOMINANTLY THE GREY MATTER

These include the neuronal ceroid lipofuscinoses, which also feature more diffuse involvement of the CNS, and a group of poorly defined conditions known as the poliodystrophies.

### POLIODYSTROPHIES

Poliodystrophies form a heterogeneous group of disorders known collectively as Alpers or Alpers-like disease. The poliodystrophies are characterised pathologically by predominant involvement of the grey matter, which is reduced in volume and of abnormally firm consistency. At a late stage, the brain is usually grossly atrophic, the so-called ‘walnut brain’. Neurons are greatly reduced or lacking altogether, or in a focal or laminar topography. There is marked glial proliferation, often associated with a spongy appearance of the neuropil, hence the term glioneuronal spongy degeneration used by some authors. At an early stage, the focal distribution of lesions is remarkable or they may be minimal. Such grey matter degeneration is difficult to differentiate from other conditions such as hypoxic sequelae, hypoglycaemia or postepileptic encephalopathy, and undoubtedly some such cases have been included among reports of poliodystrophy. Therefore, the diagnosis should be based not only on pathological findings but also on the notion of a progressive illness. Most authentic cases of poliodystrophy have an established or probable genetic origin with an autosomal recessive inheritance.
The best-defined group among the poliodystrophies is the progressive neuronal degeneration of childhood (PNDC) with hepatic involvement or Alpers-Huttenlocher syndrome, an autosomal recessive progressive disorder considered today as an infantile or childhood-onset polymerase-γ-related disorder (Saneto and Cohen 2013) and also known as mitochondrial DNA depletion syndrome 4A (Alpers type; MIM #203700), caused by homozygous or compound heterozygous mutations in the nuclear gene POLG on chromosome 15q26.1 encoding mitochondrial DNA polymerase-γ. Although the first report of this condition dates from 1890 (Bullard 1890), Alpers described the clinical picture in 1931 (Alpers 1931). The description of the associated hepatic features and CSF findings and the confirmation of autosomal recessive inheritance happened 45 years later (Fluttenlocher et al. 1976). More than 20 years later, Harding described 32 patients with a distinctive liver and brain pathology, defining the typical clinical course of the disease (Harding 1990). The biochemical and enzymatic relevance of polymerase-γ to Alpers-Huttenlocher syndrome was established by Navaux et al. with their description of mitochondrial DNA depletion and reduced POLG enzyme activity in a child with Alpers syndrome (Navaux et al. 1999). In 2004, mutations in POLG were shown to be responsible for the clinical entity of Alpers-Huttenlocher syndrome (Navaux and Nguyen 2004). The onset of this disorder is usually between 2 and 4 years of age (range 3 months to 8 years) (Harding 1990; Wiltshire et al. 2008). In other cases, disease progression is slower (Tzoulis et al. 2006; Saneto and Navaux 2010b). Signs of hepatic disease that may end in terminal liver failure often become obvious only late in the course or in autopsy findings (Harding 1995). Exposure to valproic acid inducing severe liver dysfunction has been a defining feature of Alpers-Huttenlocher syndrome (Bicknese et al. 1992; Navaux and Nguyen 2004; Nguyen et al. 2005; Wolf et al. 2009; Saneto et al. 2010a). Such cases may be easily mistaken for valproate hepatotoxicity (Bicknese et al. 1992; Delarue et al. 2000). The histochemical changes induced by valproic acid are identical to those observed without exposure (Harding 1990; Nguyen et al. 2006) and differ from those in other chemically induced or toxic liver disorders (Simonati et al. 2003). The exact mechanism of liver alterations remains elusive.

Mutations in POLG are associated with other mitochondrial disorders involving the gastrointestinal system, muscle and/or CNS. More than 180 pathogenic mutations of POLG, with both dominant and recessive modes of inheritance, have been described resulting in a wide phenotypic spectrum. Recessive mutations represent the predominant disease inheritance pattern and they can occur throughout all exons in POLG and produce several clinical syndromes as well as multiple organ system diseases with onset throughout the lifespan that do not cluster within distinct phenotypic syndromes (Wong et al. 2008; Saneto and Navaux 2010b; Tang et al. 2011). Furthermore, other mitochondrial DNA depletion syndromes due to mutations in other genes exist, resulting in hereditary progressive disorders with variable age at onset and involvement of multiple organs, including in some cases the liver and the brain (Finsterer and Ahting 2013; El-Hattab and Scaglia 2013; Uusimaa et al. 2014).

**THE CEROID LIPOFUSCINOSES**

**Neuronal Ceric Lipofuscinosis (Batten Disease)**

The neuronal ceroid lipofuscinoses (CLNs) are a clinically and genetically heterogeneous group of disorders, collectively called *Batten disease*, characterised by the intracellular storage of certain lipopigments that present morphological and tinctorial similarities with lipofuscin, an autofluorescent ‘wear-and-tear pigment’ accumulating in the cells of many animal tissues during ageing. They constitute a special group within the inherited lysosomal storage disorders. Zeman and Dyken (1969) referred to these conditions as the ‘neuronal ceroid lipofuscinoses’. Goebel (1995) provided a comprehensive review of the CLNs and noted that they are possibly the most common group of neurodegenerative diseases in children.

CLNs are a panethnic group of diseases; however, local variations are marked. Their incidence rates vary from 1 / 67 000 in
Italy and Germany to 1:14,000 in Iceland, and their prevalence rates vary from 1:1000000 in some regions to 1:100000 in the Scandinavian countries (Williams 2011). Some forms seem to have a higher frequency in certain populations, as is the case of CLN6 in Southern European countries (Teixeira et al. 2003) and CLN7 in certain Mediterranean populations (Aiello et al. 2009; Aldahmeh et al. 2009; Kousi et al. 2009; Stogmann et al. 2009).

Despite the clinical and genetical heterogeneity, all forms of NCL share a remarkably uniform morphological phenotype, the basis of the NCL concept (Haltia 2003; Haltia et al. 2011). All forms of NCL share at least two essential features: (1) Autofluorescent, electron-dense, periodic acid–Schiff (PAS) and Sudan black B-positive granules, resistant to lipid solvents, accumulate in the cytoplasm of most nerve cells and, to a lesser extent, in many other cell types. (2) This storage is associated with progressive and selective loss of neurons, particularly in the cerebral and cerebellar cortex and, less constantly, in the retina, leading to cognitive, motor and visual deterioration with refractory epilepsy.

Although the term lipofuscin, which designates the pigment that accumulates in neurons with age, is often used, the lipopigments that constitute the storage substance, termed ceroid, differ (Seehafer and Pearce 2006). The chemical nature of these pigments is not fully characterised. A major component of the pigment stored in infantile and juvenile ceroid lipofuscinosis comprises subunit C of the respiratory chain enzyme ATP-synthase. Ceroid accumulates mainly in lysosome-like structures that give a positive acid phosphatase reaction. Their ultrastructural appearance is also distinct. The lipopigment pattern seen most often in all forms of CLN1, in CLN10, as well as in the autosomal dominant adult-onset form CLN4b is referred to as granular osmiophilic deposits (GRODs). The pattern most often observed in CLN2 is curvilinear, and in CLN3 fingerprint, less frequently mixed. The other forms of CLN often show combinations of curvilinear, rectilinear and fingerprint profiles (for review see Anderson et al. 2013).

Since 1995, over 360 mutations in 13 different genes underlying the various established human forms of NCL have been identified (Kousi et al. 2012). The NCL genes are of vital importance for the maintenance of cerebral neurons. Intracellular localisation and function (where known) of the defective proteins are different: four NCL types are caused by defects in lysosomal enzymes (CLN1, CLN2, CLN10, CLN13), others by defects in transmembrane proteins (CLN3, CLN6, CLN7, CLN8) (Jalanko and Braulke 2009). Mutations in an ATPase gene (CLN12) (Bras et al. 2012) and a potassium channel gene (CLN14) (Staropoli et al. 2012) also cause NCL disease. The recently identified CLN4 gene (DNAJC5) codes for a protein with putative function in synapses (Arsov et al. 2011). How these genetic defects lead to neurodegeneration is still not well understood.

The original classification of the NCLs (Zeman 1976) was based on their clinical and neuropathological phenotypes, mainly on the age at onset of the clinical manifestations and the ultrastructure of the storage cytosomes. The advances in molecular genetics have made this old classification problematic, since different mutations in a given gene may give rise to varying phenotypes, including widely different ages at onset. A purely genetic classification of the NCLs has therefore been proposed, in which they are classified numerically according to the underlying gene defect into 14 genetic forms from CLN1 to CLN14, regardless of the age at onset (Mole et al. 2005). A new NCL classification that identifies each CNL both genetically and clinically has been developed in an attempt to be universally understood and of value for clinicians responsible for diagnosis and treatment, research scientists, patients and families (Mole et al. 2011; Williams et al. 2011; Williams and Mole 2012). It classifies the NCLs using both the defective gene as well as the age at onset (Table 10.6). In 13 of the 14 NCL forms described to date, the responsible genes are currently isolated and characterised, located on different chromosomes. All but one (the autosomal dominant adult-onset CLN4b) show an autosomal recessive mode of inheritance, and the age at onset can vary, resulting in congenital, infantile, late infantile, juvenile and adult forms. The clinical manifestations are the result of the progressive degeneration of CNS and, less constantly, of retinae. In the childhood forms, the clinical picture is dominated by epilepsy, myoclonus and cognitive deterioration, expressing the predominant involvement of the grey matter (Santavuori et al. 2001), as well as by progressive loss of vision, while the adult forms usually present with dementia.

The diagnosis of NCL may be difficult especially in the less usual forms. Neurophysiological features, such as an abnormal ERG and a peculiar response of the EEG to slow light stimulation (1–3Hz), are of value in late infantile and some adult-onset forms. Brain atrophy on neuroimaging is usually present early in the childhood onset forms, but it may also not be found in the first year and it may be absent in the adult-onset forms. A decreased T2 signal in the thalamus found in CNLs 1, 2, 3, 5, 6 and 7 is suggestive but not specific (Autili et al. 2007). Cerebellar atrophy and leukoencephalopathy are also frequently found (Jadav et al. 2012).

The term neuronal ceroid lipofuscinosis is not entirely accurate as the lipopigment is also found in many extraneuronal tissues. Most diagnostic brain biopsy investigations were carried out before this widespread accumulation of lipopigments in extracerebral tissues had been recognised, and have then been superseded by those of skin, rectum, skeletal muscle and even blood lymphocytes, that have traditionally been the basis of the diagnosis. The demonstration of low activity of the lysosomal enzyme in some forms, or the identification of the responsible gene mutations in most, now allows accurate diagnosis. However, ultrastructural examination of extracerebral tissues is still necessary in atypical cases, particularly the late infantile onset variants and the relatively stable figures (10–12%) of molecularly undetermined cases.

Prenatal diagnosis has been made by demonstration of the enzyme activity deficiency or the presence of the typical ultrastructural storages in chorionic villus biopsies in CNLs 1, 2 and 3, less frequently in other forms. This procedure has been

GRODs, granular osmophilic deposits.
replaced by molecular testing in at-risk pregnancies and for suspected carriers.

In 1998 an electronic CLN Mutation Database was created, maintained by Dr Sara Mole at University College London. The database is now part of the ‘NCL Resource – a gateway for Batten disease’ (www.ucl.ac.uk/ncl/index.shtml), providing up-to-date information on the NCLs for clinicians, families and researchers on a free access basis.

To date, there is no curative treatment for any of the NCLs. Anticonvulsant treatment is essential in most types. Sodium valproate and/or clonazepam are often effective, but antiepileptic treatment should be individualised and seizures may be totally refractory. Supportive care to the patients and families is essential and helps lessen the impact of these devastating diseases. In recent times, preclinical experiments in the murine model of infantile NCL have shown that gene therapy, enzyme replacement, stem cell transplantation and small-molecule drugs, alone and especially in combination, can significantly slow disease progression (for review see Kohan et al. 2011; Sands 2013). Some of them have already been tried in children with NCL (Selden et al. 2013). Similar approaches may be useful to treat other forms of NCL, but different targets will need to be identified in order to design novel therapeutic strategies.

**CLN1**

**Infantile Classic; Santavuori Disease; Santavuori-Haltia Disease**

CLN1 is the classic form of infantile-onset CLN, also known as Santavuori disease or Santavuori-Haltia disease. It is due to homozygous or compound heterozygous mutations in the gene *PPT1/CLN1* on chromosome 1 (1p34.2) that codes for the enzyme palmitoyl protein thioesterase (PPT1), a lysosomal enzyme involved in the catabolism of lipid-modified proteins during lysosomal degradation (Camp et al. 1994). The early development of affected infants is normal. From 6 to 12 months of age, intellectual deterioration and ataxia are the main features. Anxiety and autistic-like features may be prominent, together with the abnormal stereotypic hand movements (‘knitting movements’) that may wrongly suggest the diagnosis of Rett syndrome (see Chapter 5). Myoclonic jerks appear during the second year of life and there is progressive microcephaly due to brain atrophy. Optic atrophy and macular and retinal degeneration without pigment aggregation are frequent, and the ERG is always extinguished, except perhaps in the first few months of the illness. The EEG showing progressive slowing and loss of amplitude leading to an isoelectric tracing (‘vanishing EEG’) during the third year of life (Santavuori 1988). Seizures may not be as prominent as in later onset forms. From 3 to 4 years of age, the disease appears to be ‘burnt out’, spasticity develops and the children remain vegetative without contact with their surroundings until death between 6 and 15 years (Santavuori et al. 1993).

The disease produces an extraordinary degree of brain atrophy. This is well demonstrated by MRI that showing, in addition hypodensity of the thalami, a peripheral ring of increased T2 signal around the ventricles and a reversal of the normal white–grey contrast in late stages (Vanhanen et al. 1995). Surviving neurons, as well as a number of extraneural cells, contain large amounts of ceroid with a homogeneous, finely granular internal structure (Fig. 10.12). Extracerebral storage cytosomes are commonly seen in muscle, eccrine sweat glands of the skin, ganglion cells of the enteric nervous system and to a lesser extent circulating activated macrophages and fibroblasts. Skin biopsy or blood sample for lymphocyte examination and less frequently rectal biopsy are used for the assessment. The storage cytosomes are membrane-bound granular osmiophilic deposits (GRODs). No vacuolated lymphocytes are found. The demonstration of low activity of the enzyme PPT1 or the analysis of the mutation confirms the diagnosis.

Beside the classic infantile-onset CLN1, distinct mutations of the *CLN1* gene can express later in life, giving rise to a late infantile-onset form, a juvenile-onset form and an adult-onset form of CLN1. Diagnosis, as in the infantile-onset form of CLN1, is through testing of PPT1 activity and mutation analysis.

Late infantile-onset CLN due to *CLN1* mutations presents between the age of 1 and 4 years with visual and cognitive decline followed by ataxia and myoclonus (Bonsignore et al. 2006).

Juvenile-onset CLN due to *CLN1* mutations (Kalvainen et al. 2007) presents between the ages of 5 and 10 years with cognitive decline most commonly as the earliest symptom. Seizures may be prominent and diverse in type. Motor decline occurs, but there is typically neither parkinsonism nor myoclonus. Spasticity and ataxia may develop. Vision loss is late in this form, occurring usually between the ages of 10 and 14 years.

Adult-onset NCL due to *CLN1* mutations (Ramadan et al. 2007) presents after 18 years of age with cognitive decline and depression, followed by ataxia, parkinsonism and vision loss.
**CLN2**

**Late Infantile Classic; Jansky–Bielschowsky Disease**

CLN2 is the classic form of late infantile onset CLN, also known as Jansky–Bielschowsky disease. It is due to homozygous or compound heterozygous mutations in the gene \(TPP1/CLN2\) on chromosome 11 (11p15.4), which codes for the lysosomal enzyme tripeptidyl peptidase 1 (TPP1). The clinical onset is between 18 months and 4 years of age (Steinfeld et al. 2002). The first symptom is an arrest and rapid regression of development, usually in the second or third year of life. Epilepsy is the prominent feature but usually begins after 30 months of age, soon followed by language regression, dementia and marked ataxia. Seizures may be diverse in type and are often refractory to treatment. They are often myoclonic and are associated with erratic and intention myoclonus, and may simulate Lennox-Gastaut syndrome or other myoclonic epilepsies. Loss of motor skills and spasticity develop rapidly and the children become bedridden by 3.5–6 years of age. Visual failure is usually late: after the age of 6 years. Retinal degeneration, more visible in the macula, and optic atrophy usually appear by 3–4 years of age, and at onset even the ERG may be normal. Death occurs between 6 and 15 years of age.

The neurophysiological picture is characteristic. The EEG showing, in addition to multifocal spikes and slow background rhythm, a peculiar response to photic stimulation at a low rate, each flash producing a spike in the posterior scalp regions (Harden and Pampiglione 1982). The ERG is extinguished. Visual evoked potentials and somatosensory evoked responses are also very large, although VEPs may become abolished at a late stage (Fig. 10.13).

Neuroimaging demonstrates brain atrophy less marked than in infantile-onset CLN1. Extracerebral tissues show cytosomes containing curvilinear profiles (see Fig. 10.12). The lymphocytes are not vacuolated. The demonstration of low activity of the enzyme TPP1 or the analysis of the mutation allows the diagnosis.

**CLN3**

**Juvenile Classic, Batten Disease; Vogt-Spielmeyer Disease; Spielmeyer-Sjögren Disease**

CLN3 is the classic form of juvenile-onset CLN, also known as Batten disease, Vogt-Spielmeyer disease or Spielmeyer-Sjögren disease. It is due to homozygous or compound heterozygous mutations in the gene \(CLN3\) on chromosome 16 (16p11.2) that codes for CLN3, a membrane protein of 438 amino acids involved in lysosomal function. It presents between the ages of 4 and 7 years with insidious onset of visual loss caused by retinal degeneration, more visible in the macula, and optic atrophy usually appear by 3–4 years of age, and at onset even the ERG may be normal. Death occurs between 6 and 15 years of age.

Myoclonic seizures are common but other generalised, and partial seizures may also supervene. Deterioration is initially absent or mild but behavioural disturbances such as angry outbursts, physical violence, and anxiety with features of depression may be prominent, often leading to a misdiagnosis of a psychiatric condition. A special type of dysarthria with precipitate and indistinct emissions becomes obvious by 10–15 years of age. Neurological signs develop slowly and include extrapyramidal manifestations (parkinsonism with tremor and rigidity, sometimes responsive to L-DOPA) and slight cerebellar and pyramidal signs. In addition to the neurological features, CLN3 patients manifest a cardiac conduction abnormality in the second decade of life. The course is relentlessly progressive leading to death between 15 and 30 years of age.

Ophthalmological examination reveals macular degeneration with pigment aggregates, present from 10 years onward. The EEG may show pseudoperiodic bursts of high-amplitude slow waves or a low-amplitude, rather featureless tracing (Harden and Pampiglione 1982). The ERG and VEPs are decreased or abolished early in the course. Neuroimaging showing mild to moderate atrophy. Extensive calcification is present pathologically and may be apparent on CT.

Lymphocytes are usually vacuolated and show storage with a predominance of fingerprint profiles. The ultrastructural examination of other extracebral tissue also showing storage with a predominance of fingerprint profiles (Fig. 10.13), but mixed populations of cytosomes with fingerprint, rectilinear and, less frequently, curvilinear profiles may be found. Diagnosis relies on the demonstration of these morphological features and on mutations in \(CLN3\), where a typical deletion is found in the wide majority of cases.
**CLN4**

**Classic Adult-Onset CLN; Kufs Disease**

Classic adult-onset CLN, also known as Kufs disease, is a CLN without retinal involvement. Berkovic et al. (1988) separate two phenotypes: one characterised by progressive myoclonic epilepsy and neuropsychiatric changes, also observed by Sadzot et al. (2000), and another one, characterised by dementia and motor, cerebellar and extrapyramidal manifestations. These two classic phenotypes correspond to two currently well differentiated CLNs: (1) CLN4 type A, autosomal recessive, which is actually due to mutations of CLN6, other mutations of which are also responsible for CLN6 (Arsov et al. 2011), and (2) CLN4 type B, autosomal dominant, due to mutations of DNAJC5/CLN4 (Noskova et al. 2011; Cadieux-Dion et al. 2013). Both types have their onset around age 30 years, and neither develops retinal degeneration or blindness.

CLN4 type A, also known as autosomal recessive adult-onset CLN4 or Kufs type A variant of adult-onset CLN is caused by homozygous or compound heterozygous mutations in the CLN6 gene on chromosome 15q21-q23, the same responsible for the CLN6, therefore this form can also be classified as adult-onset CLN6. It has an onset around 30 years of age with progressive myoclonic epilepsy followed by development of dementia and ataxia. Dysarthria is prominent. There is no vision loss. Death typically occurs within 10 years. The EEG may show a remarkable response to photic stimulation, with high-amplitude spikes synchronous with flashes at low rhythm of repetition. Vacuolated cells can be found in skin and rectal biopsies and ultrastructural investigations may reveal aggregates of fingerprint profiles surrounded by a single membrane of lysosomal origin. Ultrastructural investigation of blood lymphocytes is not helpful. Mutations in the CLN6 gene are diagnostic. Arsov et al. (2011) noted the striking phenotypic differences between patients with earlier-onset CLN6 and patients with CLN4a or adult-onset CLN6. Patients with earlier-onset CLN6 have retinal involvement, whereas none of the Kufs syndrome patients had retinal involvement. The authors suggested that CLN4 type A or adult-onset CLN6 patients may have some residual mutant protein function or that there are other disease modifiers.

CLN4 type B, also known as autosomal dominant adult-onset CLN4, autosomal dominant Kufs disease or Parry type variant of adult-onset CLN is caused by heterozygous mutations in the gene DNAJC5/CLN4 on chromosome 20q13.33 (Noskova et al. 2011; Cadieux-Dion et al. 2013). DNAJC5, a cysteine-string protein alpha acting in synaptic vesicles (Noskova et al. 2011), is responsible for the CLN6, therefore this form can also be classified as adult-onset CLN6. It has an onset around 30 years of age with progressive myoclonic epilepsy followed by development of dementia and ataxia. Dysarthria is prominent. There is no vision loss. Death typically occurs within 10 years. The EEG may show a remarkable response to photic stimulation, with high-amplitude spikes synchronous with flashes at low rhythm of repetition. Vacuolated cells can be found in skin and rectal biopsies and ultrastructural investigations may reveal aggregates of fingerprint profiles surrounded by a single membrane of lysosomal origin. Ultrastructural investigation of blood lymphocytes is not helpful. Mutations in the DNAJC5 gene have been described (Pineda-Trujillo et al. 2005; Xin et al. 2011). In the late infantile onset forms, mean age at onset is 5.6 years, and clinical onset commences usually with cognitive deterioration or ataxia. Visual symptoms (macular dystrophy and progressive optic atrophy), epileptic manifestations and neurophysiological abnormalities are observed after 7–8 years of age, and the course is slower than in the classic late infantile onset. The lipopigment patterns observed most often in CLN5 comprise mixed combinations of curvilinear and fingerprint and, less frequently, rectilinear and granular profiles. Diagnosis depends on analysis of the CLN5 gene.

**CLN5**

**Finnish Variant Late Infantile; CLN with Variable Age at Onset**

CLN5, also known as Finnish variant late-infantile-onset CLN (Wisniewski et al. 1993) or CLN with variable age at onset, is caused by homozygous or compound heterozygous mutations in the gene CLN5 on chromosome 13q22.3, that codes for a soluble lysosomal protein with unknown function (Isosomppi et al. 2002). Despite the name, it occurs worldwide (Savukosky et al. 1998; Moore et al. 2008; Lebrun et al. 2009; Xin et al. 2011). Age at onset in the late infantile onset form is more variable (4–7 years) than in classic late infantile onset CLN (CLN2), and apart from the late infantile onset, some juvenile and even adult-onset CLN5 cases have been described (Pineda-Trujillo et al. 2005; Xin et al. 2011). In the late infantile onset forms, mean age at onset is 5.6 years, and clinical onset commences usually with cognitive deterioration or ataxia. Visual symptoms (macular dystrophy and progressive optic atrophy), epileptic manifestations and neurophysiological abnormalities are observed after 7–8 years of age, and the course is slower than in the classic late infantile onset. The lipopigment patterns observed most often in CLN5 comprise mixed combinations of curvilinear and fingerprint and, less frequently, rectilinear and granular profiles. Diagnosis depends on analysis of the CLN5 gene.

**CLN6**

**Lake-Cavanagh, Early Juvenile; Indian Variant, Late Infantile-Onset**

Mutations affecting the CLN6 gene are related to a wide phenotypic spectrum. Thus, CLN6 gene mutations can give rise to Lake-Cavanagh early juvenile CLN (Lake and Cavanagh 1978), to Indian variant late-infantile-onset CLN (Sharp et al. 1997), as well as to adult-onset form (adult-onset CLN6, CLN4a or Kufs type A variant of adult-onset CLN, see above). The CLN6 gene on chromosome 15q21-q23 encodes a conserved, transmembrane polytopic protein of the endoplasmic reticulum (CLN6) whose function has yet to be identified (Sharp et al. 2003). The relevance of the autophagolysosomal compartment observed in human fibroblasts, however, suggests that the mutated protein CLN6 may hamper lysosomal function. Mutations in the CLN6 gene have worldwide distribution, with elevated frequency in Southern European countries compared to those further North (Teixeira et al. 2003).

The clinical features of CLN6 disease of childhood onset are similar to those of classic late infantile CLN (CLN2), and to variants associated with mutations in the CLN7 or CLN8. The age at onset may vary from 18 months to 8 years. The rate of disease progression may vary, with a relatively slower course, but the disease symptoms are similar to the other late infantile CLN, with motor delay, dysarthria, ataxia, vision loss and
seizures. Seizures are an early feature, starting before age 5 years in the majority of patients. Vision loss occurs also early in about half of patients. Deterioration is rapid leading to severe disability in adolescence. Death usually occurs by the end of the second decade in life. Both ERG (extinction) and evoked potentials (giant cortical evoked potentials) are abnormal. Ultrastructural analysis of skin biopsy or blood lymphocytes is useful, particularly during the early stages of the disease. The storage population in CLN6 disease is mixed and pleomorphic: curvilinear and fingerprint profiles are the major components, and rectilinear and granular material less frequently seen. Diagnosis depends on analysis of the CLN6 gene.

CLN7
Turkish Variant; Late Infantile
CLN7 has been described in Turkish patients (Ranta et al. 2004; Topçu et al. 2004). The clinical picture was similar to that of the Finnish variant (CLN5) but with a greater severity. It is caused by homozygous or compound heterozygous mutations in the gene MFSDF8/CLN7 on chromosome 4q28.3, that codes for the protein MFS8D8, a putative lysosomal transporter (Siintola et al. 2007). Despite the name, it occurs worldwide, but its frequency seems to be higher among Mediterranean populations (Aiello et al. 2009; Aldahmesh et al. 2009; Kousi et al. 2009; Stogmann et al. 2009). Age at onset is 2–7 years, mean 5.1 years. The initial symptom is typically seizures followed by myoclonus, progressive motor impairment with ataxia, speech and cognitive deterioration, vision loss, and behavioural and sleep disturbances. The rate of progression is quite steady, most patients becoming non-ambulatory within 2 years after onset and death occurs within the second decade. Cases with later onset and protracted course have been described (Kousi et al. 2009). Both ERG (extinction) and evoked potentials (giant cortical evoked potentials) are abnormal. The features distinguishing the CLN7 from other late infantile onset CLNs include the more severe clinical course and the presence of fingerprint profiles alone or mixed with curvilinear, rectilinear and less frequently granular profiles on electron microscopic examination of extracerebral tissues including skin, muscle, rectal mucosa and blood lymphocytes, and lack of vacuolated lymphocytes. Diagnosis depends on analysis of the CLN7 gene.

CLN8
Late Infantile Variant; Northern Epilepsy
Variant; Progressive Epilepsy with Intellectual Disability
The gene CLN8 on chromosome 8p23.3 codes for a transmembrane protein of the endoplasmic reticulum involved in sphingolipid metabolism, which is thought to play a role in cell proliferation during neuronal differentiation and in protection against cell death (Vantaggiato et al. 2009; Haddad et al. 2012). Mutations in CLN8 give rise to two distinct allelic forms of CLN8 with different clinical courses and geographical distribution: a form of progressive epilepsy with intellectual disability known as Northern epilepsy, and a variant of late infantile onset CLN.

The Northern epilepsy, first described in the population of northern Finland by Hirvsnieri et al. (1994), was recognised by Herva et al. (2000) as a form of CLN with an exceptionally protracted course. It is characterised by an onset between 5 and 10 years of age with frequent tonic–clonic seizures, the frequency of which decreases after puberty, and progressive cognitive deterioration that begins 2–5 years after the onset of epilepsy, and continues during adulthood despite good epilepsy control, leading to intellectual disability by middle age. Unlike the late infantile variant, in Northern epilepsy visual loss is not a prominent feature, there is no myoclonus, and the clinical progression is slower.

Mutations of gene CLN8 were shown to be responsible for late infantile onset CLN in a subset of Turkish patients initially thought to suffer CLN7. The late infantile variant CLN8 has been recognised to have a worldwide distribution (Strong et al. 2007; Reinhardt et al. 2010). The age at onset can be quite early (within the second year of life), with seizures and progressive ataxia, followed by psychomotor regression and myoclonus. The visual system with retinal involvement is always affected, with ERG extinction. Severe involvement of cortical structures is indicated by the giant cortical evoked potentials elicited. The outcome is fatal by the end of the second decade.

The lipopigment patterns observed most often in extracerebral tissues in CLN8 comprise mixed combinations of curvilinear and fingerprint profiles, and, less frequently, granular and rectilinear profiles. No vacuolated lymphocytes are found. Diagnosis is through CLN8 gene analysis.

CLN9
A small number of patients presenting with a juvenile-onset of CLN but without any known gene mutation have been classified as CLN9 (Schulz et al. 2004). Clinical onset is by the age of 4 years with visual loss and seizures followed by progressive cognitive decline and ataxia and death at the end of the second decade. Vacuolated lymphocytes have been described, either empty, or containing electron-dense storage with fingerprint pattern. A brain biopsy from one patient has shown neurons with granular and curvilinear storage. CLN9 is associated with decreased levels of dihydromeramide and decreased dihydroceramide synthase activity in fibroblasts, and the CLN9 protein is thought to be a regulator of dihydroceramide synthase (Schulz et al. 2006).
**CLN10**

### Congenital Classic

CLN10 is the classic form of congenital onset CLN. It is due to homozygous or compound heterozygous mutations in the gene *CTSD/CLN10* on chromosome 11p15.5 that codes for the lysosomal enzyme cathepsin D (Siintola et al. 2006; Steinfeld et al. 2006).

First described in 1941 (Norman and Wood 1941), CLN10 is the only CLN where the symptoms are present at birth, in the form of seizures and microcephaly, and death usually occurs within hours or days. There is granular storage material in tissue cells. Confirmation of the diagnosis is based on demonstration of the enzymatic deficiency and a mutation in the *CLN10* gene.

Later onset forms of CLN10 have been reported in the literature (Steinfeld et al. 2006) and are thought to be due to partial inactivation of the *CTSD* gene. These cases present after prior normal development with progressive ataxia, visual loss and cognitive decline, and with a slower course. Interestingly, ultrastructural examination of extracerebral tissues in these cases showed no storage material.

---

**CLN11**

CLN11 is caused by homozygous mutations in the *GRN/CLN11* gene on chromosome 17q21.31 that codes for progranulin. To date, only one family with CLN11 has been described. Heterozygous mutations in the *GRN* gene cause frontotemporal lobar degeneration with TDP43-inclusions. Smith et al. (2012) signalled the remarkable phenotypic differences between heterozygous and homozygous mutations, and suggested that progranulin may have a lysosomal function.

The reported family had an adult-onset CLN with rapidly progressive visual loss due to retinal dystrophy, seizures, cerebellar ataxia, and cerebellar atrophy. Cognitive decline may also occur. To date, it is the only adult-onset NCL with retinopathy. Electron microscopic examination of a skin biopsy demonstrated numerous fingerprint profiles. Diagnosis is through *GRN/CLN11* gene analysis.

---

**CLN12**

CLN12 is caused by homozygous mutations in the *ATP13A/CLN12* gene on chromosome 1p36.13 which encodes a lysosomal type 5 ATPase. Only one family with CLN12 has been reported to date (Bras et al. 2012). Homozygous or compound heterozygous mutations in the *ATP13A2* gene cause Kufor-Rakeb syndrome, also known as Parkinson disease-9 (PARK9).

The reported family had a juvenile-onset CLN with learning difficulties and, several years later, progressive motor impairment with parkinsonism, spasticity, pseudobulbar syndrome, extrapyramidal symptoms, choreic movements, slow extraocular eye movements and cognitive decline. All patients also developed a peripheral neuropathy and one of them had seizures and myoclonus. No retinal involvement was observed. Lymphocytes showed vacuoles and, ultrastructurally, contained NCL-typical lipopigments, which, on biopsy, were also seen in nerve and skeletal muscle in the form of fingerprint-like profiles. Diagnosis is through *ATP13A/CLN12* gene analysis.

---

**CLN13**

### Kufs Type B

CLN13, also known as Kufs type B, is caused by homozygous or compound heterozygous mutations in the *CTSF/CLN13* gene on chromosome 11q13.2 that codes for the lysosomal enzyme cathepsin F.

Only a few cases have been reported to date. It is characterised by adult-onset of progressive cognitive decline and motor dysfunction including tremor, ataxia, dystonia and pyramidal and extrapyramidal signs, leading to dementia and often early death. Some patients develop seizures. Neurons show abnormal accumulation of autofluorescent material with fingerprint profiles. The pathological features in extracerebral tissues are yet to be reported. Diagnosis is through *CTSF/CLN13* gene analysis.

---

**CLN14**

### Progressive Myoclonic Epilepsy 3, with or without Intracellular Inclusions

Mutations in *KCTD7/CLN14*, a gene on chromosome 7q11.21 which encodes a member of the potassium channel tetramerisation domain-containing protein family, cause a severe neurodegenerative phenotype characterised by onset of intractable myoclonic seizures before age 2 years and accompanied by developmental regression. The initial description was consistent with a form of progressive myoclonic epilepsy (progressive myoclonic epilepsy 3, with or without intracellular inclusions, EPM3), whereas a later report identified intracellular accumulation of autofluorescent lipopigment storage material, consistent with neuronal ceroid lipofuscinosis (Staropoli et al. 2012).

To date it has been described in three families from Mexico, Morocco and Turkey. It is characterised by infantile onset (9–24 months of age) with progressive myoclonic epilepsy, ataxia, motor and cognitive decline, without retinal involvement. Ultrastructural findings on skin biopsies appear to be variable. Electron microscopy of lymphocytes has shown lysosomal storage material containing fingerprint-like profiles and GRODs. The axons of a myelinated nerve contained vacuole-bound rectilinear profiles. Diagnosis is through *CTSF/CLN13* gene analysis.
UNDETERMINED FORMS OF NCLS

In about 10–12% of patients affected with a progressive neurological disorder, whose clinical and neurophysiological features are consistent with a diagnosis of NCL, the gene mutations remain undefined. Most of them are late infantile-onset forms, but later onset cases can also be found. Ultrastructural analysis of peripheral tissues showing the presence of lipopigments and endolysosomal storage with heterogeneous patterns, but rarely containing classic cytosomes. The identification of new informative NCL families is, therefore, necessary in order to recognize new NCL genes.

THE SPINOCEREBELLAR DEGENERATIONS, ATAXIAS, HEREDITARY SPASTIC PARAPLEGIAS AND RELATED CONDITIONS

The terms spinocerebellar degenerations and hereditary ataxias designate a broad category of inherited ataxic disorders, principally involving the cerebellum and its connections, that are characterized by the slow premature death of cells as a consequence of a variety of cellular functional defects. This group of conditions includes a large number of heterogeneous diseases. Most cases of inherited ataxias are caused by repeat expansions in the relevant genes but point mutations also occur. The broad range of mutation types found in inherited ataxias contributes to their complexity. Inheritance patterns include autosomal dominant, autosomal recessive, X-linked and mitochondrial transmission.

In the past 30 years, there has been an expansion in the understanding of these conditions (Koeppen 2005), so that there are now approximately 40 autosomal recessive spinocerebellar ataxias (SCARs) and numerous dominant SCAs with at least 23 known genes and a further nine identified by locus only. Much is known about the mutated gene products but a good deal less about their precise functional role. Many of the known pathogenetic mechanisms are described by Storey (2014).

From a clinical point of view, it is important to remember that cases of apparent ‘atypical spinocerebellar degeneration’ can result even from an infectious origin (e.g. prion diseases) or from many different metabolic disorders (e.g. glycosylation defects), wherein appropriate metabolic, virological or DNA investigations may permit a more precise diagnosis. Such studies and, where appropriate and available, molecular genetic investigations will often provide the precise diagnosis, permitting better-informed management, appropriate genetic counselling and sometimes prenatal diagnosis and/or (eventually) targeted treatment, although no treatment other than symptomatic is currently available.

Various systems of classification of the spinocerebellar degenerations have been proposed. Classification on the basis of pathological findings has not been convincing because the lesions associated with the same genetic defect are often variable and even the pathological findings in several members of the same family may not be identical. Thus, cases of olivopontocerebellar atrophy can coexist in the same pedigree with cases that do not involve the olivary nuclei! In other SCAs, cases from the same family have been classified under different subgroups. However, a new classification proposed in France and based on mode of inheritance and molecular findings brings about new insights into pathogenic mechanisms and is likely to replace older schemes (Vallat et al. 2016).

For example, in this new classification, conditions currently named spinocerebellar ataxias (SCAs types 1–40 and related conditions) will be referred to as autosomal dominant cerebellar ataxias, the gene (where known) will be attached and their denomination will be by the gene, rather than a number. Thus, SCA1 (AD) will be designated AD-CA-ATXN1 (see Table 10.7). Autosomal recessive SCAs would be included (Table 10.8) and designated as, for example, AR-CA-FRDA for Friedreich Ataxia. In a similar fashion, in regard to the hereditary spastic paraplegias, (Table 10.9) the currently named SPG1, for example, would be abbreviated as XL-SPG-Lican and so forth, and for the spastic ataxias, one such as Spax1 (AD) would be AD-SPAX-VAMPI (see Tables 10.7–10.10). It is anticipated that the new classification will be formally adopted in the near future.

AUTOSOMAL DOMINANT FORMS OF SPINOCEREBELLAR ATAXIAS

The dominant forms of spinocerebellar degeneration comprise a large number of unrelated diseases with many shared clinical features. In assessing cases, it is often impossible, without gene identification, to decide whether one is dealing with a particular condition which has different clinical presentations or with a separate disorder that shares some common clinical and pathological features. In view of this, the traditional nomenclature is retained in the rest of this chapter. Some hereditary ataxias do have features which are strongly suggestive of a particular genotype; for example, visual failure in childhood and young adult cases of spinocerebellar ataxia 7 (SCA7), but for many there is a wide overlap preventing a precise diagnosis of the type on clinical grounds. Where available, the ‘new genetics’ techniques are resolving many of these issues.

Many of these disorders (SCAs 1, 2, 3, 6, 7, 17, denatatorubral + pallidoluysian atrophy (DRPLA), and possibly SCA 8) are associated with the presence in the genes of expanded trinucleotide (CAG)n repeats that code for expanded polyglutamine (poly Q) tracts. The proteins bearing these expanded

Continued
poly Q tracts accumulate in the nucleus and/or cytoplasm of neurons in the form of inclusions, although these are probably markers rather than being pathogenic. Poly Q tracts may interfere with intracellular traffic by jamming metabolic pathways (Gunawardena and Goldstein 2005) or result in a gain-of-function toxicity (van de Warrenburg et al. 2005).

In other types, such as SCAs 10, 12 and 31, the repeats are not translated and not associated with polyglutamine inclusions. Their mechanisms of action are various and may include inhibition of gene translation (Everett and Wood 2004; Dueñas et al. 2006; Storey 2014), while others often remain unclear.

SCAs are mostly disorders of adults and only a few of them are encountered with any frequency in children, usually as a result of the phenomenon of anticipation; that is, earlier onset in subsequent generations, correlating with intergenerational expansion of the CAG tract. Anticipation is more prominent when the condition is inherited from the male parent, and is more likely to be extreme in SCA 7, where there are no stabilising non-CAG trinucleotides, or in SCA2, where interposed stabilising CAA trinucleotides are lost.

The SCAs can be sub-divided based on the proposed pathogenetic mechanism into three subclasses: subclass 1 includes SCAs caused by CAG repeat expansions such as SCA1-SCA3, SCA17 and DRPLA; subclass 2 includes trinucleotide or other repeat expansions that fall outside the protein-coding regions of the disease gene and includes SCAs 10, 12 and 31. Subclass 3 contains disorders caused by specific gene deletions, missense mutations and nonsense mutations, and includes SCAs 5, 11, 13, 14, SCA15/16, SCA27 and SCA28.

Diagnosis is based on clinical history, physical examination, molecular genetic testing and exclusion of other diseases (Whaley et al. 2011). MRI showing marked cerebellar atrophy (involving primarily the vermis) and brainstem atrophy, particularly of the pons whose normal bulge is classically no longer visible (Wüllner et al. 1993; Döhlinger et al. 2008). The degree of atrophy is typically greatest in SCA2, followed by SCA1 and then SCA3.

The global prevalence of these conditions is not precisely known but an overall combined prevalence of about 6/100 000 is a fair approximation. Population prevalence studies of hereditary ataxias have been carried out in Norway (5.2/100 000), Italy (9.3/100 000), and Singapore (3.7 families/100 000). Founder effects no doubt contribute to the variable prevalence between populations. Broadly speaking, in Western countries, the most common type is SCA3 (Machado–Joseph disease), followed by SCA2, SCA6, SCA1 and SCA8 (Whaley et al. 2011). Even in tertiary centres, these conditions are seen rather infrequently in children.

In the Australian state of New South Wales where DNA on 900 persons of all ages has been examined for SCAs 1, 2, 3, 6 and 7, only two cases aged under 16 years have been discovered, a male aged 11 with ataxia, vision problems and a relevant family history who was positive (~51 repeats) for SCA7 and a boy aged 15 with ataxia and a positive family history who had SCA3 (~74 repeats) (Nicolson and Aziz, personal communication 2014). Two siblings in a Sydney family with early-onset SCA6 studied in another laboratory are also known. SCA3 is also present in isolated aboriginal communities in Northern Australia.

Onset in children aged less than 1 year has been recorded in SCA2 (Di Fabio et al. 2012), SCA7 and DRPLA and as early as age 4, 5, 1 and 3 years respectively in SCA1, SCA3, SCA6 and SCA17.

The types that are more often observed in children – SCA1, SCA2, SCA3, SCA7, SCA17 and DRPLA (dentatorubral–pallidoluysian atrophy) – are listed in Table 10.7 (Vallat et al. 2016) and will be briefly described below. SCAs which are largely confined to specific ethnic groups (such as SCA4 in Utah, SCA10 in Mexico and southern Brazil) or to small, even notable kindreds (such as SCA5 in members of Abraham Lincoln’s family, with a mutation in the gene for spectrin [Ikeda et al. 2006]) will not be discussed further.

### SPINOCEREBELLAR ATAXIA TYPE 1

SCA1 is caused by mutations in the ATXN1 gene which are associated with expansion of its CAG repeats. The normal gene contains 6–44 CAG repeats. If, however, the CAG repeats in the 36–44 range are not interrupted by 1–3 CAT trinucleotide repeats, they may be in the ‘mutable normal’ range (36–38 CAG repeats) where there is a risk of anticipation in following generations or, if there are 39–44 uninterrupted CAG repeats, pathogenic to the carrier. It used to be thought that the expanded polyglutamines, encoded as a result of the CAG expansion, caused misfolding of mutant ataxin-1 leading to insoluble aggregates which accumulated and interfered with cellular protein refolding and subsequent proteolysis (Cummings et al. 1999). However, there is evidence for host protein specificity in SCA1, in that the expanded poly Q tract alters the interaction of ataxin-1 with a number of its protein partners – such as RBM17 and Capicua – in the control of RNA transcription and splicing (Orr 2012).

SCA1 has an estimated incidence of one to two per 100 000 in Western countries but there is marked variation in its frequency worldwide. Onset with symptoms and signs of cerebellar disease is typically in the third or fourth decade but childhood cases with onset as young as 4 years develop, in addition, severe brainstem dysfunction which progresses rapidly, leading to death within 4–8 years of symptom onset (Zoghbi et al. 1999). In adult-onset SCA1, the duration of illness from onset to death ranges from 10 to 30 years. In addition to the cerebellar symptoms, affected individuals may display spasticity with brisk deep tendon reflexes, hypermetric saccades, and sometimes nystagmus. The latter occurs in only about 10–25% of cases and thus is a point of distinction from SCA3 and SCA6. It may appear in the early stages of disease but later disappears. As the disease progresses the saccadic velocity slows, and an up-gaze palsy develops. Optic atrophy and variable degrees of ophthalmaparesis may be detected in some individuals.

Later, muscle wasting, hyporeflexia and impairment of proprioceptive and vibration sensation may supervene. Neuropathological studies indicate a neuronopathy (van de Warrenburg et al. 2004). Dysphagia and extrapyramidal signs such as chorea and dystonia as well as cognitive decline may occur. Affected individuals eventually develop respiratory failure, which is the main cause of death.

### SPINOCEREBELLAR ATAXIA TYPE 2

SCA 2 is due to a (CAG)n repeat expansion in the ATXN2 gene, encoding ataxin 2 (Vinthe-Jensen et al. 2013). This cytoplasmic protein is involved in the regulation of mRNA translation, through its interactions with the polyalanine binding protein (PABP) and ataxin-2-binding protein. Interestingly, intermediate expansions of ATXN2 of 27–33 repeats, often smaller than the 32 repeat threshold for SCA2, have emerged as an important genetic risk factor for ALS.

SCA 2 is particularly common in southern Italy and Cuba, as well as in India where it was first described phenotypically by Wadia and Swami (1971). The onset is typically in middle age, although it is subject to extreme anticipation, and infantile cases are therefore well-described. It is characterised by very slow, almost viscous saccades, with progressive sensory loss and areflexia overtaking early pyramidal signs. Cognitive impairment, beyond the usual mild dysexecutive syndrome seen in cerebellar ataxias generally as part of the cerebellar cognitive affective syndrome, is often a feature. Some patients, particularly those of East Asian descent, may present with dopa-responsive parkinsonism (Gwinn-Hardy et al. 2000).

### SPINOCEREBELLAR ATAXIA TYPE 3 (MACHADO-JOSEPH DISEASE)

Mutations at the SCA3 locus are the cause of Machado–Joseph disease (Dürr et al. 1996b), the most common type of SCA in Western Europe although uncommon in Italy, the UK and Slavic countries. Like SCA1, it is also due to an abnormal trinucleotide expansion in ATXN3 containing 52–86 CAG repeats. The disease is more common among persons originating from the Azores Islands and Portugal, and their descendants. Like SCA1, it is also due to an abnormal trinucleotide expansion in ATXN3 containing 52–86 CAG repeats. Machado–Joseph disease is very uncommon in young children. Onset is usually in the third or fourth decade with a mean survival of 20–30 years.

Before the discovery of the ATXN3 gene mutation, phenotypic studies had recognised three sub-phenotypes, emphasising the degree of phenotypic heterogeneity. Type I, with the earliest onset (usually 10–30 years), showed rapid progression with akinsia and rigidity or dystonia, pyramidal features, and variably, cerebellar ataxia. The extrapyramidal features are often responsive to dopaminergic agonists, which may cause confusion with dopa-responsive dystonia or parkinsonism. Type II, with an intermediate age at onset of 20–50 years, was characterised by spasticity and hyper-reflexia associated with cerebellar ataxia so that, in some families, the hyper-reflexia and upper motor neuron signs may suggest hereditary spastic paraplegia. Type III, of later onset (over 40 years), was typified by predominant cerebellar ataxia with significant peripheral wasting and generalised areflexia due to peripheral neuropathy or neuronopathy, the lower motor neuron involvement causing fasciculations and bulbar palsy. Ataxia gradually progresses and...
SPINOCEREBELLAR ATAXIA TYPE 6

SCA type 6 is caused by mutations involving CAG repeats on the calcium channel-encoding CACNA1A gene on chromosome 19. Missense and nonsense mutations at the same site are reported to cause familial hemiplegic migraine and episodic ataxia type 2, and the phenotypes for all three disorders may sometimes overlap. Downbeating nystagmus is a frequent feature. SCA 6 has very rarely been reported in children. Most cases present in adulthood (age range 14–73 years). The following case history describes typical early features in two siblings who are among the youngest patients reported to date. Although SCA6 is usually regarded as a ‘pure’ ataxia, other manifestations can include hyper-reflexia and extensor plantar responses, dystonia and blepharospasm. Dysphagia can be serious. Cognitive functions are usually preserved. Increased severity in pregnancy has been reported. Life span is not shortened, at least in typical cases.

Neuropathological studies have revealed degeneration of Purkinje and granule cells.

CASE REPORT 1 (COURTESY DR C TROEDSON, SYDNEY)

Two sisters presented at the ages of 14 and 32 months with frequent falls. The older child had a suspected esotropia with subtle abnormalities of upward gaze. She seemed to fall over more often when wearing glasses and resisted wearing them. Nystagmus was subsequently detected and hypometric saccades were noted at age 4. The younger sister had similar ocular findings, considered to be consistent with oculomotor apraxia but neither child had definite cerebellar signs on neurological examination. MRI showed mild cerebellar atrophy.

The mother, who also suffered from migraine without hemiplegia, was known to have had apraxia and dystarthis with a significant deterioration after her pregnancies (and a motor vehicle accident). Her MRI revealed diffuse cerebellar atrophy.

DNA studies on the mother and both daughters revealed the presence of a missense mutation in exon 25 of the CACNA1A gene in all three, indicating a diagnosis of SCA 6.

SPINOCEREBELLAR ATAXIA TYPE 7

SCA type 7 condition was previously described as Olivopontocerebellar atrophy type 3 (OPCA3) and autosomal dominant cerebellar ataxia type 2 (ADCA2). The gene SCA7 maps to 3p12–p21.1 (Benomar et al. 1995) and codes for the protein ataxin 7. Inclusions within the cell nuclei contain both ataxin and ubiquitin (Ansorge et al. 2004). Ataxin 7 itself is a component of transcription regulation complexes, including the retinal transcription factor CRX, and these functions are perturbed by the poly Q expansion. It also appears that non-cell autonomous toxicity may be involved in SCA 7 pathogenesis, with impaired glutamate uptake by Bergmann glia implicated (Garden and La Spada 2008).

The picture in adults is that of a macular degeneration with progressive cerebellar ataxia. The macular degeneration may long remain isolated. Cases under 50 years tend to present with visual symptoms first, and those over 50 with ataxic symptoms first.

A remarkable degree of anticipation can be observed in affected lineages, and a very early onset (from age 6 months) may occur. Benton et al. reported a child with early hypotonia, dysphagia causing failure to thrive, congestive heart failure, cerebellar atrophy and inability to track objects visually. Other similar infantile onset cases are described. Such cases run a rapidly fatal course (see Case Report 2).

CASE REPORT 2 (COURTESY DR P GRATTAN-SMITH, SYDNEY)

A 23-month-old girl presented with progressive ataxia. There had been no problems in the pregnancy or neonatal period.

The mother reported that the infant may have been ataxic from around the age of 12 months. At 21 months, an esotropia developed and at 23 months she had not yet begun talking. On examination at 23 months, her head circumference was on the 50th centile. There was a pigmentary retinopathy but normal pupillary response to light. She could reach out unsteadily with either hand to grasp objects and required assistance to walk because of ataxia and head titubation. Tone, strength and reflexes were normal.

She continued to deteriorate and when reviewed at 30 months, although her comprehension seemed intact, she was no longer able to roll, sit, cruise or crawl. She had become grossly ataxic and adopted a chin-down posture. Both maculae were deeply pigmented and there was diffuse background retinopathy. The optic discs were pale and the retinal vessels were attenuated. Eye movement testing revealed bilateral limitation of abduction. She was generally hypotonic, weak and had poor muscle bulk. Her deep tendon reflexes were now absent.

Normal investigations included full blood count (no acanthocytes), electrolytes, liver function tests, serum ammonia and lactate, immunoglobulins, alpha-fetoprotein, transferrin isofoms, 7-dehydrocholesterol, lysosomal enzymes, long chain fatty acid ratios, cholesterol, triglycerides, vitamin E, urine amino and organic acid screens, urine heavy metal screen and CSF lactate and glucose. An ECG and EEG were both normal. The mitochondrial DNA mutations T8993G and T8993C were absent in muscle. Respiratory chain enzymes in the liver and muscle were normal. No frataxin expansion was seen. An ERG showed a flat scotopic response and reduced photopic response, indicating widespread photoreceptor dysfunction. Nerve conduction studies showed absent sensory action potentials but normal motor responses. Sural nerve biopsy demonstrated an axonal neuropathy.
There was progressive cerebellar and cerebral atrophy on serial MRI scans. She died at home aged 3 years and 3 months. No post mortem was performed. The father, aged 33 years, had a 4–5 year history of blurred vision which had become worse in the preceding 2 years. He was seen by an ophthalmologist who found his visual acuity to be 6/60 in both eyes. He had also been ataxic for approximately 2 years and when examined by a neurologist was found to have a broad-based ataxic gait but no limb ataxia. DNA testing confirmed the presence of SCA7 in the father and the fetus in a subsequent pregnancy.

### SPINOCEREBELLAR ATAXIA TYPE 17

SCA type 17 (SCA17) is caused by mutations of the TBP gene on chromosome 6q27 which result in CAG repeat expansions in the TATA-box binding protein (a transcription initiation factor). It is characterised by predominant ataxia, associated with parkinsonism and involuntary movements, including chorea and dystonia. Psychiatric symptoms, dementia, pyramidal signs and rigidity are common and may be the presenting feature, especially with smaller repeat sizes (43–50), a clue being the concomitant cerebral and cerebellar atrophy seen on MRI.

The onset may occur at up to 55 years or, on occasion, as young as 3 years, due to anticipation. Such anticipation is, however, rare compared with that seen in the other poly Q disorders (especially SCAs 2 and 7, and DRPLA), probably due to the presence of CAA intrusions (also coding for glutamine) within the CAG repeat sequence.

### DENTATORUBRAL–PALLIDOLUYSIAN ATROPHY

Dentatorubral–pallidoluysian atrophy (DRPLA) is a condition associated with an expansion of a CAG trinucleotide repeat and has many characteristics of the autosomal dominant SCAs but is usually treated separately. It is due to mutations of repeat and has many characteristics of the autosomal dominant adion associated with an expansion of a CAG trinucleotide.

Dentatorubral–pallidoluysian atrophy (DRPLA) is a condition associated with an expansion of a CAG trinucleotide repeat and has many characteristics of the autosomal dominant SCAs but is usually treated separately. It is due to mutations of repeat and has many characteristics of the autosomal dominant adion associated with an expansion of a CAG trinucleotide.

Pathologically, there is atrophy of the dentate-rubral efferent system as in Ramsay Hunt syndrome, associated with nonspecific pallidoluysian atrophy. Intranuclear inclusions are seen in neurons as well as glia. White matter changes may also be seen.

The disease is uncommon outside Japan but cases have been reported in China, Europe, South America and in African-Americans (Licht and Lynch 2002; Wardle et al. 2009), so it should be thought of in cases of childhood myoclonic epilepsy as well as of ataxia.

### AUTOSOMAL RECESSIVE FORMS OF SPINOCEREBELLAR ATAXIAS

Over 40 autosomal recessive hereditary ataxias (SCARS) are now recognised, of which Friedreich ataxia (FRDA) is by far the most frequent. Table 10.8 lists the commoner entities and those for which specific therapy is available.

In the following section, FRDA will be discussed in detail including its differential diagnosis and followed by summaries of the more distinctive or treatable SCARS.

### FRIEDREICH ATAXIA

Although virtually absent from East Asian and sub-Saharan African populations, FRDA is by far the most common and most important type of degenerative ataxia seen in childhood in most Western countries. Its overall prevalence is about one in 29,000 Caucasians. The average reported age at onset was between 10 and 15 years (Harding 1993; Dürr et al. 1996a; Delatycki 1999) but in family studies, careful examination of some affected children may detect signs before the age of 3 years.

### GENETICS

The gene for Friedreich ataxia (FXN, previously known as X25), found at 9q13, includes a repeat GAA sequence in intron 1 that is expanded from the 5 to 33 repeats in normal individuals to 66–1700 repeats in typically affected patients with FRDA. Mutatable normal alleles, which contain 34–65 pure (uninterrupted) GAA triplet repeats, are not associated with FRDA but may expand during intergenerational transmission, resulting in disease-causing alleles in the offspring.

Up to 94% of patients with typical FRDA are homozygous for the GAA expansion, although the length of the repeat is usually unequal on each of the pair of chromosomes (Dürr et al. 1996a). A few have only one allele with an expanded sequence, with an inactivating point mutation or deletion at the homologous allele occurring in such cases (Delatycki and Corben 2012). If there is not at least one expanded triplet repeat allele, there is no point sequencing the genes for point mutations, as the homozygous state for point mutations is presumably lethal in the embryo.

The size of the expanded GAA repeat (particularly the shorter expanded allele, GAA1) partly explains the variability
in symptom onset, severity, and disease progression seen in FRDA. GAA1 length has an inverse correlation with age at symptom onset, and time from symptom onset to wheelchair dependency. However, this is thought to explain only about 40% of the variability (Mateo et al. 2004). GAA1 size also correlates with the presence of cardiomyopathy and scoliosis (Dürr et al. 1996a; Delatycki 1999). As expected, age at symptom onset also correlates with disease progression (Montermini et al. 1997).

Up to 25% of patients with FRDA who are homozygous for the GAA triplet repeat expansion have ‘atypical’ FRDA as they vary from the classic FRDA phenotype originally described by Harding (1993) (Dürr et al. 1996a; Lamont 1997). These include later onset FRDA (onset after 25 years of age) and FRDA with retained reflexes (FARR). It is better to consider these phenotypes as being a spectrum of disease severity, with the size of GAA1 accounting for at least some of these differences. Those with later onset FRDA have lower rates of skeletal deformity, areflexia, and cardiomyopathy (Bhidayasiri et al. 2005; La Pean et al. 2008).

The normal gene product is a mitochondrial protein, frataxin, which binds iron and is required for the synthesis both of iron-sulphur clusters and of enzymes in the respiratory chain. Frataxin deficiency results in secondary deficiency of iron-sulphur cluster-containing enzymes, mislocalisation of cellular iron, and increased sensitivity to oxidative stress (Bidichandani and Delatycki 2012).

A second gene on chromosome 9p23–p11 which had been suggested to account for rare cases clinically indistinguishable from classic FRDA (referred to as Friedrich 2) (Christodoulou et al. 2001) has now been shown to be the cause of ataxia with ocular motor apraxia (AOA type 1).

The main clinical manifestations of FRDA are summarised in Table 10.10. They were determined in three studies including 115 patients from 90 families studied by Harding (1981a) and two more recent series based on cases with gene confirmation (Dürr et al. 1996a; Delatycki et al. 1999).

The onset of ataxia is mostly between 5 and 16 years with a few cases manifesting frequent stumbles and falls as early as 4–5 years of age. At presentation, children with FRDA can rarely stand on one leg for more than a few seconds. They can rarely perform smooth tandem walking. Pes cavus, or at times pes planus, is also an early sign. In persons with Charcot–Marie–Tooth neuropathy, foot strength is usually worse than in FRDA with visually similar cases of pes cavus. Distal wasting is present in almost half the cases. Involvement of the upper limbs with resulting clumsiness is seen early in only 25% of cases. Scoliosis, tremor and cardiac symptoms are rarely the first manifestation, but they eventually develop, especially in those with early onset. Examination showing absent deep tendon reflexes in the lower limbs in 70–95% of cases but extensor plantar responses are very common and sometimes exaggerated knee and ankle jerks are found in the legs (FARR). Dysarthria and loss of joint position and vibration sense appear later but are eventually almost constant findings. Nystagmus is frequent (20–50% of cases). Nystagmus is frequent (20–50% of cases), and square wave jerks (a sign of fixation instability) are seen in most patients. Other ocular findings include macropsicadic oscillations (ocular flutter), dysmetria, abnormalities of saccades with slow broken pursuit, unstable fixation and impaired vestibular-ocular reflexes (Fahey et al. 2008). Optic atrophy occurs in up to 30% of patients but is rarely obvious before puberty. Sudden loss of central vision with or without recovery may occur (Fortuna et al. 2009). Sensorineural hearing loss occurs in 10–15% of patients, but speech perception (particularly in background noise) is far more common and impacts everyday living circumstances. Neurogenic bladder symptoms occur in up to 50% of individuals with FRDA. Sleep disordered breathing has been shown to be more common in FRDA compared to the general population (Corben 2013).

Intelligence has been thought to be unaffected but recent reports have documented impairment in verbal fluency, visuospatial reasoning with reduced speed of information processing. Difficulties with attention and working memory have also been demonstrated.

Cardiac involvement is found by electrocardiogram (ECG) in two-thirds of cases, or even more when ECGs and echo-cardiography are performed systematically. In consequence, the most specific clue for the diagnosis of FRDA in an ataxic patient is the presence of cardiomyopathy, T-wave changes and abnormalities of the ST segment are early signs. Echocardiography typically reveals asymmetric septal and concentric left ventricular hypertrophy. The repolarisation abnormalities (T-wave changes) on ECG seem to be more sensitive to cardiac involvement than echocardiography.

It is thought that progression from a hypertrophic to dilated cardiomyopathy occurs over time. However, the natural history of cardiac disease in FRDA is not well understood, and disease duration and neurological disability do not correlate with the severity of cardiomyopathy. Cardiac failure is seldom a presenting feature although occasional cases of unexpected sudden death occur, even in childhood. Progressive cardiac failure, often asymptomatic because of the patient’s neurologically enforced lack of mobility, or arrhythmias with atrial fibrillation eventually develop and over half the patients die of cardiac failure (Leone et al. 1988).

Diabetes mellitus is a further complication in 8–32% of patients. It tends to be associated with optic atrophy. Diabetic coma is sometimes the cause of death.

In the large study conducted by Harding in the early 1980s, the neurological course was slow but progressive. On average, patients lost the ability to walk by 25 years of age after a median illness duration of 15.5 years. The average age at death was 37 years (Harding 1981a). In a more recent study (Tsou et al. 2011), the mean age of death was 36.5 years but
survival into the sixth, seventh and even the ninth decades has been documented. The most common cause of death was cardiac (38/61), with the remainder (17/61) being non-cardiac (most commonly pneumonia) or of unknown cause (6/61).

**Pathological findings in FRDA**
The main pathological lesion is a degenerative process affecting the axons of the long ascending and descending tracts of the spinal cord and the large sensory fibres of peripheral nerves and posterior root ganglia (Ouvrier et al. 1982; Saïd et al. 1986). Loss of nerve fibres has also been documented in the optic pathways. In the brain, the cerebellum itself is mildly affected in childhood but later its white matter is gliotic and the superior cerebellar peduncles degenerate. The dentate nuclei are usually affected. In some cases the cochlear and vestibular nuclei are also affected. There is loss of cells in the gracile and cuneate nuclei and of pyramidal cells in the motor cortex. The heart is enlarged, and in over half the cases, there is a hypertrophic cardiomyopathy with muscle fibre necrosis and fibrosis, mainly involving the left ventricle.

**Investigations — Neuroimaging**
MRI is often normal in the early stages of FRDA. Indeed, the presence of significant cerebellar atrophy on MRI at presentation makes FRDA less likely. With advanced disease, atrophy of the cervical spinal cord and cerebellum may be observed (Bhidayasiri et al. 2005). Atrophy of the superior cerebellar peduncle, the main outflow tract of the dentate nucleus, may also be seen (Akhlaghi et al. 2011). Diffusion weighted imaging showing evidence of a pathological process also involving the optic radiation, independent of optic nerve damage (Fortunata at el. 2009).

**Investigations — Clinical Neurophysiology**
Motor conduction velocity is typically slightly decreased in most cases. Sensory nerve action potentials are markedly reduced or absent. A mild reduction in motor conduction velocity in combination with preserved or mildly reduced compound muscle action potentials is present in some individuals. Denervation changes are also evident on EMG in some cases (Ackroyd et al. 1984; Caruso et al. 1987; De Michele et al. 1996). Somatosensory evoked potentials are absent or markedly reduced. Visual evoked potentials are diminished or delayed (in about half of patients) (Fortunata et al. 2009).

The differential diagnosis and management of FRDA and other inherited ataxias are discussed after the other inherited ataxias.

**Other Autosomal Recessive Cerebellar Ataxias**
These are mostly rare conditions which have been divided into three subgroups:

1. Those in which the available data point to involvement of the spinocerebellar system and a sensory neuropathy;
2. Those in which sensorimotor neuropathy is a major feature;
3. Those in which there is apparently pure cerebellar involvement (Koenig 2003).

The main disorders are listed in Table 10.7. Detailed information on these and other even rarer conditions is found in Boltshauser and Schmahmann (2012). A few that are of special interest are discussed below.

Ataxia with isolated vitamin E deficiency (AVED) is of therapeutic interest as treatment may stabilise or even improve the clinical manifestations (Roubertie et al. 2003; Mariotti et al. 2004). However, treatment may not totally prevent the late appearance of new neurological signs, despite the initial and persistent good effect on the neuropathy. Abetalipoproteinaemia and hypobetalipoproteinaemia, many of the manifestations of which result from vitamin E deficiency, are discussed in Chapter 9.

**Ataxia with Coenzyme Q10 Deficiency**
Deficiency of coenzyme Q10 presents in protean ways including enccephalomyopathy, severe infantile multisystemic disease, nephropathy, cerebellar ataxia and isolated myopathy. Early manifestations of the ataxic form include hypotonia, development delay, clumsiness and frequent falls. Other manifestations such as dystarthis, epilepsy, nystagmus and ophthalmoplegia, pyramidal signs and a sensorimotor neuropathy with distal weakness, scoliosis and cognitive impairment may emerge. Muscle levels of CoQ10 are low but serum levels may be normal. MRI scans reveal diffuse cerebellar atrophy. Mutations of several genes in CoQ production (COQ4 and, as most prevalent in the ataxic form, ADCK3) have been described (Lagier-Tourenne et al. 2008; Salvati et al. 2012). Treatment may halt progression but is ineffective in some patients (Quinzii et al. 2005).

Infantile early-onset spinocerebellar ataxia (IOSCA) is linked to mutations of the C10orf2 gene on chromosome 10. The disease has been reported mostly from Finland as O-HAHA syndrome with ophthalmoplegia, hypertonus, ataxia, hypotonia and athetosis being the strikingly suggestive clinical features. Onset is neonatal or in the first two years (Lonnqvist et al. 1998). The course is progressive. Sensorineural deafness is a prominent symptom and may have an abrupt onset, often after the age of 3 years with resulting loss of language.

**Spinocerebellar Ataxias and Hypogonadotrophic Hypogonadism**
Boucher–Neuhauser syndrome (BNHS) is caused by mutations in the PNPLA6 gene and is characterised by hypogonadotrophic hypogonadism in association with a spinocerebellar syndrome and the presence of a choroidal dystrophy or pigmentary retinopathy. A clinically similar condition, the Gordon Holmes syndrome, is accompanied by hyper-reflexia. In nine patients from four unrelated families with BNHS studied
by Synofzik and colleagues (2014), the age at onset was variable, but most patients developed one or more symptoms in the first decade of life. A patient from a fifth family who did not have chorioretinopathy also carried a PNPLA6 mutation. The authors concluded that BNHS is part of a spectrum of neurodegenerative diseases associated with mutations in the PNPLA6 gene that also includes hereditary spastic paraplegia type 39. The PNPLA6 gene encodes an enzyme that catalyses the de-esterification of membrane phosphatidylcholine into fatty acids and glycerophosphocholine.

The constellation of ataxia and hypogonadism can also be present in other conditions, such as 4H syndrome (MIM #607694 and 614381), Marinesco–Sjögren syndrome, galactosaemia, CDG syndrome, STUB1 mutations (MIM #615768) and RNF216/OTUD4 mutations (MIM #212840).

A very rare disease is the optic-cochleo-dentate syndrome, of which the earlier-onset type with hypotonia from birth, blindness, deafness and early death has been recently shown to be a peroxisomal disorder (Schröder et al. 2004). See MIM #261515 for peroxisomal D-bifunctional protein deficiency. Many progressive conditions can eventually cause this triad of symptoms, including the potentially treatable riboflavin transporter defect.

Ataxia with ocular motor apraxia (AOA) exists in two types: AOA1 is the more common form in childhood and has been described together with ataxia–telangiectasia because of their similarities in Chapter 4 even though its pathophysiology seems closer to that of the spinocerebellar ataxias (see below). One important biological sign is hypoalbuminaemia which is almost always eventually found and is of diagnostic significance but may not be evident for up to 10 years from onset. The disorder is caused by mutations in the aprataxin gene which encodes senataxin, a protein involved in DNA processing and DNA repair. Many progressive conditions can eventually cause this triad of symptoms, including the potentially treatable riboflavin transporter defect.

Ataxia with ocular motor apraxia (AOA) exists in two types: AOA1 is the more common form in childhood and has been described together with ataxia–telangiectasia because of their similarities in Chapter 4 even though its pathophysiology seems closer to that of the spinocerebellar ataxias (see below). One important biological sign is hypoalbuminaemia which is almost always eventually found and is of diagnostic significance but may not be evident for up to 10 years from onset. The disorder is caused by mutations in the aprataxin gene which encodes senataxin, a protein involved in DNA processing and DNA repair. Many progressive conditions can eventually cause this triad of symptoms, including the potentially treatable riboflavin transporter defect.

Autosomal Recessive Ataxia of Charlevoix–Saguenay

This spastic–ataxic syndrome was originally described in Quebec but has since been recognised in other parts of the world including Europe, Japan, Tunisia and Turkey (Vermeer et al. 2008). It is due to a mutation in the sacsin gene on chromosome 13q12 (Engert et al. 2000). Its phenotype features early-onset ataxia often so severe in the lower limbs as to prevent normal walking but relatively mild in the upper limbs. Marked spasticity, which may precede ataxia, involuntary movements, dysarthria, abnormal eye movements and distal muscle wasting due to a neuropathy develop later. A frequent finding is of a striated ocular fundus due to hypermyelinated fibres radiating from the optic disc, sometimes partially embedding the vessels. Dementia is not a feature. Brain MRI showing cerebellar atrophy mainly in the vermis with linear T2 hypointensities in the pons.

**Case report 3** (courtesy Dr C Burke and Dr M Shekeeb, Brisbane)

A 16-year-old boy of English–Irish parentage had had ataxia dating from around 3–4 years of age. He had mild motor delay predating obvious ataxia. This progressed slowly over a decade and by 16 years of age he was in a relatively stable phase with independent ambulation, a slightly wide base to his gait, spasticity in the lower limbs which were weaker than the upper limbs, nystagmus and normal dorsal column function but with a motor and sensory axonal neuropathy involving all four limbs. Successive brain MRI showed slowly progressive antero-superior vermian atrophy. On a review, his scans from 10 years of age showed transverse linear hypointensities in the pons which have been reported in autosomal recessive ataxia of Charlevoix–Saguenay. This initiated investigation for other features of the disorder. Fundus examination showed prominence of the nerve fibres overlying the central retinal vessels. An optical coherence tomogram showed hypertrophy of the retinal nerve fibre layer. On genetic testing, he was found to have two truncating heterozygous mutations in exon 9 of the SACS gene on chromosome 13q12.12.

**Marinesco–Sjögren Syndrome and Progressive Encephalopathy with Peripheral Edema, Hypsarrhythmia and Optic Atrophy**

Two other rare autosomal recessive syndromes comprise a very slowly progressive ataxia and can be dealt with together with the SCAs. Even though their pathology and mechanisms are probably different, they share several clinical features.

Marinesco–Sjögren syndrome results from mutations of the SIL1 gene, which encodes a nucleotide exchange factor for BiP, a member of the heat-shock protein family 70 (HSP70), involved as a chaperone in the major functions of the endoplasmic reticulum (Senderek et al. 2005; Krieger et al. 2013). There is probable interference in protein folding. It is associated with cerebellar atrophy predominantly involving the vermis, with early onset of slowly progressive ataxia, cataracts, mild intellectual disability and the development of a peculiar myopathy and sometimes hypogonadism. Electron microscopy reveals autophagic vacuoles, membranous whorls and electron-dense double-membrane structures associated with muscle nuclei (Sewry et al. 1988).
Progressive encephalopathy with peripheral Edema, Hypsarhythmia and Optic atrophy syndrome (PEHO), also termed cerebello-optic syndrome, is a recessive disorder reported primarily from Finland (Salonen et al. 1991), although cases have been observed elsewhere. The main features are seizures of early-onset, mild dysmorphism, peripheral oedema and regression from 3 to 5 months of age. Optic atrophy develops towards the end of the first year (Haltia and Somer 1993). Presence of cerebellar atrophy beyond 18 months is a required diagnostic criterion. Degeneration of the cerebellar granular cells is a prominent finding at autopsy but extensive cerebral changes also evolve. The genetic basis is unknown but autosomal recessive inheritance is likely.

X-linked Spinocerebellar Ataxia

Only a handful of cases with X-linked transmission are on record, mostly in adult patients (Caramins et al. 2013). In a few families, X-linked cerebellar degeneration had its onset in infancy or in adolescence (Bolshhauser and Schmahmann 2012). Cases with and without brainstem and spinal involvement may occur in the same lineage. The distinction between these rare forms of spinocerebellar ataxias and cerebellar parenchymal ataxias is hardly possible in cases without genetic studies and/or postmortem examination.

Maternal Inheritance

Mitochondrial disorders in the young are commonly associated with ataxia. Conditions which are very likely to produce ataxia as a key manifestation include neuropathy, ataxia, and retinitis pigmentosa (NARP), Leigh syndrome, infantile-onset SCA, Kearns-Sayre syndrome and POLG-1 disorders such as sensory ataxic neuropathy, dysarthria and ophthalmoparesis (SANDO) and mitochondrial recessive ataxia syndrome (MIRAS). These disorders are discussed in the Mitochondrial Disorders section in Chapter 9.

DIFFERENTIAL DIAGNOSIS AND MANAGEMENT OF FRIEDREICH ATAXIA AND OTHER INHERITED ATAXIAS

Differential diagnosis

The presence of cardiomyopathy in a patient with a chronic progressive ataxia is an important clue to the diagnosis of FRDA. In contrast, the presence of significant cerebellar atrophy on MRI at presentation, significant intellectual disability, or preserved sensory responses on nerve conduction studies makes FRDA less likely (Schulz et al. 2009).

Vitamin E deficiency can mimic many of the clinical features of FRDA and must be excluded early. It may occur in malabsorption syndromes, including AVED (see the Other Autosomal Recessive Cerebellar Ataxias section), cystic fibrosis, abetalipoproteinemia (in which serum cholesterol is consistently very low), Allagile syndrome and other hepatic disorders. MRI tends to be normal in these ‘metabolic ataxias’.

Ataxia–telangiectasia (see Chapter 4 and Chapter 22) usually has an earlier onset. A history of repeated infections and the finding of conjunctival and cutaneous telangiectases are suggestive, although the latter are usually not evident at initial presentation and may take several years to develop. Alpha-fetoprotein is consistently elevated to about ten times the normal level. Ataxia–ocular motor apraxia type I has characteristic eye movement findings (see above or Chapter 22). The Roussy–Levy syndrome was once considered a forme fruste of FRDA but is usually attributable to one of the hereditary demyelinating neuropathies. The axonal degenerative forms of hereditary motor and sensory neuropathy (e.g. HMSN/CMT type 2), which often are accompanied by similar nerve conduction abnormalities, constitute by far the most common area of misdiagnosis. It is important not to misdiagnose them as their prognosis is much more favourable than FRDA. In general, ataxia is more prominent in FRDA and distal weakness more marked in CMT type 2. Giant axonal neuropathy may be confused if the typical hair changes are lacking but usually has a more severe clinical picture. Sural nerve biopsy or DNA studies will allow distinction. Other disorders which may be confused include chronic GM2 gangliosidosis (where macular cherry red spot is not a feature), alpha-L-iduronidase deficiency and mitochondrial disorders, particularly NARP and POLG disorders (see Poliodystrophies section). Other spinocerebellar degenerations which may, at times, be confused with FRDA include autosomal recessive spastic ataxia of Charlevoix–Saugenay and in older patients, spinocerebellar ataxias (SCA) types 4 and 25.

Benign familial chorea due to NKX2–1 mutations may present as a ‘pure’ cerebellar ataxia. After a few years, chorea becomes the dominant clinical feature (McMichael et al. 2013).

Among numerous other confusing ataxic phenotypes, the recently delineated riboflavin transporter deficiency syndrome may present with an ataxic sensory neuropathy often accompanied by deafness and visual impairment. The diagnosis may be supported by abnormalities in urinary acyl-carnitines and confirmed by testing for mutations in the SLC52A gene (Foley et al. 2014).

Management

Drug treatment: Bidichandani and Delatycki (2014) have summarised the needs of patients with FRDA in detail. Apart from the use of idebenone and certain drugs being trialled specifically for FRDA, many of the recommendations are applicable to the other spinocerebellar ataxias.

Antioxidants including coenzyme Q10, vitamin E, idebenone (a short-chain analogue of coenzyme Q10) and iron chelation therapy (with deferiprone) have been well-studied in numerous trials.

In a study of 70 children with FRDA aged 8–18 years (Lynch et al. 2010), idebenone treatment for 6 months did not significantly alter neurological function. A recent Cochrane evaluation (Kearney et al. 2012) found
that no randomised controlled trial using idebenone or any other pharmacological treatment has shown significant benefit on neurological symptoms associated with FRDA. In several studies, idebenone has shown a positive effect on left ventricular heart mass but this has not been consistently demonstrated (Lagedrost et al. 2011).

Trials of resveratrol, erythropoietin and histone deacetylase inhibitors (modifiers of frataxin expression) are currently in progress.

Equipment often required and treatment of clinical manifestations: Prostheses, walking aids and wheelchairs for mobility; speech, occupational, and physical therapy; pharmacological agents for spasticity when present (such as botulinum toxin injections and other systemic agents); orthopaedic interventions for scoliosis and foot deformities; hearing devices for auditory involvement; dietary modifications and placement of a gastrostomy for dysphagia; antiarrhythmic agents, medications for cardiac failure, anticoagulants and pacemaker insertion for cardiac disease; dietary modification, oral hypoglycaemic agents or insulin for diabetes mellitus; anti-spasmodics for bladder dysfunction; psychological support, both pharmacologic and counselling.

Prevention of secondary complications: Exercise and physical therapy programmes to maintain flexibility, optimise physical condition, and prevent contractures; maintenance of healthy body mass index; establishment of appropriate home and work environment to maximise independence and safety; management of dysphagia to prevent aspiration pneumonia.

Surveillance in FRDA: At least annual assessment of overall status; examination for complications including spasticity, scoliosis, and foot deformity; annual ECG, echocardiogram, and fasting blood sugar to monitor for diabetes mellitus; hearing assessment every 2–3 years; a low threshold for sleep studies to investigate for obstructive sleep apnea.

HEREDITARY SPASTIC PARAPLEgia

The familial or hereditary spastic paraplegias (HSPs or SPGs) form a heterogeneous group of diseases clinically characterised by spasticity and weakness with exaggerated reflexes predominating in, or limited to, the lower limbs. An SPG is classified as pure if neurological signs are limited to the lower limbs (although urinary urgency and mild impairment of vibration perception in the distal lower extremities may occur). Complicated forms display additional neurological and MRI abnormalities such as ataxia, more significant peripheral neuropathy, intellectual disability, other movement disorders or a thin corpus callosum. However, both clinical types can occur within the same group (dominant) and may be impossible to distinguish from one another and from some of the spinocerebellar degenerations on clinical grounds (Fink and Hereda 1999). Some forms of SPG, especially early-onset forms, are hardly, if at all, progressive; others are really degenerative disorders with more or less rapid deterioration.

Pathologically, the disorders affect predominantly the distal part of axons of the pyramidal tracts and of the posterior funiculi, but may also, in certain forms, involve other neural structures including anterior horn cells.

The group is also genetically extremely heterogeneous: dominant inheritance is most common (Fink 2002), but spastic paraplegias with autosomal recessive inheritance and with sex-linked transmission are also known. Table 10.9 lists the numerous types and their chromosomal location, also indicating the responsible genes and mutant proteins when known.

At least 86 types of SPG are currently known and new types are still being added; 43 responsible genes have been identified (Fink 2014). Autosomal dominant transmission is observed in 70–80% of all cases and typically results in pure HSP. Overall, the commonest form in Western Europe is SPG4. SPG3 is also common (Dürr et al. 2004) especially in childhood, as it rarely commences after the second decade.

In a large combined adult and paediatric series from the Netherlands, symptom onset prior to 18 years was found in 72 of 175 (41%) patients; 47 of the 72 early-onset cases (65%) were autosomal dominant, 12 of 72 (17%) autosomal recessive and 13 of 72 (18%) were sporadic. In children, gait difficulties were the presenting symptom in 81%, at a mean age of 8 years. A complicated phenotype was present in 25% (de Bot et al. 2010).

For autosomal dominant forms, several products of SPG genes are known: AT11 encoding atlastin (a dynamin-like GTPase) in SPG3A; SPAST encoding spastin (which is involved in microtubule activity subserving axonal transport) in SPG4; NIPA1 (encoding a magnesium transporter) in SPG6 which usually presents in the second and third decades or later; KIF5A in SPG10 and SPG12. REEP1 mutations cause SPG31, another pure form of HSP which has its onset before 20 years in over two-thirds of cases. REEP1 encodes the mitochondrial protein receptor expression-enhancing protein 1.

Autosomal recessive forms include SPG7, due to paraplegin mutations and SPG20 caused by spartin mutations.

The X-linked types include (a) SPG1 due to mutations in the LI gene encoding LICAM and (b) SPG2 due to PLP1 mutations allelic to those of Pelizaeus–Merzbacher disease. SPG2 mutations are also responsible for the MASA syndrome (mental retardation, aphasia, spastic paraplegia and adducted thumbs) (see X-linked Paraplegias section and Chapter 7).

The particular clinical and MRI features of these conditions in childhood are well-described by de Bot et al. (2010).

PURE SPASTIC PARAPLEgia
(STRÜMPPELL–LORRAIN TYPE)

Pure spastic paraplegia is characterised pathologically by degeneration of the pyramidal tracts and of the posterior columns below the cervical level and clinically by bilateral paraplegia or paresis with spasticity and increased tendon reflexes
beginning and predominating in the lower limbs. Involvement of the upper limbs is unusual, but deep tendon reflexes in the arms are often exaggerated (Polo et al. 1993). Bladder disturbances are common in 20% of cases but are often late. Sensory disturbances are mild, affecting only vibration but not position sense.

Pure spastic paraplegia is a fairly common condition: Harding (1981b) in her study of 22 families separated type I cases, with onset below 35 years of age, and type II cases, where the apparent onset occurred after 35 years. She found a dominant inheritance pattern in 19 families and a recessive mode in only three. Considerable heterogeneity has been shown within the ‘pure’ group that can result from mutations at different loci (Kobayashi et al. 1996). Although 40% of Harding’s patients had symptoms by 5 years of age, there is no doubt that mild cases are common and easily go unrecognised. Of the 41 patients in one series, only seven had sought medical advice, and it is a common experience to discover the disease in one apparently healthy parent of affected children, so that actual examination of both parents is essential for diagnosis.

The uncommon recessive forms may have an earlier onset than dominant cases. The children are often slow to walk, clumsy, fall frequently and tend to walk on tiptoes. In rare cases, mild cerebellar symptoms and signs are present. Urinary symptoms are often present, and mild impairment of vibration and position sense may be seen. Motor and sensory nerve conduction velocities are normal. The course of dominant forms is slow and may remain stationary until late in adulthood. Recessive forms may run a faster course.

Occasional cases are seen, however, who present with abrupt deterioration diagnosed as myelitis, and marked fluctuations of signs, in some cases in association with respiratory infections.

**COMPLICATED SPASTIC PARAPLEGIA**

Hereditary spastic paraplegia can occur in association with many different symptoms and signs, thus producing a number of syndromes whose description is often based on only a few cases or even a single family. These syndromes have been mainly described in adults, but onset often occurs in childhood or even infancy. Their inheritance is usually autosomal recessive but dominant cases are known and X-linked inheritance has been recognised (Appleton et al. 1991). They include hereditary spastic paraplegia with ocular and extrapyramidal symptoms, the so-called Ferguson–Critchley syndrome which has finally been shown to be a form of Machado–Joseph disease (SPC3) (Teive et al. 2004); cases of paraplegia associated with dystonia; SPG11 and SPG15; familial spastic paraplegia with amyotrophy, ophthalmoplegia and central retinal degeneration or Kjellin syndrome due respectively to mutations of spatacsin and ZYFVE-zinc finger domain-containing protein 6 (Leys et al. 2000; Hanein et al. 2008); paraplegia and deafness (Wells and Jankovic 1986); paraplegia with palmoplantar keratosis; paraplegia with disordered pigmentation; and paraplegia with isolated intellectual disability (Nicolaides et al. 1993).

A complex syndrome featuring optic atrophy, abnormal choreic movements, mild intellectual disability and sometimes ataxia in addition to spastic paraplegia was recognised by Costeff et al. (1989). This has been shown to be associated with 3-methylglutaconic aciduria. A multitude of syndromes can be observed (Fortini et al. 2003) including cases with a sensory neuropathy involving either the small fibres and responsible for trophic lesions or the large fibres without trophic damage (Thomas et al. 1994), with epilepsy, bulbar symptoms (Bertini et al. 1998) and other neurological abnormalities.

The complicated forms often tend to run a faster course than pure paraplegia (Appleton et al. 1991).

**SPASTIC PARAPLEGIA WITH COGNITIVE IMPAIRMENT AND THIN CORPUS CALLOSUM**

A characteristic neuroimaging pattern of spastic paraplegia with cognitive impairment and thin corpus callosum (SPG11) (MIM #604260) is a thin corpus callosum in the anterior aspect. White matter signal abnormalities in the corresponding ‘para-callosal’ parts of the frontal white matter are also characteristic (though not specific, as several complicated forms of SPG have white matter abnormalities).

**SILVER SYNDROME**

The allelic autosomal dominant motor neuron diseases, Silver syndrome/spastic paraplegia 17 (SPG17), distal hereditary motor neuropathy type V and Charcot–Marie–Tooth disease type 2 (CMT2) with predominant hand involvement have been described in association with KIF5A (Goizet et al. 2009), spastin and atlastin mutations but are also caused by gain-of-toxic-function mutations in the BSCL2 (seipin) gene. Detailed phenotypic analyses have revealed that upper motor neurons, lower motor neurons and peripheral motor axons are variously affected in patients with these mutations even in the one family. Ito et al. (2011) showed that the N88S and S90L mutations disrupt the N-glycosylation motif of seipin, enhance ubiquitination, and appear to lead to the production of proteins that are improperly folded, leading to accumulation of the mutant protein in the endoplasmic reticulum.

A similar clinical picture is seen in SPG43 due to C19orf12 mutations (Meilleur et al. 2010).

**TROYER SYNDROME**

Troyer syndrome (SPG 20) is a rare disease outside the old Amish community in the United States and caused by...
Chapter 10  Heredodegenerative Disorders

The diagnosis of an SPG is often by exclusion and many conditions need to be excluded either because they are treatable (e.g. slow spinal cord compression) or because their prognosis is significantly different, usually more severe, than that of early-onset hereditary paraplegias. The new genetics are extremely valuable in confirming the diagnosis, as well as for genetic counselling purposes.

In the absence of a compatible family history and negative examination of both biological parents, treatable conditions such as spinal compression, lesions of the parasagittal motor strip and hydrocephalus should be ruled out. To exclude a tumour or syringa, all index cases require MRI of the brain and spinal cord.

AIDS and HTLV-1 virus infection may produce a very similar syndrome. The latter disorder has been reported in three members of a family indicating the possibility of vertical transmission (Salazar-Grueso et al. 1990). Vitamin B12 deficiency, metabolic conditions such as adrenomyeloneuropathy, other leukodystrophies, glycine encephalopathy, cerebral folate deficiency, homocarnosinosis and hyperarginaemia (Brockstedt et al. 1990) and others should be thought of in priority. Purine nucleoside phosphorylase deficiency may closely resemble spastic paraplegia but is to be suspected in the presence of frequent infections, lymphopenia, anaemia, failure to thrive and low serum uric acid levels. Neurological symptoms may divert the focus of investigations and delay the diagnosis in some cases (Tabarki et al. 2003).

In a child presenting as a typical pure HSP with a family history suggesting autosomal dominant inheritance, mutation analysis of \textit{ATL1} (SPG3A) and \textit{SPAST} (SPG4) is recommended as the first test of choice. If negative, \textit{REEP1} (SPG31) would be the next choice. In suggestive sporadic presentations, where screening tests for other causes of paraparesis are negative, \textit{ATL1} and \textit{SPAST} mutation analysis should be considered (de Bot et al. 2010). Spastic paraparesis without ataxia may rarely be seen in FRDA cases with smaller expanded alleles on the \textit{FXN} gene (Berciano et al. 2002).

Management of spastic paraplegias

Treatment is mainly based on physiotherapy and occupational therapy. Walking aids and ankle-foot orthoses are often helpful. When the precise diagnosis of a spastic syndrome remains uncertain, a trial of levodopa should be strongly considered since dopa-responsive syndromes, notably Segawa disease, can present as a typical spastic paraplegia, even without diurnal fluctuation. Genetic counselling and support are crucial.

Botulinum toxin and other anti-spasticity agents such as baclofen, tizanidine, dantrolene as well as drugs to reduce urinary urgency (e.g. oxybutynin) may be useful. Orthopaedic supervision with appropriate intervention for contractures and spinal complications is important.

Cerebellar hypoplasia

General remarks

Cerebellar hypoplasia is a purely descriptive term. It refers to a cerebellum with a reduced volume, but a normal shape. It is a common but nonspecific neuroimaging finding. It can be associated with a highly heterogeneous group of disorders.
Part IV  Metabolic and Heredodegenerative Disorders

Aetiologies include primary (mainly genetic) as well as (pre- and perinatally) acquired conditions. The distinction between primary and secondary causes is important in guiding the diagnostic work-up, prognostication and genetic counselling.

**IMAGING PATTERNS OF CEREBELLAR HYPOPLASIA**

Cerebellar involvement is heterogeneous. From a pattern recognition point of view, cerebellar hypoplasia can be grouped into those with:

- unilateral cerebellar involvement, as ‘unilateral cerebellar hypoplasia’, considered disruptive in aetiology; and PHACE[S] syndrome;
- mainly midline (vermis) involvement: (typical examples: Dandy-Walker malformation, Joubert syndrome, rhombencephalosynapsis – see Chapter 3);
- global cerebellar hypoplasia, affecting vermis and hemispheres.

A subgroup of patients with non-progressive congenital ataxia is found to have dilated interfolial spaces, mimicking cerebellar atrophy. However, since the clinical course as well as the imaging findings are non-progressive, this is considered as a form of ‘hypoplasia’. Therefore, a single imaging study may not definitely allow distinction between hypoplasia and atrophy. The volume reduction in this form of hypoplasia is likely related to a markedly reduced number of granular cells.

About 70% of the volume of the cerebellar folia consists of granular cells. The patho-mechanism is not clear (possibly decreased proliferation of granule neuron progenitors).

**CLINICAL SPECTRUM ASSOCIATED WITH CEREBELLAR HYPOPLASIA**

The clinical phenotype associated with cerebellar hypoplasia is wide and depends also on associated brain malformations or additional unrelated symptoms. Generally, children present with muscular hypotonia and global developmental delay and develop cerebellar signs later (Bolduc and Limpropoulos 2009). Neurological findings include truncal

NPJA, non-progressive cerebellar ataxia.
ataxia (49–93%), hypotonia (47–49%), ocular movement disorders (40–46%), dysarthria (38%), intention tremor (9–35%) and microcephaly (20%) (Wassmer et al. 2003). Seizures are more prevalent than in the general population (28–56%).

Intellectual disability is present in more than 60% of patients and is severe in 35% of them (Wassmer et al. 2003). Speech and language disorders are common and range from mild impairment to total absence of language development. Behavioural abnormalities are also common and 5–20% of patients have autistic features (Wassmer et al. 2003). The spectrum of cognitive and behavioural abnormalities matches the cerebellar cognitive affective syndrome (Schmahmann and Sherman 1998). This syndrome delineates the contribution of the cerebellum to non-motor functions and includes disturbance of executive function, visuospatial disorganisation and impaired visuospatial memory, personality changes and language difficulties.

**AETIOLOGICAL CONSIDERATIONS IN GLOBAL CEREBELLAR HYPOPLASIA AND PONTOCEREBELLAR HYPOPLASIA**

Table 10.11 summarises the broad spectrum of possible aetiologies (congenital infections, teratogens, chromosomal abnormalities, metabolic disorders, genetic syndromes, non-progressive cerebellar ataxias). For most conditions imaging abnormalities are not specific, and diagnostic work-up has to consider all available information from family history, personal history, clinical findings including extraneural anomalies, and so on. In clinical practice a large proportion of cerebellar hypoplasias remain unexplained.

**NON-PROGRESSIVE CEREBELLAR ATAXIAS**

The term non-progressive cerebellar ataxia (NPCA) refers to children with early evidence of cerebellar ataxia without progression on follow-up (Poretti and Boltshauser 2012). Ataxia, which is first manifested between 2 and 3 years of age is preceded by hypotonia and delayed motor and language milestones (Steinlin et al. 1998). Cognitive impairment is common and is the most limiting factor in older children and young adults (Steinlin et al. 1999). In NPCA, familial recurrence has been observed repeatedly, mostly compatible with recessive inheritance. In recent years, genetic mutations have been detected in a small fraction of patients. Neuroimaging in NPCA is variable, it can be normal, but often interfolial spaces are dilated, ‘mimicking’ cerebellar atrophy. Some disorders represent ‘pure’ NPCA, while others manifest ‘plus’ symptoms, such as severe epilepsy, hearing impairment and optic atrophy. Some of these patients have been diagnosed as ‘ataxic cerebral palsy’, a potentially misleading term suggesting a residual disorder with low recurrence risk. Rare pedigrees with dominant or X-linked NPCA are on record (Zanni et al. 2012). It is expected that next generation sequencing will facilitate identification of a large number of involved genes.

Recently a new entity was reported with the clinical findings of congenital ataxia, variable degrees of intellectual disability, ocular motor apraxia, high myopia and a characteristic neuroimaging pattern consisting of marked cerebellar dysplasia, cerebellar cysts, abnormal shape of the fourth ventricle, while supratentorial imaging was normal (Poretti et al. 2014). Aldinger et al. (2014) confirmed the phenotype, identified mutations in LAMA1 and suggested it be designated the Poretti–Bolshauser syndrome (MIM #615960).

**PONTOCEREBELLAR HYPOPLASIA**

The use of the term pontocerebellar hypoplasia (PCH) is not uniform. It is often used in a nonspecific descriptive manner to imply volume reduction of pons and cerebellum. In a more restrictive sense, PCH is used for an enlarging clinically and genetically heterogeneous group of autosomal recessively inherited neurodevelopmental disorders. The concept of prenatal-onset degenerative disorders was initially put forward by Peter Barth (Barth 1993). The initial classification suggested two subtypes PCH1 and PCH2, depending on the presence or absence of anterior horn cell degeneration. As of 2014, MIM lists ten types of PCH, some only observed in very few patients/families. PCH3 and PCH8 seem to have a non-progressive course, in contrast to the other types. With increasing experience milder presentations and variants have been described. It is expected that additional genetic forms will be reported. For a current overview, we refer to Rudnik-Schöneborn et al. (2014).

**PCH TYPE 1**

Clinical features of the initially reported ‘classic’ PCH1 include prenatal onset, congenital respiratory and feeding difficulties, contractures and short lifespan. Subsequent experience pointed to a more prevalent ‘milder’ form with severe hypotonia, generalised weakness and mostly absent motor and speech development. Seizures are not a feature of PCH1 (in contrast to PCH2). Mutations in VRK1 and EXOSC3 have been associated with PCH1. Neuroimaging does not allow distinction of PCH1 from PCH2. There is an imaging spectrum ranging from early and severe volume reduction of pons and cerebellum to later onset and milder evolution. In the severe forms, there is relative sparing of the vermis compared to the hemispheres, giving a ‘dragonfly’ pattern on coronal views. In advanced stages, some supra-tentorial atrophy with subsequent ventricular dilatation is common.
PCH TYPE 2

This is the most prevalent PCH form. Typical features include restlessness in the neonatal period, persistent poor sucking and swallowing, secondary microcephaly and marked extrapyramidal dyskinesia. Seizures are prevalent. Developmental progress is usually lacking. Survival is variable. Currently, four subtypes are known based on various gene mutations (TSEN54, TSEN2, TSEN34, SEPSECS). TSEN54 mutations are by far the most prevalent (>80%). PCH2, PCH4 and PCH5 represent a spectrum of clinical manifestations caused by different mutations in the TSEN genes. TSEN, SEPSECS, and RARS2 (mutated in PCH6) genes have functions in a common pathway of RNA processing.

Differential Diagnosis in PontoCerebellar Hypoplasias

Cerebellar disruption in preterm infants can mimic the imaging pattern of PCH (Messerschmidt et al. 2005). Distinction from the genetic PCH forms should not be problematic in the whole clinical context. Risk factors for the cerebellar injury are ‘extreme’ preterm birth (<30 weeks gestation), intraventricular haemorrhage, and neonatal complications. Congenital disorders of glycosylation (mostly CDG1a) and some forms of congenital muscular dystrophies (alpha-dystroglycanopathies) can imitate imaging findings of PCH but again, the whole clinical and imaging context should allow distinction from genetic PCH. Distinction from CASK mutations may not be as straightforward. CASK mutations (X-linked, presumed lethal in males, with exceptions) affect mostly females. Typical features are rapidly evolving microcephaly in the first few months, and seizures are prevalent. Imaging findings show a marked reduction of pontine and cerebellar volume, usually with no dragon-fly pattern. Reduced gyration is not consistent (Burglen et al. 2012).

Some patients with mutations in tubulin genes display a small pons and cerebellum, but there are usually additional imaging findings (such as callosal dysgenesis, dysmorphic basal ganglia and cortical malformations).

Infections of the central nervous system (CNS) remain common life-threatening conditions. Despite recent advances in health care, and the development of new antibacterial and antiviral agents, they still are associated with an unacceptably high mortality and morbidity. Over the past few decades, many different therapeutic agents have been trialed, but few have resulted in any significant improvements in outcome. In the same period, conjugate vaccines have brought about dramatic changes in the epidemiology of bacterial CNS infection; however, there remains a wide range of infectious organisms for which no preventive vaccines exist. Early diagnosis and institution of treatment, careful monitoring of its efficacy and rapid detection of emerging complications give the best chances of an optimal outcome; but until we gain a greater understanding of the pathogenesis and pathophysiology of acute CNS infections, outcomes are unlikely to improve significantly.

### ACUTE BACTERIAL MENINGITIS IN INFANTS AND CHILDREN

Meningitis makes a major contribution to morbidity and mortality worldwide, contributing over 30 million disability-adjusted life-years across all ages according to 2012 estimates [World Health Organization (WHO) 2012c] and is one of the top 20 causes of years of life lost (WHO 2014). Approximately 180,000 children under 5 years of age die annually from meningitis while 393,000 neonatal deaths occur as a result of sepsis, a substantial proportion of which are attributable to meningitis (Liu et al. 2012). Despite a downward trend in rates of meningitis, it remains a leading cause of death especially in resource-poor settings (Liu et al. 2012). Several factors contribute toward this disappointing situation: inadequate access to key vaccinations, delayed diagnosis because of the nonspecific character of the symptoms, emergence of resistant strains of common pathogens, weakness of the immunological defences of the newborn infant, and our inability as yet to prevent the damage caused by the host inflammatory response through adjunctive neuroprotective or anti-inflammatory mechanisms.

**Epidemiology of acute bacterial meningitis**

The relative incidence of acute bacterial meningitis varies according to age, socio-economic conditions, geographic location and immunisation policies. In the developed world over the past decade, the epidemiology of acute bacterial meningitis has undergone a dramatic change and the incidence has fallen, whereas in many developing countries it remains high. Vaccination has brought about this radical change by reducing the relative frequency of the three main pathogens: *Haemophilus influenzae*, *Neisseria meningitidis* and *Streptococcus pneumoniae*.

*H. influenzae* type B (Hib) used to be the most common form of childhood bacterial meningitis in the UK, with incidence rates ranging from 21 to 44 per 100,000 in those under 5 years of age, a peak age of 6–7 months, and case fatality rates of 2.4–4.3% (reviewed in Heath and McVernon 2002). Hib protein–polysaccharide conjugate vaccine has been introduced into the national schedules of a number of countries worldwide since the early 1990s and has proven to be highly effective at reducing rates of meningitis due to Hib, due to direct effects and herd immunity, in a range of settings. In countries where vaccine coverage is high, Hib meningitis is a rare disease leaving *S. pneumoniae* and *N. meningitidis* as the most common pathogens causing meningitis. However, in many regions of the world where access to the conjugate vaccine is still limited, Hib remains a major cause of CNS infection (Morris et al. 2008).

In 2000, the incidence of pneumococcal meningitis in children under 5 years of age varied from around six per 100,000 in Europe to 38 per 100,000 in Africa, with associated mortality ranging from a case fatality rate of 38% in Europe to 73% in Africa respectively (O’Brien et al. 2009). Long-term neurological sequelae are particularly common following pneumococcal meningitis with rates as high as 38% in some studies. Figures are substantially worse in the developing world (Ramakrishnan et al. 2009; Chandran et al. 2011). There is a seasonal variation, with a peak in the winter months. Younger children are most affected, with 60% of cases occurring in children
under 2 years of age. A highly effective 7-valent pneumococcal protein–polysaccharide conjugate vaccine (covering seven common disease-causing serotypes) became available in 2000. Since then, 10 and 13-valent pneumococcal conjugate vaccines have been licensed and are being rolled out globally.

Countries that have had pneumococcal conjugate vaccine introduced into their immunisation programmes have seen dramatic reductions in invasive pneumococcal disease, leaving *N. meningitidis* as the most common pathogen causing meningitis. The incidence of invasive disease due to *N. meningitidis* is currently estimated at between 0.11 and 8.9 per 100 000 in European countries (Jafri et al. 2013), with overall rates reported as 0.75 per 100 000 [European Centre for Disease Prevention and Control (ECDC) 2013] and 0.15 per 100 000 in the United States [Centers for Disease Control and Prevention (CDC) 2012b]. Rates can be as high as 230 per 100 000 in some regions of Africa, where epidemics commonly occur (Jafri et al. 2013). The most common serotypes are Groups B and C in European countries with serogroup B now dominant (ECDC 2013; Jafri et al. 2013).

Polysaccharide and protein–polysaccharide conjugate vaccines against groups A, C, Y, W135 are available and an outer membrane vesicle vaccine against group B has recently been licensed (although not as yet introduced into many national schedules). Polysaccharide vaccines are mainly used in at-risk individuals and are in the national schedule of only a few countries. Monovalent conjugate vaccines against group A and C are available as well as polyvalent conjugates against A, C, Y, W135. As is the case with the other conjugate vaccines described above, group C conjugate vaccine has proved highly effective in countries where vaccine coverage is high (Ali et al. 2014).

The highest burden of invasive meningococcal disease occurs in sub-Saharan Africa, in an area known as the ‘meningitis belt’, an area that stretches from Senegal in the west to Ethiopia in the east. In the dry season large epidemics with very high incidence rates can occur, mainly due to serogroups A, C and W135 (Jafri et al. 2013; Ali et al. 2014). Current global immunisation campaigns are promoting vaccination in these regions. For example, the Meningitis Vaccine Project has led to the rapid development and roll out of a *N. meningitidis* group A conjugate vaccine in several African countries (Ali et al. 2014) with initial reports of highly successful short-term efficacy (Dauga et al. 2014).

Another worrying epidemiological trend is the emergence of drug-resistant pathogens, with high rates of penicillin, erythromycin and cephalosporin-resistant invasive pneumococcal isolates reported in some European countries. Resistant invasive meningococcal isolates are also starting to emerge (European Centre for Disease Prevention and Control 2011).

**Pathophysiology and Immunology of Acute Bacterial Meningitis**

Effective invasion of the CNS involves four stages: first, adherence and colonisation of the nasopharynx by the pathogen; second, mucosal invasion and subsequent multiplication and bacteraemia; third, traversing the blood–brain barrier (BBB) to enter into the subarachnoid space – the exact mechanism of how this occurs is still unclear; and finally multiplication within the subarachnoid space, generating a host inflammatory response.

**Adherence and colonisation**

The exact mechanisms by which bacteria attach to and penetrate the mucosal surface are still unclear. Multiple surface proteins on both the organism and on host cells are involved. In the case of *N. meningitidis*, adhesion is thought to be initially mediated by type IV pili possibly binding to membrane bound CD46 followed by a number of mechanisms to ensure ongoing colonisation, including further surface protein interactions (e.g. adhesins), biofilm production and specialised mechanisms of nutrient acquisition (Trivedi et al. 2011). *S. pneumoniae* uses a number of strategies to initiate and maintain colonisation including expression of molecules which adhere to epithelial cell components (e.g. ChoP, CbpA) and bind to extracellular matrix components (e.g. PavA, Eno) and also strategies to disrupt the protective mucus layer and expose host cell surface molecules (e.g. polysaccharide capsule, neuraminidase) (Bogaert et al. 2004; Kadioglu et al. 2008).

**Invasion**

The organism-specific mechanisms by which transition from colonisation to invasion occurs are poorly understood. However, in the case of *S. pneumoniae* it requires a switch in the expression of virulence determinants (including capsular polysaccharide, PspA and CbpA) to allow transport to and survival within an altered microenvironment (Bogaert et al. 2004; Kadioglu et al. 2008). An increasing array of virulence factors which aid adherence and invasion have been identified with different levels of importance at different stages in the process (van der Poll and Opal 2009).

**CNS penetration**

For pathogens to penetrate the CNS, the organism must first survive in the blood stream and then the BBB and/or blood–cerebrospinal fluid (CSF) barrier must be breached. Extracellular bacteria that normally colonise the host’s nasopharynx or digestive tract use various molecular mechanisms to evade host immunity and gain access to the CNS. Some of the mechanisms in which this is achieved by *N. meningitidis* have recently been elucidated. Meningococci interact with host endothelial cells via type IV pili resulting in rearrangement of host cell structure and protein expression and eventual opening of intercellular junctions (Coureuil et al. 2012). Pneumococci take advantage of a similar array of mechanisms to cross the BBB via both intracellular and intercellular pathways (Mook-Kanamori et al. 2011). A variety of mechanisms used by other bacteria commonly causing meningitis have recently been characterised (Kim 2010).
**Multiplication**

Once inside the CSF, an area of impaired host defence, the pathogens are likely initially to survive and multiply. However, their presence stimulates leukocyte migration into the CSF through a multistep process incorporating different adhesion molecules and ligands (e.g. selectins and integrins) with emigration guided by a chemotactic gradient triggered by the presence of the invading pathogen. Leukocytes then destroy the pathogens, and it is this destruction that precipitates the inflammatory cascade that causes the secondary tissue damage (Hoffman and Weber 2009). Activation of the immune response to invading bacteria occurs in part through binding of bacterial components to pattern recognition receptors. For example, Toll-like receptors bind to bacterial cell wall components including lipopolysaccharide from the Gram-negative organisms such as *N. meningitidis* and *H. influenzae* (Ivey et al. 2005), and lipopeptides/peptidoglycans from Gram-positive organisms such as *S. pneumoniae* (Hoffman and Weber 2009), as well as peptidoglycans (Mook-Kanamori et al. 2011) and bacterial DNA itself (Deng et al. 2001). After a time-lag of a few hours, pro-inflammatory cytokines and chemokines are induced (Mook-Kanamori et al. 2011; Bociaga-Jasik et al. 2012; Coutinho et al. 2013; Grandgirard et al. 2013; Wall et al. 2014). These precipitate a cascade of other cytokines, chemokines, proteolytic enzymes and reactive oxygen species and nitrogen intermediates from macrophages, neutrophils and platelets.

Vascular congestion and increased vessel permeability result in cytotoxic and vasogenic brain oedema and increased intracranial pressure (ICP), further decreasing cerebral perfusion pressure, increasing the risk of herniation and irreversible brain damage. The CSF volume increases during the first two or three days of disease (Ashwal et al. 1992), along with levels of endotoxin (Mertsola 1991) and of the cytokines mentioned above (Armitt et al. 1989; Mook-Kanamori et al. 2011; Bociaga-Jasik et al. 2012; Coutinho et al. 2013; Grandgirard et al. 2013; Wall et al. 2014). Whether the levels of cytokines are predictive of outcome remains to be determined (Vazquez et al. 2012, Wall et al. 2014).

Ultimately, these pro-inflammatory processes combine to result in endothelial and neuronal injury and dysfunction, resulting in the potential for cerebral oedema and raised intracranial pressure through a number of pathways including vasogenic, cytotoxic and interstitial oedema and increased brain blood volume (Scheld et al. 2002).

**Pathology of acute bacterial meningitis**

The fundamental pathological change is inflammation of the two meningeal coverings of the brain and spine (arachnoid and pia mater) with initial hyperaemia, followed by migration of neutrophils into the subarachnoid space and the production of a purulent exudate. This exudate rapidly increases and extends into the Virchow–Robin spaces and along the penetrating vessels. Within 48–72 hours, inflammatory involvement of these vessels is seen, initially of the subarachnoid arteries and then of the meningeal veins. Such changes can produce thrombosis of involved vessels with haemorrhagic cortical infarction and secondary necrosis. The necrosis may be limited to one vascular territory or diffusely involve a large portion or the whole of the cerebral cortex (Dodge and Swartz 1965).

Oedema (cytotoxic, vasogenic and interstitial) is often present and, in isolation or in association with acute obstructive hydrocephalus due to purulent cisternal exudate, can result in intracranial hypertension and secondary herniation of brain tissue. This in turn can further impede cerebral perfusion (Minns et al. 1989; Scheld et al. 2002), setting the stage for a vicious circle. Apoptotic neuronal damage also occurs. In the case of pneumococcal meningitis this is particularly in the dentate gyrus of the hippocampus. This is of potential importance, as there is evidence that this damage may contribute to meningitis-related learning difficulties (Loeffler et al. 2001). This apoptosis is thought to be a result of host response to various pneumococcal virulence factors, through caspase-dependant and independent pathways (Parthasarathy and Philipp 2012). Organisation of the meningeal exudate may lead to chronic hydrocephalus, especially in young infants. Hydrocephalus can also result from aqueductal stenosis that may supervene as a consequence of ventriculitis. The latter is most common in neonates, being found in as many as 92% of autopsy cases (Berman and Banker 1966).

**Clinical manifestations and diagnosis of acute bacterial meningitis**

The importance of an early diagnosis is self-evident. However, because meningitis is relatively rarely seen in general practice, compared with the frequency of common, mostly viral febrile diseases, late diagnosis remains frequent. Delay in administration of appropriate antibiotics is associated with poorer neurological outcomes (Bargui et al. 2012). Meningitis is often preceded for a few days by fever so that it may be impossible to determine its actual onset. A substantial proportion of patients may have received antibiotics prior to diagnosis (Kaplan et al. 1986), decreasing the likelihood of isolating the infecting organism in culture. Mode of onset can be a prognostic feature: a progressive onset merging with previous disease may predict a more favourable outcome, while a fulminating onset is of ominous significance (Radetsky 1992; Kilpi et al. 1993).

Early symptoms and signs of meningitis in both infants and children can be nonspecific contributing to delayed diagnosis. Classic symptoms and signs, including fever, headache, photophobia, neck stiffness, bulging fontanelle and vomiting may not be present, especially in very young children (Amarilyo et al. 2011). A systematic review found that a history from a caregiver of bulging fontanelle or neck stiffness increased the likelihood of meningitis significantly as well as a history of febrile seizures outside the normal age-range for simple febrile convulsions and also reduced feeding. Regarding physical signs, the presence of a bulging fontanelle, clinical neck stiffness, positive Kernig’s or Brudzinski’s sign were predictive of meningitis. High temperature (>40°C) was somewhat predictive; however, it is important to note that the absence of high temperature did not rule out meningitis (Curtis et al. 2010).
A retrospective study of the sequence and timing of symptoms of meningococcal disease in 448 children (including 99 children with meningitis) found a history of preceding symptoms of respiratory tract infection in around a quarter of children. Evolution of symptoms was usually rapid (over 24 hours). In young children, fever was an early feature, whereas in older children headache was earliest. Nonspecific early symptoms of nausea, vomiting and loss of appetite were very common. Subsequent to this, symptoms and signs of sepsis occurred including leg pain, abnormal skin colour and cold hands and feet. These have been highlighted as important early warning signs of possible meningococcal disease that may be of use in primary care settings. More classic signs of meningococcal disease (neck stiffness, bulging fontanelle, photophobia) developed relatively late. Haemorrhagic rash was only seen in 42–70% of cases (Thompson et al. 2006).

The presence of a maculopapular rash can be an early sign of meningococcal sepsis, or represent a viral illness. Petechiae or a purpuric rash is suggestive of meningococcal disease (Fig. 11.1), although can also occasionally be found in association with sepsis secondary to Hib, pneumococcus or some viral illnesses (e.g. Echovirus 9). Focal neurological signs such as cranial nerve palsies or hemiparesis usually develop late in the course of bacterial meningitis, or can occur earlier as a complication of raised ICP (particularly VIth nerve palsies). Papilloedema is rarely evident early on; in fact, the presence of papilloedema should raise suspicion of a focal intracranial process such as brain abscess or a mass lesion, and is an indication for neuroimaging prior to lumbar puncture.

As a result of the low frequency of signs that are both specific and sensitive for bacterial meningitis in children (Brouwer et al. 2012), diagnostic investigations are of great importance, although early laboratory test results can also lack sensitivity and specificity. First-line investigations classically include sampling of blood, urine and CSF with or without neuroimaging. An accurate scoring system has been developed and validated which can predict whether a child older than 2 months of age with CSF pleocytosis does not have bacterial meningitis and can possibly be treated safely in an ambulatory setting while awaiting confirmatory culture results. This Bacterial Meningitis Score consists of five predictors (positive CSF Gram stain, CSF neutrophil count ≥1 000 cells per mm³, CSF protein ≥80mg/dl, peripheral blood neutrophil count ≥10 000 cells per mm³, seizure). If none of these predictors is present then the child is very unlikely to have bacterial meningitis (Nigrovic et al. 2012).

A key step in the diagnosis of bacterial meningitis is lumbar puncture. Concerns as to the possible complications of lumbar puncture can often lead to reluctance by clinicians to perform this procedure, despite its importance in diagnostics and planning of care. The possibility of cerebral herniation brought about as a result of lumbar puncture performed in the context of raised intracranial pressure has been of concern for many years; however, direct evidence for this is lacking (Benjamin et al. 1988; Rennick et al. 1993; Kneen et al. 2002; Brouwer et al. 2012). The theoretical chance of this alongside other rare severe complications of lumbar puncture (uncontrolled haemorrhage, infection) allows a reasonable list of contraindications to lumbar puncture to be constructed (NICE 2010) (Table 11.1).

Adapted from Kneen et al. (2002) and NICE (2010).

GCS, Glasgow Coma Scale.
have nonspecific signs and for this reason a lumbar puncture is recommended as part of the diagnostic workup of all febrile neonates.

The value of computerised tomography (CT) in detecting oedema or increased ICP is extremely limited (Pike et al. 1990; Heydeman et al. 1992; Nickerson et al. 2012), and it cannot predict the risk of coning. CT has been shown to change management in less than 5% of cases, and it delays lumbar puncture on average by 2.5 hours (Gopal et al. 1999). Delaying lumbar puncture for unnecessary CT has been shown to be associated with a decreased yield from CSF culture in adults with meningitis (Michael et al. 2010). In addition, a normal CT does not mean it is safe to perform a lumbar puncture (Nickerson et al. 2012), and in 36% of patients who coned, the CT had been normal. By using stringent patient selection, the use of CT can be dramatically reduced (Hasbun et al. 2001).

Simple febrile convulsions are common in childhood. A recent systematic review and meta-analysis of seizures in the context of fever in children in resource-rich settings found the overall risk of bacterial meningitis to be low (0.2% in those with a simple febrile convolution). The utility of performing routine lumbar puncture in the absence of clinical signs or symptoms suggestive of bacterial meningitis is therefore very low (Najaf-Zadeh et al. 2013). In the context of a classic simple febrile convolution (i.e. in the absence of any symptoms or signs indicative of meningitis) in a child over 12 months a lumbar puncture is not always indicated. If a younger child is unimmunised against Hib, pneumococcus or meningococcus, or if there is concern regarding the possibility of partially treated meningitis (e.g. prior administration of oral antibiotics), then lumbar puncture should be considered (American Academy of Pediatrics [AAP] 2011).

Laboratory Diagnosis of Acute Bacterial Meningitis

Cerebrospinal fluid

Examination of the CSF is an essential step. Routine examination of CSF includes: complete cell count, differential leukocyte count, Gram stain, bacterial culture, glucose and protein concentration with nucleic acid amplification tests [e.g. polymerase chain reaction (PCR)] and antigen detection tests in addition when indicated. Characteristically, the CSF is under increased pressure (>18cm H₂O) and cloudy. In some children, however, the fluid may initially be clear and contain only a few cells or be altogether normal with a negative culture but subsequently demonstrate a positive culture when re-examined 48–72 hours later (Teele et al. 1981). Cultures may be positive for pathogenic bacteria in the presence of normal cytological and chemistry findings, if the lumbar puncture is done after bacterial invasion but before the inflammatory response (Onorato et al. 1980). If clinical suspicion persists, repeat lumbar puncture is indicated within 6–12 hours.

Age-related normal CSF parameters have been defined based on historical data (Table 11.2) (Health Protection Agency 2014). Recent studies have called into question the validity of earlier defined upper limits of normal in young infants and neonates (Martin-Ancel et al. 2006; Kestenbaum et al. 2010; Byington et al. 2011; Srinivasan et al. 2012). It is therefore advised that infants and neonates with values approaching the upper limit of normal who have any symptoms or signs of meningitis should be treated with antibiotics until the diagnosis has been definitively excluded. At times lumbar puncture may result in a ‘traumatic tap’ whereby CSF is contaminated with fresh blood during the procedure. Various methods/formulae have been proposed for calculating whether a white cell count in CSF is significant when this occurs. However, none of these has been validated and caution should be taken when considering a raised white cell count as non-significant in CSF following a traumatic tap (Greenberg et al. 2008; Bonadio 2014; Srinivasan et al. 2012).

Organisms may be seen intracellularly and extracellularly in smears. Gram stain is positive in a substantial proportion of cases of bacterial meningitis, the rate at which this occurs depending on the organism (Brouwer et al. 2010). Counting the number of colony-forming units gives an idea of the concentration of organisms in the CSF. It is possible to isolate an organism and determine its sensitivity to antibiotics in 90% of untreated cases of bacterial meningitis (Bohr et al. 1983). Prior treatment with antibiotics can be associated with lower protein levels and higher glucose in CSF but the white blood cell count does not appear to be affected (Nigrovic et al. 2008). Prior antibiotic exposure can sterilise CSF, the speed at which this occurs depending on the infecting organism (Kanegaye et al. 2001). A raised protein level is unusual, both as a result of disruption of the BBB and from local production of immunoglobulins (Maida and Horvatits 1986). The CSF:blood glucose ratio is usually reduced. Blood and CSF glucose levels should therefore be determined simultaneously (Donald et al. 1983). A normal glucose level is found in up to 20% of cases (Lambert 1994) and does not exclude the diagnosis. Patterns of CSF abnormality characteristic of bacterial infection compared to other types of infection (viral, fungal, mycobacterial) have been described:

Table 11.3: Causes of ‘aseptic’ meningitis syndrome

### Infectious causes

- **Bacteria**: Actinomyces spp., *Borrelia burgdorferi* (Lyme disease), *Brucella melitensis*, Leptospira spp., *Mycoplasma pneumoniae* and *M. hominis*, *Mycobacterium tuberculosis*, atypical mycobacteria, Nocardia spp., *Rickettsia rickettsii* (Rocky Mountain spotted fever), *Treponema pallidum*. Conditions including, for example, bacterial endocarditis, brain abscess and parameningeal suppuration, partially treated meningitis, virus thrombophlebitis, children with systemic infection.

- **Viruses**: Arboviruses (e.g. West Nile virus), tick-borne encephalitis virus, arenaviruses (lymphocytic choriomeningitis), enteroviruses (e.g. polio, coxsackie, echo), parechoviruses, adenoviruses, herpes viruses (e.g. HSV-1/2, HHV-6/7, varicella, cytomegalovirus and Epstein–Barr virus), retroviruses (e.g. human immunodeficiency virus), paramyxoviruses (e.g. mumps, measles), orthomyxoviruses (e.g. influenza), parvovirus B19, live viral vaccines.

- **Protozoa**: *Toxoplasma gondii*, *Cryptococcus neoformans*, *Coccidioides immitis*, *Histoplasma capsulatum*, *Sporothrix schenckii*, *Plasmodium falciparum*, *Toxoplasma gondii*, visceral larva migrans.

- **Cestodes**: *Cysticercosis*.

### Noninfectious causes

- **Malignancies**: Leukaemia, lymphoma, metastatic brain tumours.

- **Collagen and vascular diseases**: Lupus erythematosus, panarteritis, other vasculitides.

- **Trauma**: Following lumbar puncture, subarachnoid haemorrhage, postoperative meningitis.

- **Toxin**: Intrathecal contrast media, air, anaesthetics, systemic toxicity (lead, mercury).

- **Drug-induced meningitis**: (Azathioprine, cytosine-arabinoside, isoniazid, nonsteroidal anti-inflammatory drugs, penicillin, cephalosporins).

### Unknown mechanisms

Multiple sclerosis, Schilder disease, uveomeningitis syndromes (e.g. Behçet, Harada–Vogt–Koyanagi), Kawasaki disease, Mollaret meningitis.

### Part V: Postnatal Extrinsic Insults

Raised opening pressure, white blood cell count more than 1000 × 10^3 per litre, low glucose, raised protein (Brouwer et al. 2010; Kim 2010; Brouwer et al. 2012). Their significance should not be over-emphasised as results can be variable, especially in the context of early infection and in neonates. Polymorphonuclear cells characteristically predominate although they can also be a feature in viral and mycobacterial meningitis and are not a defining feature. Very high white cell counts with predominantly polymorphonuclear cells are, however, strongly predictive of bacterial meningitis (Spanos et al. 1989).

Positive bacterial culture from CSF is the criterion standard for confirmation of bacterial CNS infection. In the case of prior antibiotic administration, yield from traditional culture methods decreases (Kanegaye et al. 2001; Brouwer et al. 2010). Both sequential-multiplex PCR and 16S ribosomal RNA PCR are quick and useful adjunctive investigations and have good specificity and sensitivity for detecting pathogens in CSF especially in the context of prior antibiotic exposure (Corless et al. 2001; Schuurman et al. 2004; Chiba et al. 2009; Kim 2010; Brouwer et al. 2012; Srinivasan et al. 2012). Latex particle agglutination can be used for the rapid detection of antigens from the three common pathogens and group B streptococci. The sensitivity of this test has been shown in a number of studies to be low and its clinical utility is therefore limited (Brouwer et al. 2010).

In patients with meningitis but no bacteria grown from the CSF or other sites the physician must consider other causes of the aseptic meningitis syndrome. Many aseptic meningitides are due to viral infections, but other causes are possible (Table 11.3). Such children should have a tuberculin skin test (or mantoux) with or without interferon gamma release assay (IGRA) for tuberculosis, and exclusion of other possibly treatable causes. Careful clinical, neuroradiological and laboratory examinations should be considered, as applicable to the individual child.

### Other laboratory procedures

Blood cultures may be positive in a substantial proportion of cases of bacterial meningitis, the likelihood of this varying according to the infecting organism (Brouwer et al. 2010). Overall blood cultures have been shown to have a sensitivity of 73% and specificity of 88% in children with bacterial meningitis with the probability of isolating the infecting organism highest in neonates (Sarkar et al. 2011). Bacterial PCR performed on blood may also contribute to the detection of causative organism (Carrol et al. 2000; Wu et al. 2008b). Nose and throat cultures are neither sensitive nor specific. Urine cultures and Gram-stained smears of skin lesions may provide clues to the identity of pathogens, the latter immediately (Brouwer et al. 2010). Immunochromatographic detection of pneumococcal antigen in urine is of use in adults to detect pneumococcal disease (Marcos et al. 2001). However, its utility is limited in children as a result of low specificity resulting from higher rates of asymptomatic pneumococcal carriage leading to a positive test (Charkaluk et al. 2006). Bacteriological study of the middle ear fluid obtained by aspiration in the case of associated otitis media may show the same organism as is present in the CSF and can be used to guide antibiotic therapy.

Alternative diagnostic markers have been assessed including CSF levels of lactate, heparin-binding protein, TREM-1, IL-1β, IL6, IL12, TNF-α, complement component B and
complement component 3. Predictive value of serum levels of C-reactive protein (CRP) and procalcitonin have also been addressed in retrospective studies. Some of these markers have good sensitivity and specificity for distinguishing between bacterial and aseptic meningitis. However, small study numbers limit conclusions and the majority of them are not currently in clinical use (Brouwer et al. 2012).

**Neuroimaging of acute bacterial meningitis**

Commonly available imaging modalities of use in CNS infection include cranial ultrasound (in neonates), CT and magnetic resonance imaging (MRI). MRI has benefits over CT in that it is more sensitive, can provide high-resolution imaging and does not involve exposure to ionising radiation. However, scanning can be a lengthy process and may require general anaesthesia (with its associated risks) in order to acquire useful images. Nevertheless, recent advances in availability of different sequences (e.g. diffusion-weighted imaging [DWI], fluid attenuated inversion recovery [FLAIR]) have made this imaging modality invaluable for assessing the effects of infectious processes on soft tissue. Early imaging may be normal, or may show meningeal enhancement with contrast, but its main use is in the exclusion of other CNS pathologies and for the diagnosis of complications such as infarction, abscesses, hydrocephalus, ventriculitis, empyema and venous sinus thrombosis (Klein et al. 1986; Foerster et al. 2007; Nickerson et al. 2012). Patterns of abnormality on imaging may be suggestive of the causative organism; however, there is considerable overlap (Jaremko et al. 2011). In the acute setting, UK National Institute for Health and Care Excellence (NICE) guidelines recommend performing a CT prior to lumbar puncture if there is significantly reduced or fluctuating consciousness or focal neurological signs (NICE 2010). Riordan and colleagues previously suggested the following indications for CT: prolonged depressed consciousness, prolonged partial or late seizures, focal neurological abnormalities, enlarging head circumference, evidence of continuing infection and recurrence of symptoms and signs (Riordan et al. 1993).

**Management of acute bacterial meningitis**

**Antibacterial chemotherapy**

Antibiotics for meningitis must be able to cross the BBB and be able to kill the infecting organism while resulting in minimal toxicity to the host. Higher than usual doses are sometimes required in order to ensure adequate CSF concentrations although inflammation of the meninges during active infection may enhance CSF drug levels (van de Beek et al. 2012). Frequency of administration should be considered, especially if planning outpatient parenteral antibiotic therapy. Antibiotic decisions should be tailored to the antibiotic sensitivity of an isolated organism. There are three main circumstances when decisions as to which antibiotic to use must be made. The first is when choosing initial empiric therapy, as is usually the case prior to results of laboratory tests being available. The choice of empiric antibiotic will depend on the age of the child (neonate, young infant, older child) and hence the most likely infecting bacteria (Table 11.4) and whether the infection was acquired in the community or in hospital. Local microbiological sensitivity patterns must also be taken into account. The second circumstance is when a specific bacterium has been isolated and antibiotic cover can be rationalised depending again on local antibiotic sensitivity patterns. The third is when in vitro antibiotic sensitivity of the organism has been formally assessed and can be used to further tailor antibiotic therapy.

With regard to empiric therapy, in children younger than 3 months, Gram-negative organisms (e.g. *Escherichia coli*), group B streptococcus and *Listeria monocytogenes* are more common than in older children and this should guide antibiotic choice. In most regions a combination of third generation cephalosporin and ampicillin or amoxicillin (the latter in view of Listeria being resistant to cephalosporins) should provide adequate cover. Despite the almost universal adequacy of this first-line choice, guidelines for first-line antibiotic for neonates with sepsis alone or together with meningitis are highly variable (Fernando et al. 2008; Lutsar et al. 2014). If there is a possibility of resistant Gram-negative organisms (e.g. nosocomial infection) then meropenem may be a better first-line choice. Choice of a third generation

Table 11.4 Suggested first-line antibiotic therapy for acute bacterial meningitis (children ≥2 months). Always adjust according to sensitivities, consult local guidelines and consider local patterns of antimicrobial resistance.
cephalosporin may be guided by the known risks of using ceftriaxone in very young or unwell children (related to exacerbation of jaundice and incompatibility with calcium containing infusions). In children over 3 months, despite the resounding success of conjugate vaccination, haemophilus, meningococcus and pneumococcus are still the most likely organisms causing meningitis. Third generation cephalosporin is usually adequate for bacterial meningitis, vancomycin alone or together with rifampicin may be required as it has more convenient once a day dosing. A switch to ceftriaxone can then be made should a prolonged course of antibiotic be required as it has more convenient dosing. In regions where cephalosporin resistance of *S. pneumoniae* is a possibility (or in children travelling from these areas), vancomycin alone or together with rifampicin should be added until formal sensitivities are known.

Once an organism is identified modification of antibiotic choice and treatment duration can be planned. For *S. pneumoniae*, *H. influenzae* and *N. meningitidis*, a third generation cephalosporin is usually adequate although vancomycin alone or together with rifampicin may need to be added if there is cephalosporin resistance. Group B streptococcus may be treated with a third generation cephalosporin or benzylpenicillin or amoxicillin combined with an aminoglycoside. For *L. monocytogenes*, ampicillin/amoxicillin and gentamicin are the preferred option (Klein et al. 1986). Other Gram-negative organisms may be highly resistant, especially when acquired in a healthcare setting. When they are identified in culture a switch to a broader spectrum antibiotic, such as meropenem alone or together with an aminoglycoside, may be considered until formal sensitivities are available. Fluclaxacillin is the first-line antibiotic when *Staphylococcus aureus* is the causal organism; however, initial treatment with vancomycin alone or together with rifampicin may be indicated until the organism is confirmed to be non-methicillin resistant staphlococcus aureus (MRSA), especially in regions of high MRSA prevalence (NICE 2010; van de Beek et al. 2012).

Inhibition of growth is not enough, and bacterial concentrations may need to be 10–30 times the minimum inhibitory concentration (Quagliarello and Scheld 1997). This can be achieved, in most cases, with adequate plasma concentration; direct instillation of the drug into the ventricles is only very rarely indicated (Feigin et al. 1992) and a recent Cochrane review of intraventricular antibiotics concluded that this practice should be avoided in neonates as one study found increased relative risk of mortality (Shah et al. 2012). It has been suggested that continuous infusion of antibiotic may be more beneficial in treating meningitis than intermittent bolus dosing. A recent randomised trial set in Africa attempted to assess this by comparing outcomes following cefotaxime infusion vs. cefotaxime bolus dosing in the first 24 hours of meningitis. Results showed no differences between the two strategies for bacterial meningitis overall, but a subgroup analysis suggested that there may be some benefit from continuous infusion for pneumococcal meningitis (Pelkonen et al. 2011). This strategy is not recommended at present.

**Duration of treatment**

Evidence to inform duration of treatment in bacterial meningitis remains limited. Standard duration of therapy for uncomplicated meningitis in children with *N. meningitidis*, *H. influenzae* and *S. pneumoniae* are 7, 10 and 10–14 days respectively (Lin et al. 1985; Jadavji et al. 1986; NICE 2010). A meta-analysis found no difference in outcomes for short versus long course antibiotics in meningitis (without individual analysis by organism) (Karageorgopoulou et al. 2009). A subsequent large randomised controlled trial comparing 5 versus 10 days of intravenous ceftriaxone for bacterial meningitis in children found no difference in assessed outcomes (Molyneux et al. 2011). Nevertheless, national guidance still favours the treatment durations similar to those mentioned above (Tunkel et al. 2004; NICE 2010).

For younger infants and neonates, standard recommended duration of treatment for the commonly infecting organisms *L. monocytogenes* and Gram-negative organisms should be at least 21 days and for group B streptococcus, at least 14 days. These recommendations are again made in the absence of strong randomised controlled trial evidence. In all ages, when the infecting organism has not been identified, duration of empiric therapy should be sufficient to treat the likely organism using the longest recommended treatment course in that age group. If the course of treatment is complicated then longer duration of therapy may be indicated.

**Monitoring of treatment**

‘End of treatment’ lumbar puncture is not recommended in regular cases of childhood meningitis as the cell and chemical composition of the CSF is extremely variable (Schaad et al. 1981; Durack and Spanos 1982). However, any child who remains febrile or does not appear to be responding to treatment, warrants a repeat lumbar puncture, as does meningitis complicating CSF shunt (Chaudhuri et al. 2008).

**Adjuvant and supportive treatment**

Whether to use corticosteroids remains controversial in treatment of acute bacterial meningitis in children (Esposito et al. 2013b), although there is clear evidence of benefit under certain circumstances. A recent Cochrane review found adjunctive steroid therapy to be associated with a reduction in hearing loss in *H. influenzae* meningitis in all settings. It also found a reduction in hearing loss and short-term neurological sequelae in all causes of bacterial meningitis combined in high-income countries. The authors concluded that adjunctive corticosteroids are of benefit in bacterial meningitis in children in high-income countries (Brouwer et al. 2013). The UK NICE guidelines provide additional guidance, recommending that steroids be used in children over 3 months with probable bacterial meningitis indicated by any of: frankly purulent CSF, CSF white cell count more than 1000 cells per µl, raised CSF white cells with protein more than 1 mg/dL, bacteria on Gram stain (NICE 2010). A US guideline also recommends their use in this age group (Tunkel et al. 2004). Concerns regarding the contribution of
corticosteroid therapy to an increased risk of delayed cerebral thrombosis in adults with pneumococcal meningitis (Schut et al. 2009) have not so far been raised in paediatric practice.

Ideally, dexamethasone should be given empirically with or before the first dose of antibiotic, continuing a dose of 0.15mg/kg 6-hourly for the first 48–72 hours of antibiotic therapy. The concern raised has been that steroids may delay sterilisation of the CSF; however, in children with cephalosporin-resistant pneumococci, CSF penetration of vancomycin seemed unaffected by adjunctive use of corticosteroids (Morris 2004). A subsequent study in adults has also shown no effect of adjunctive corticosteroids on CSF concentration of vancomycin when treating pneumococcal meningitis (Ricard et al. 2007).

New potential targets for adjuvant therapy are urgently being sought. The use of osmotic therapies to reduce cerebral oedema has been explored. A Cochrane review found no evidence for benefit of glycerol in the treatment of bacterial meningitis in children (Wall et al. 2013), a conclusion supported by the results of a randomised trial of adjunctive glycerol and paracetamol in children with meningitis (predominately pneumococcal) in children in Malawi, which also demonstrated no benefit (Molyneux et al. 2014).

The cascade of cytokines, chemokines, proteases, antioxidants and apoptotic enzymes, among others, that are induced by the host inflammatory response provide many potential targets for neuroprotection. Various models have shown promising results with therapies including inhibition of complement activation, pro-inflammatory cytokines, pattern recognition receptors and caspases as well as modification of leukocyte migration and the use of non-bactericidal antibiotics (reviewed in Mook-Kanamori et al. 2011). The use of a CS5-specific antibody in a mouse model of pneumococcal meningitis prevented death in all treated mice, highlighting the future potential of one such novel strategy (Woehrl et al. 2011).

Careful management of fluid and electrolyte balance is essential in meningitis, as both over- and under-hydration may be associated with adverse outcomes. A Cochrane review found insufficient generalisable evidence to guide practice, although there is some evidence that maintenance fluids rather than fluid restriction in the first 48 hours might improve outcomes in settings with high mortality rates and late presentation (Maconochie and Bhaumik 2014). Fluid restriction is not routinely indicated for patients with meningitis, and sufficient amounts of fluids are essential for the prevention of shock. A recent trial of intracranial pressure targeted therapy in adults with bacterial meningitis and low Glasgow Coma Scale (GCS) scores, has shown promising results relating to both morbidity and mortality (Glimaker et al. 2014), whereas a randomised trial in children with CNS infection (the majority of which was bacterial) found cerebral perfusion pressure-targeted therapy to be associated with improved morbidity and mortality when compared with intracranial pressure-targeted therapy (Kumar et al. 2014). The use of these strategies to improve outcomes in the intensive care setting is an exciting and evolving field.

Hyponatraemia frequently represents dehydration, rather than the syndrome of inappropriate antidiuretic hormone (SIADH), and fluid restriction may further compromise cerebral circulation. Arginine–vasopressin concentrations in blood normalise when children with meningitis are given adequate maintenance and replacement fluid therapy, indicating that high levels are a response to dehydration (Powell et al. 1990).

Convulsions should be stopped with intravenous midazolam or lorazepam. If unsuccessful, treatment of status epilepticus should be followed as per local protocols (see Chapter 16). Preventive treatment is used in some centres, although it is not routinely advocated.

Complications of Acute Bacterial Meningitis

Cerebrovascular complications including arterial stroke, venous thrombosis and intracranial haemorrhage are common in the context of bacterial meningitis especially in association with pneumococcal disease (Chang et al. 2003; Kastenbauer and Pfister 2003; Jaremko et al. 2011; Mook-Kanamori et al. 2011; Pryde et al. 2013; Boelman et al. 2014). The aetiology of ischaemic injury has widely been considered to be vasculitic, based on the results of imaging reports and historical histopathological studies. More recently adult post-mortem findings in the context of pneumococcal meningitis have shown that ischaemic damage is not always associated with vasculitis and that intravascular coagulation may also contribute (Vergouwen et al. 2010). The role of endothelial dysfunction and dysregulation of coagulation are currently under investigation (Mook-Kanamori et al. 2011). A recent retrospective case series has highlighted the potential for antithrombotic therapy in prevention of stroke in bacterial meningitis in children (Boelman et al. 2014). The location of ischaemic foci is variable, from localised well-defined areas to diffuse necrotic lesions that may be responsible for multicystic encephalomalacia (Fig. 11.2). Ischaemic lesions can be found in the absence of vascular thrombosis. The inflammatory disruption of small vascular walls within the CNS can permit organisms to invade the parenchyma, producing small foci of septic necrosis. It seems likely that such foci give rise to the cerebral abscesses that in rare cases complicate bacterial meningitis. Spinal cord infarction is an uncommon complication related to vascular involvement (Moffett and Berkowitz 1997; Almasanu et al. 2005). Exceptionally it has been seen as a presenting feature (Boothman et al. 1988). The appearance of bilateral sensory or motor deficit in the course of bacterial meningitis should suggest spinal cord infarction (Glista et al. 1980).

Other unusual neurological abnormalities include movement disorders (Burstein and Breningstall 1986), hypothalamic dysfunction (Karadag-Oncel et al. 2015) and central diabetes insipidus (Greger et al. 1986). Neuroimaging procedures permit a good assessment of the type and location of the responsible lesions. Such lesions may be partly haemorrhagic. Cranial nerve deficits in nontuberculous bacterial meningitis are rare. However, paralysis of the IIIrd, Vth, or less commonly the VIIth cranial nerves can occur as they cross the inflamed leptomeningeal spaces. Opsoclonus has been reported (Rivner et al. 1982).
Seizures are common in children with acute bacterial meningitis, the post-ictal period of decreased consciousness being often longer than that observed following simple febrile convulsion (King et al. 2012). In some cases status epilepticus occurs (Chin et al. 2006) and requires emergency treatment to prevent further long-term damage (see Chapter 16).

Subdural effusion is a recognised complication of acute bacterial meningitis occurring in 20–50% of children with meningitis. The effusions are usually of limited thickness and volume and clinically of little significance (Syrogiannopoulos et al. 1986; Cabral et al. 1987). Most effusions are located over the frontoparietal region bilaterally. The subdural fluid is rarely bloody but has a disproportionately high albumin to globulin ratio (Rabe et al. 1968). Persistent or recurring fever, focal neurological signs and persistently positive CSF cultures are probably more closely related to cortical damage than to the presence of an effusion (Syrogiannopoulos et al. 1986; Snedeker et al. 1990). Large effusions with enlargement of the head or signs of increased ICP are rare but necessitate drainage. Most subdural collections resolve spontaneously. Snedeker and colleagues found that patients with effusion were more likely to have neurological abnormalities and seizures during the acute illness, but that hearing loss, seizures and developmental delay were not more frequent at follow-up (Snedeker et al. 1990). Subdural empyema is rare (Bockova and Rigamonti 2000; Cole et al. 2012). It is often marked by the persistence of fever and infective symptoms and signs in association with focal signs such as convulsions and hemiplegia. The diagnosis is made by neuroimaging that shows...
an extra-axial collection with peripheral enhancement (Fig. 11.3). Diffusion-weighted imaging may be helpful in distinguishing a simple reactive effusion from an empyema (Hunter and Morriss 2003; Wong et al. 2004; Jaremko et al. 2011).

Raised ICP is common in bacterial meningitis in children (Minns et al. 1989), can be of a severe degree and is a potentially serious complication. It can be due to different mechanisms: hydrocephalus from altered CSF absorption or obstructed flow, or cerebral oedema. Acute hydrocephalus is caused by obstruction to the circulation and resorption of CSF, as a result of the presence of thick leptomeningeal exudate in the basal cisterns or over the cerebral convexity in the vicinity of arachnoid granulations, or consequent to ventriculitis with obstruction of the aqueduct. It is usually transient but can lead to late hydrocephalus if extensive meningeal fibrosis develops. The mechanisms leading to cerebral oedema are most likely multifactorial. They include cytotoxic oedema precipitated by cell damage from the infection, vasogenic oedema due to increased capillary permeability related to the inflammatory response to infection, and interstitial oedema from disturbance to CSF resorption by the normal route. SIADH can occur with acute bacterial meningitis (Patwari et al. 1995) and lead to hyponatraemia and hypotonic extracellular fluid, which can exacerbate the cerebral oedema. However, fluid restriction does not improve outcome and is not currently recommended (Singhi et al. 1995; Maconochie and Bhaumik 2014).

The clinical manifestations of high ICP may not always be obvious. They include a decrease in the level of consciousness, headache and vomiting, tense fontanelle and split sutures, abnormal pupillary response and hypertension with bradycardia (Cushing reflex). Papilloedema is rare, particularly early on. CT may show loss of grey–white differentiation, compression of the ventricles and sulci, and small basal cisterns. MRI may show gyral swelling, and diffusion-weighted imaging can be useful in distinguishing cytotoxic oedema (restricted diffusion) from vasogenic oedema (free diffusion). Monitoring of ICP may be a necessary part of treatment in cases of marked or sustained intracranial hypertension (Goitein et al. 1983; Minns et al. 1989). Treatment consists of raising the head to approximately 30° and administering mannitol or other hyperosmolar agents (to reduce cytotoxic oedema) may help in the acute situation. More aggressive measures are described in Chapter 7. Intracranial hypertension is associated with reduced brain perfusion and reduced cerebral blood flow velocity (McMenamin and Volpe 1984), so even moderate episodes of systemic hypotension can have serious consequences and should be avoided (Kaplan and Fishman 1988). Trials of ICP targeted therapy and cerebral perfusion pressure-targeted therapy show promising results (Glimaker et al. 2014; Kumar et al. 2014).

Ventriculitis is common in neonatal meningitis but is relatively uncommon in older children. When ventriculitis is associated with stenosis of the sylvian aqueduct, infection can become localised (pyocephalus) and may behave as a cerebral abscess. Ventriculitis can be diagnosed by persistence of positive CSF cultures with or without clinical signs. Neuroimaging may allow identification of ventriculitis, with abnormal enhancement of the ventricular surface and oedema of adjacent periventricular white matter and secondary hydrocephalus.

CSF cultures with or without clinical signs. Neuroimaging may allow identification of ventriculitis, with abnormal enhancement of the ventricular surface and oedema of adjacent periventricular white matter (Fig. 11.4). Debris may be present in the ventricular cavities (Fukui et al. 2001). Diffusion-weighted imaging and FLAIR are highly sensitive MRI sequences to detect pus and debris in the ventricles, FLAIR also being of use in detecting ventricular wall abnormalities (Fujikawa et al. 2006). Ventriculitis may respond to adequate doses of parenteral antibiotics, sufficient to allow therapeutic drug levels in the ventricle, but local treatment and drainage may become necessary (Agrawal et al. 2008). If not rapidly treated, hydrocephalus is prone to develop in survivors.

Persistent fever and other septic complications are the result of concurrent bacteraemia. Complications relating to bacteraemia include septic arthritis, pericarditis, pneumonia, endophthalmitis and hypopyon (Kaplan and Fishman 1988). Arthritis appearing after 5–7 days of antibiotic therapy is probably mediated by an immune mechanism and frequently responds to anti-inflammatory agents (Rush et al. 1986). Gastrointestinal haemorrhage, anaemia and disseminated intravascular coagulation can be observed in severe cases, especially but not exclusively with meningococcal meningitis. Fever is prolonged for 10 days or longer in 13% of patients, particularly in pneumococcal disease, and recurs secondarily in
16%. Prolonged fever may be associated with other infectious foci, nosocomial infection or subdural effusion (Lin et al. 1984). Commonly, no cause is found and in such cases, repeat lumbar puncture may be indicated. If the child appears well and CSF values are approaching normal, antimicrobial therapy can generally be discontinued at the usual time.

Neurological Sequelae of Acute Bacterial Meningitis

Long-term sequelae following bacterial meningitis in neonates, infants and children are common and can have lasting socio-economic impact. The most frequently observed sequelae include seizure disorders, hearing/visual impairment, motor deficit, cognitive delay and behavioural problems. These are often found in combination. Several reviews have highlighted that rates of complication vary between studies and according to infecting organism, geographical setting, age at time of infection and duration of follow-up (Ramakrishnan et al. 2009; Edmond et al. 2010; Chandran et al. 2011). Edmond et al. summarised results from 132 articles (79% of which included data on children). Overall, the risk of major sequelae was highest for pneumococcal meningitis [24.7% (interquartile range 16.2–35.3%)] compared to meningococcal meningitis [7.2% (interquartile range 4.3–11.2%)] and Hib meningitis [9.5% (interquartile range 7.1–15.3%)]. Risk of major sequelae was approximately three times higher in African and southeast Asian regions compared to European regions. In addition, the risk of major sequelae was significantly higher in those under 5 compared to those over 5 years of age (Edmond et al. 2010). Ramakrishnan et al. reviewed data on children from 37 articles reporting from 21 African countries. Ten post-discharge studies found that 10% of children died following discharge from hospital after bacterial meningitis and that a quarter of survivors had neurological/psychological sequelae (Ramakrishnan et al. 2009). Chandran et al. reviewed 24 papers reporting on 1433 children with data available for long-term follow-up (greater than 5 years following meningitis). The majority of papers were published in North America, Europe and Australia. They found approximately half of the children had one or more long-term sequelae with the majority of these sequelae being behavioural or intellectual disorders, while hearing changes accounted for 6.7% of sequelae and gross neurological deficit accounted for 14.3% (Chandran et al. 2011).

Sensorineural hearing loss of a severe to profound degree has been found to occur in about 10% of children with meningitis (Pomeroy et al. 1990; Taylor et al. 1990; Baraff et al. 1993) and is bilateral in 4–5%. Hearing loss is thought to result from labyrinthitis, presumably due to extension of inflammation from the subarachnoid space through the cochlear aqueduct (Kaplan et al. 1981; Eavey et al. 1985). The risk of deafness is increased if the CSF glucose concentration on admission is less than 1.1 mmol/L (Dodge et al. 1984), if seizures occur before admission and if sterilisation of the CSF is delayed. Cefuroxime treatment is associated with delayed CSF sterilisation compared to ceftriaxone and this may have influenced early dexamethasone trials (Schaad et al. 1990; van de Beek et al. 2007). Deafness appears to set in early in the course of meningitis. However, it is difficult to detect clinically, therefore systematic assessment of hearing should be performed ideally before hospital discharge or within 4 weeks of being fit for testing (Vienny et al. 1984; Cohen et al. 1988; NICE 2010). Repeat examination is recommended after discharge if the results of the initial examination are abnormal. Early evoked responses may be transiently abnormal in approximately 20% of cases, with recovery in one or two months (Vienny et al. 1984). Children with severe or profound deafness should be referred for assessment for cochlear implants as soon as possible (NICE 2010; Bille and Ovesen 2014). The occurrence of deafness is not correlated to the age of the patient or the duration of illness before hospitalisation and is thus unlikely to be prevented by an early diagnosis. The use of dexamethasone treatment decreases the incidence of hearing loss (see Adjuvant and Supportive Treatment section). Ataxia may be of vestibular or cerebellar origin (Kaplan et al. 1981). Virtually all patients are able to compensate for balance deficits in a few weeks or months. A permanent seizure disorder is found in 2–5% of individuals (Pomeroy et al. 1990; Taylor et al. 1990; Baraff et al. 1993) and can be isolated but is often associated with learning difficulties and other neurological sequelae of variable severity.

Chronic hydrocephalus is another potential complication of acute childhood bacterial meningitis (Edmond et al. 2010). It can be either obstructive or communicating and is due to meningeal fibrosis of the basal cisterns or of the brain convexity or to stenosis of the aqueduct of Sylvius by granular ependymitis. Chronic hydrocephalus may follow early obstructive hydrocephalus. More commonly it develops insidiously and may not be recognised for weeks or months. Therefore systematic ultrasound examination of the CNS is indicated following neonatal meningitis, as ventricular dilatation may occur long before any increase in head circumference. Management is by an external drain in early cases, later by insertion of a shunt. Other neurological sequelae include hemiplegia, quadriplegia and limb impairments, and occur in 1–4% of individuals. Blindness following purulent meningitis is rare. It may be due to intraocular pathology, optic neuritis, or be of cortical origin.

PARTICULAR FORMS OF ACUTE BACTERIAL MENINGITIS

Neisseria Meningitidis (Meningococcus)

*N. meningitidis*, a Gram-negative diplococcus, is a relatively common cause of bacterial meningitis in Western countries, occurring predominantly in the winter months (European Centre for Disease Prevention and Control 2011) and with a primary peak incidence in the under-5s and a secondary peak in teenagers (CDC 2012b). Thirteen subtypes or serogroups have been identified, with six having potential to cause...
invasive disease (A, B, C, W, X, Y) (Harrison et al. 2013). Serogroup B, C and Y are the most common causes of invasive disease in Europe and North America (Control 2011; European Centre for Disease Prevention and Cohn et al. 2013). The incubation period is variable. Disease usually manifests in the first week after nasopharyngeal acquisition of a pathologial strain, but the incubation period can extend to several weeks (Devine et al. 1970; Edwards et al. 1977; Neal et al. 1999). Risk factors for younger children have been identified as preceding viral respiratory tract infection (Jensen et al. 2004; Jansen et al. 2008), mannose binding lectin deficiency (Hibberd et al. 1999), overcrowding (Moodley et al. 1999), lower socio-economic class and passive smoking (Stanwell-Smith et al. 1994). Risk factors for adolescents include preceding illness, kissing multiple partners, being a university student and preterm birth (Tully et al. 2006).

Nasopharyngeal carriage is a necessary precursor to invasive disease. The organism is carried in the nasopharynx asymptotically, and it is estimated that around 10% of the population carry N. meningitidis at any given time with a peak in carriage in older adolescence (Cartwright et al. 1987). The two main forms of meningococcal disease are meningococcal septicaemia and meningococcal meningitis, although a combination of both can occur (Thompson et al. 2006). Meningococcal bacteraemia without sepsis has been documented in children, sometimes referred to as ‘occult bacteraemia’ (Sullivan and LaScola 1987). Evolution of meningococcal infection from first symptoms to severe disease can be very rapid, over the course of hours. Early clinical signs of meningococcal disease in children are quite nonspecific and include leg pain, cold peripheries and abnormal skin colour. More classically described features of invasive meningococcal disease such as non-blanching rash, meningism and reduced consciousness occur later in disease course (Thompson et al. 2006). The rash can appear initially as a blanching erythematous rash similar to a viral exanthem; however, it can rapidly progress to become petechial or purpuric (Granier et al. 1998; Thompson et al. 2006), the most dramatic skin manifestation of meningococcal sepsis being purpura fulminans (see Fig. 11.1) (Darmstadt 1998). Bacteria can be identified from Gram staining of needle aspirates of skin lesions (Periappuram et al. 1995). Shock can be very severe requiring substantial fluid resuscitation and inotropic support. This can be exacerbated by adrenal insufficiency as a result of bilateral adrenal haemorrhage in fulminant disease (Migeon et al. 1967). Myocardial dysfunction is well documented and is in part brought about by negatively inotropic factors in serum such as IL6 (Pathan et al. 2004). Focal meningococcal infection of other sites including joints, eyes and heart may occur but are rare. Complications resulting from immune complex mediated disease are more common and can include arthritis, episceritis, pericarditis and vasculitis (Goedvolk et al. 2003).

Treatment is with antibiotics, usually a third generation cephalosporin as resistance rates are still relatively low, and supportive care including careful management of shock, myocardial insufficiency and raised intracranial pressure if present. In the United States, overall mortality from meningococcal meningitis is currently estimated at 5–18% while that of meningococcal sepsis is 5–20% (CDC 2012b). Deficiency in the terminal complement pathway, properdin or IgG 2 or 4 may predispose to invasive or recurrent meningococcal disease (Bass et al. 1983; Davis et al. 1983; Ross and Densen 1984; Nielsen et al. 1990) but screening for these in the absence of a preceding history of recurrent infection is unlikely to demonstrate an underlying immunodeficiency (Hoare et al. 2002). Meningitis associated with such complement deficiency is often mild and due to uncommon serogroups (Fijen et al. 1989). Host and microbial factors associated with a more severe disease course have recently been identified including meningococcal factor H binding protein variants (Piet et al. 2012) as well as variants of human complement factor H (Davila et al. 2010). Adjunctive treatment with activated protein C showed initial promise in the treatment of severe meningococcal disease. However, its use is currently not recommended as trials in children have failed to demonstrate efficacy (Nadel et al. 2007; NICE 2010).

The risk of developing the disease for household contacts is about 1000 times the endemic attack rate. Antibiotic prophylaxis is therefore recommended for household, day-care centre and nursery school contacts of a patient with meningococcal meningitis. Local guidance as to which antibiotic to use and duration of prophylaxis should be followed. Vaccines for most serotypes are now available (see Epidemiology section).

*S. pneumoniae* (Pneumococcus)

*S. pneumoniae*, a Gram-positive paired diplococcus, is one of the most common causes of invasive bacterial disease in children worldwide. In 2000 there were an estimated 103,000 cases of pneumococcal meningitis in children under 5 years of age globally with an overall case fatality rate of 59%. The case fatality rate varied from region to region with an estimate of 73% in Africa and 38% in Europe (O’Brien et al. 2009). Invasive pneumococcal disease is more common in winter months, in temperate climates, and has a bimodal age distribution, being found mainly in the very young and the elderly (European Centre for Disease Prevention and Control 2011). There are currently over 90 serotypes known, but most disease is caused by only a few serotypes with serotype frequency varying by clinical syndrome (Hausdorff et al. 2000) and geographical region (McIntosh and Reinert 2011; Weinberger et al. 2011). The pattern of serotypes causing invasive pneumococcal disease has been changing over the last decade as a result of the introduction of first 7-valent pneumococcal conjugate vaccine (covering seven serotypes) and then 13-valent pneumococcal conjugate vaccine (covering 13 serotypes) into the national schedules worldwide (McIntosh and Reinert 2011; Navarro Torne et al. 2014). The 13-valent pneumococcal conjugate vaccine covers 80–90% of invasive serotypes in developed countries, less in the developing world (McIntosh and Reinert 2011). The 23-valent pneumococcal polysaccharide vaccine covers even more serotypes. However, it has
suboptimal immunogenicity and efficacy in young children (Borrow et al. 2012).

Medical risk factors for invasive pneumococcal disease (and indications for additional pneumococcal vaccination) include CSF leak, cochlear implant, sickle cell disease, congenital or acquired asplenia or splenic dysfunction, human immunodeficiency virus (HIV) infection, nephrotic syndrome, some immunosuppressive chemotherapeutic agents and primary immunodeficiency (CDC 2010). Recently described rare autosomal recessive conditions resulting in deficiency of myeloid differentiation factor 88 (MyD88) and interleukin-1 receptor-associated kinase 4 (IRAK-4) have been shown to be particularly associated with severe recurrent invasive pneumococcal disease (including meningitis). These molecules are both involved in innate immune responses to bacterial pathogens (Picard et al. 2010).

Pneumococcal nasopharyngeal carriage is common in young children (Hendley et al. 1975) and is a prerequisite for invasive disease (Simell et al. 2012). Pneumococcal meningitis has a relatively high case fatality rate (European Centre for Disease Prevention and Control 2011) and more frequent/severe sequelae (Edmond et al. 2010) compared to other causes of meningitis. Hearing loss is more common in pneumococcal meningitis than other bacterial meningitis and this can be associated with ataxia (Koomen et al. 2003). Ischaemic stroke seems to be particularly associated with pneumococcal meningitis (Pryde et al. 2013). Diagnosis is made by either isolating the organism from blood or CSF, or from rapid antigen testing or PCR. A third generation cephalosporin is often adequate to treat pneumococcal meningitis. However, increasing incidence of antibiotic resistance in some regions has led to guidelines recommending addition of vancomycin in areas of high antibiotic resistance or following travel to one of these areas (see Epidemiology section).

Haemophilus Influenzae Type B

*H. influenza* is a small Gram-negative pleomorphic coccombacillus. It is either encapsulated or unencapsulated, with encapsulated strains being typeable. Encapsulated strains are classified into six types (a–f) (Musser et al. 1988). Over 90% of invasive disease was caused by type b in the pre-conjugate vaccine era. It is now a rare cause of meningitis and invasive disease in the developed world, thanks to the introduction of the type b conjugate vaccine (European Centre for Disease Prevention and Control 2011). The proportion of meningitis in children caused by non-type b encapsulated *H. influenzae* and non-encapsulated *H. influenzae* has subsequently increased in settings where vaccine has been introduced into national schedules (Ladhani et al. 2010; Ulanova and Tsang 2014; Van Eldere et al. 2014), but Hib is still common in those countries where vaccination is not available. The WHO estimates that in 2008, 203,000 deaths occurred in children under 5 years of age due to invasive Hib infection and that 42,100 of these deaths were due to meningitis (WHO 2012a). Hib meningitis is primarily a disease of infants and young children with approximately 60% of cases in children under 5 years of age occurring before the age of 12 months (WHO 2002).

Diagnosis is confirmed through isolation of the organism or by PCR. An extensive WHO review found the overall mean case fatality rate of Hib meningitis in children to be 13.8%. The mean case fatality rate in developing countries was 17.3%, whereas in industrialised countries it was 3.2% (WHO 2002). Sequelae occur in a substantial proportion of children (see Neurological Sequelae section), with a poorer outcome in more complicated cases. Subdural effusions can often complicate the disease but are of limited clinical significance (Snedeker et al. 1990). Hearing loss is one of the main complications; its incidence can be reduced with steroid therapy (NICE 2010). Treatment is with ceftriaxone or similar third generation cephalosporins as resistance is rarely reported. Prophylactic antibiotics for contacts of cases of invasive Hib disease are recommended as per local guidance.

Rarer Causes of Purulent Meningitis

There are many other more rare causes of purulent bacterial meningitis in children, infants and neonates. These frequently occur in the context of risk factors such as neurosurgery with insertion of foreign material (ventriculo-peritoneal or ventriculo-atrial shunt) or a congenital anatomical defect involving the CNS or primary/secondary immunodeficiency. *S. aureus* and *Staphylococcus epidermidis* are both possible organisms causing meningitis following neurosurgery. Outside the neonatal period, meningitis due to Gram-negative bacteria is unusual and should prompt investigation for underlying risk factors (Tebruegge and Curtis 2008). Meningitis due to anaerobic bacteria is rare and occurs predominately as a complication of respiratory tract infection e.g. sinusitis or shunt infections (Brook 2002). A list of possible causes of purulent meningitis is provided in Table 11.5, although this is by no means exhaustive. Treatment of meningitis due to these rare pathogens frequently needs to be tailored to the needs of the individual patient but may require prolonged courses of intravenous antibiotics.

RECURRENT BACTERIAL MENINGITIS

Recurrent bacterial meningitis in a child should lead to a thorough assessment for an underlying condition leading to susceptibility. Infection, organism, comorbidity and age at onset may provide a clue as to the reason for susceptibility; however, it may not immediately be obvious.

Recurrent bacterial meningitis can occur in children with an underlying dural fistula (congenital or acquired) facilitating infection of the nervous system, but can also occur in the context of congenital or acquired immunodeficiency (Table 11.6). Responsible pathogens include *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, *S. aureus*, *E. coli*, *Klebsiella* spp., *Proteus* spp.,...
Salmonella spp. The first three organisms are particularly associated with defects involving communication between the upper respiratory tract and the CNS. Recurrent pneumococcal meningitis can also be associated with a range of primary or secondary immuno-deficiencies. Recurrent meningococcal meningitis has been reported in association with complement deficiency. Gram-negative organisms are associated with lumbosacral defects, whereas Salmonella spp. are particularly associated with HIV infection (Lieb et al. 1996; Tebruegge and Curtis 2008).

A CSF leak occurs in approximately 2% of all head-injured patients. The majority of cases resolve spontaneously. They can persist, however, and cause recurrent meningitis. On occasion recurrent meningitis may be the presenting feature of an occult CSF leak from a past injury (sometimes after a number of years) (Friedman et al. 2000). Pneumococcus is the most commonly reported infecting organism (Lieb et al. 1996; Friedman et al. 2000; Tebruegge and Curtis 2008).

Non-traumatic fistulae (as listed in Table 11.6) may be difficult to detect through clinical examination alone. In the context of recurrent meningitis, detailed examination of the skin, especially the occipital and lumbosacral regions, is required along with thorough otological examination. High-resolution CT or MRI may be required, and ultimately CT or radionuclide cisternography may be required to pinpoint the exact location of a defect relating to recurrent meningitis (Tebruegge and Curtis 2008).

Initially, empiric therapy should be used directed against the most likely infecting organism. Following identification of the organism more directed therapy may be initiated. Prevention of recurrence depends upon the underlying risk factor with surgery being indicated for anatomical defects (Lieb et al. 1996). Antibiotic prophylaxis and vaccination against pneumococcus should be considered.

**BACTERIAL MENINGITIS IN NEWBORN INFANTS**

The range of organisms causing bacterial meningitis in the first few months of life is different from that for older children and adults. In developed countries, group B streptococcus and *E. coli* predominate as causative organisms, especially in the

### Table 11.6  Causes of recurrent bacterial meningitis in children

**Anatomical:**
- Cranial/cervical defects:
  - Meningocele/meningoencephalocele
  - Congenital skull defects (ethmoid, petrosal, sphenoid)
  - Dermoid cyst/epidermoid cyst/dermal sinus tract
  - Neurenteric cyst
  - Inner ear abnormality
  - Mondini dysplasia
  - Head injury/basal skull fracture

**Lumbosacral defects:**
- Meningocele
- Dermal sinus/dermoid cyst

**Immunodeficiency:**
- HIV
- Complement deficiency
- Agammaglobulinaemia
- IgG subclass deficiency
- Common variable immunodeficiency
- IRAK-4 deficiency
- Asplenism (congenital or acquired)

**Other**
- Chronic otitis media/mastoiditis

Adapted from Tebruegge and Curtis (2008).
first weeks after birth. Organisms discussed in the Peculiarities of Particular Forms of Acute Bacterial Meningitis section increase in frequency as the child ages.

There are few up-to-date thorough epidemiological investigations of neonatal meningitis. Three studies from the UK, however, have provided a relatively robust picture of neonatal meningitis in the developed world over the past three decades. The first summarised data on meningitis in children under 1 year of age from England and Wales over a 2-year period from 1985 to 1987. The incidence of meningitis was 0.32 per 1000 in the first month (0.22 per 1000 confirmed bacterial) and 1.6 per 1000 births in the first year. Case fatality rate was 19.8% for neonates and 5.4% for post-neonatal infants. Group B streptococcus (28%), E. coli (18%), and Listeria monocytogenes (5%) were the most frequently reported organisms in neonates, whereas H. influenzae (30%), pneumococcus (10%) and meningococcus (30%) were more common after 1 month of age. Meningitis due to group B streptococcus occurred up to 6 months of age and had a 25% mortality (de Louvois et al. 1991).

The second study summarised data from the same region during an 18-month period from 1996 to 1997 for all infants under 1 month of age. The incidence of meningitis was 0.39 per 1000 births (0.21 per 1000 confirmed bacterial). Meningitis was attributable to group B streptococcus in 25% of cases and to E. coli in 10% of cases. Overall case fatality rate was 6.6% (12% for group B streptococcus meningitis, 15% for E. coli). Complications due to ventriculitis, hydrocephalus, relapse or convulsions were reported in 26% of cases (Holt et al. 2001).

The third study summarised data from the UK and Ireland on meningitis in infants less than 90 days old, over a 13-month period from 2010 to 2011. The incidence of bacterial meningitis was 0.38 per 1000 live births (0.27 per 1000 for neonates). In culture confirmed bacterial meningitis in neonates, 58% were due to group B streptococcus, 15% E. coli, 6% S. pneumoniae, 5% L. monocytogenes. Incidence of N. meningitidis and S. pneumoniae increased with age, predominating after 3 months; however, group B streptococcus remained a relatively common pathogen. Overall case fatality rate was 7.6% and was higher for preterm and low birthweight infants and following pneumococcal meningitis (Okike et al. 2014a). All three studies found a higher incidence in infants with low birthweight and those with low gestational age (de Louvois et al. 1991; Holt et al. 2001; Okike et al. 2014a).

Taken together these three studies highlight that the pattern of causative organisms has not significantly changed in neonatal bacterial over the past 30 years in England and Wales. This is despite efforts to prevent group B streptococcus disease in particular through screening and the use of intrapartum antibiotics. Case fatality rates have improved, in particular for group B streptococcus; however, the incidence remains unacceptably high and long-term sequelae are often severe (see below). The finding of group B streptococcus and E. coli being the predominant organisms is in agreement with studies from the United States and elsewhere in Europe (Gaschignard et al. 2011; Thigpen et al. 2011). Other much less frequently isolated organisms in the neonatal period include Gram-negative organisms (Pseudomonas spp., Klebsiella spp., Enterobacter spp., H. influenzae, Citrobacter spp., Serratia spp.) and Gram-positive organisms (coagulase negative staphylococcus, S. aureus, Enterococcus faecalis, Streptococcus pyogenes, Streptococcus bovis) (de Louvois et al. 1991; Holt et al. 2001; Polin and Harris 2001; Gaschignard et al. 2011; Thigpen et al. 2011; Okike et al. 2014a). In the developing world, differences in the organisms causing bacterial meningitis in early life compared to older children and adults are also observed. However, the relative predominance of organisms such as group B streptococcus, E. coli, L. monocytogenes and pneumococcus varies according to geographical region. Mortality rates are much higher (40–58%) in these settings (Furyk et al. 2011).

Clinical diagnosis of meningitis in neonates can be challenging as neonates frequently present with nonspecific signs compared to older children and adults. Common presenting symptoms include temperature instability, irritability, poor feeding, seizures, respiratory distress, apnoeas and bulging fontanelle (Pong and Bradley 1999). The majority of these can be the presenting features of bacterial sepsis in general (although they are often seen together). Early-onset neonatal meningitis and sepsis share a number of common risk factors including: invasive group B streptococcus in a previous infant maternal group B streptococcus colonisation or bacteriuria, prelabour rupture of membranes, preterm birth following spontaneous labour, prolonged rupture of membranes in a preterm birth, intrapartum fever or chorioamnionitis, suspected/confirmed infection in another infant in multiple pregnancy (Polin and Harris 2001; NICE 2012). In view of the nonspecific clinical presentation, it is recommended that young infants should be fully assessed for sepsis and meningitis when presenting with these symptoms (including lumbar puncture except in one of the rare circumstances when it is contraindicated) and there should be a low threshold for commencing empiric antibiotic therapy while awaiting test results (especially in the context of existing risk factors for sepsis) (Galiza and Heath 2009; NICE 2012).

As discussed in the Laboratory Diagnosis section, the normal ranges for CSF parameters in the neonatal period differ from those in later infancy and childhood. Furthermore, these normal ranges are again different in the context of prematurity. Attempts have been made to provide reference ranges (Polin and Harris 2001; Srinivasan et al. 2012). However, in view of the potentially severe long-term sequelae, if the clinical picture is suggestive of invasive bacterial infection and the CSF values are approaching the upper limit of ‘normal’, it is prudent to recommend taking a cautious approach and to treat as for confirmed bacterial meningitis, irrespective of isolation of an organism. It is important to note that bacterial cultures can be positive even in the context of CSF findings within published reference ranges (Polin and Harris 2001; Galiza and Heath 2009; Srinivasan et al. 2012). Repeating a lumbar puncture 48–72 hours into antibiotic therapy is
recommended by some, in order to detect persistent culture positivity which may be indicative of antimicrobial resistance or complications such as empyema or abscess, although if there is good clinical recovery and the antibiotic choice is appropriate to the isolated organism this may not be necessary (Pong and Bradley 1999; Polin and Harris 2001; Heath et al. 2003; Galiza and Heath 2009; NICE 2010). Routine repeat lumbar puncture at the end of therapy is not currently recommended in uncomplicated cases (Heath et al. 2003; Tunkel et al. 2004; Galiza and Heath 2009; NICE 2010).

Likely organism, and hence choice of empiric antibiotics, varies with gestational age, birthweight, comorbidity and whether the infection is early or late onset, nosocomial or community-acquired. Choice of first-line empiric therapy for neonatal sepsis varies considerably between centres (Fernando et al. 2008; Lutsar et al. 2014). Ideally it should be guided by local patterns of microbial infection and prevalence of resistant organisms. In most settings, if meningitis is strongly suspected then a combination of third generation cephalosporin plus ampicillin/amoxicillin should provide adequate cover (Tunkel et al. 2004; Hoffman and Weber 2009; Brouwer et al. 2010; NICE 2010; van de Beek et al. 2012). Once an organism is isolated, antibiotic choice can be more targeted. The evidence base on which to base recommendations is small; however, it is generally recommended that group B streptococcus meningitis is treated with amoxicillin/ampicillin or penicillin plus an aminoglycoside or with a third generation cephalosporin for at least 14 days, *L. monocytogenes* should be treated with amoxicillin/ampicillin for 21 days plus gentamicin for at least the first 7 days and Gram-negative bacterial meningitis requires 21 days of a third generation cephalosporin. Information on *in vitro* sensitivity of isolated organisms can subsequently guide directed therapy.

If the index for suspicion is high for bacterial meningitis but no organism is isolated, then a 14 day course of a third generation cephalosporin plus amoxicillin/ampicillin should be adequate. Intraventricular antibiotics are not currently recommended (NICE 2010; van de Beek et al. 2012; Shah et al. 2012). No adjunctive therapy has so far been shown to improve outcome. Corticosteroids are not recommended for neonatal meningitis (Galiza and Heath 2009; NICE 2010). There are few recent trials of different treatment strategies in bacterial meningitis in early infancy and the neonatal period (Oeser et al. 2013). A trial is currently underway evaluating the efficacy, safety and pharmacokinetics of meropenem in this context (Neomero 1 and 2: NCT01551394, NCT01554124).

Imaging can be used to assess for complications of neonatal bacterial meningitis. MRI, CT and cranial ultrasound scan all have a role. Potential complications include cerebral oedema, infarction, raised intracranial pressure, hydrocephalus, ventriculitis, empyema and cerebral abscesses, the latter being particular associated with *Citrobacter* spp., *Serratia* spp. and *Proteus* spp. (Polin and Harris 2001; Jaremko et al. 2011; Schneider 2011) (Fig. 11.5). The pattern of abnormality can provide clues as to the likely infecting organism (Jaremko et al. 2011). Electroencephalogram (EEG) can be useful in the assessment of clinical and subclinical seizures and may be of prognostic value (ter Horst et al. 2010).

Outcomes following neonatal meningitis in the developed world are worse than those in older children. In a case series from the UK, the rate of severe disability following neonatal meningitis was around 23% overall and sequelae included cerebral palsy, epilepsy, hearing impairment and developmental delay (de Louvois et al. 2005). A study from the United States reporting outcomes in group B streptococcus meningitis found the incidence of sequelae (seizures,
hypertonicity, dysphagia) to be 22% among survivors (Levent et al. 2010). Outcomes are worse in Gram-negative bacterial meningitis with 61% of survivors having long-term sequelae (seizures, hydrocephalus, physical disability, developmental delay, hearing loss) (Unhanand et al. 1993). Neurodevelopmental outcomes for low weight or preterm infants are worse in those suffering severe bacterial infection including meningitis (Stoll et al. 2004).

Incidence and neurodevelopmental outcomes following neonatal bacterial meningitis have not improved significantly over the past 30 years. New strategies are required to prevent infection occurring. It is hoped that strategies including maternal vaccination, improved infection control practices and more effective strategies for chemoprophylaxis in at-risk pregnancies and infants will reduce the incidence of this potentially devastating disease in the coming years (Galiza and Heath 2009).

**SUBACUTE OR CHRONIC AND GRANULOMATOUS BACTERIAL MENINGITIS**

**Tuberculous Meningitis**

Tuberculosis is caused by infection due to *Mycobacterium tuberculosis* (*M. tuberculosis*). Over the past two decades, global incidence, prevalence and mortality from tuberculosis have been slowly falling. Estimating the burden of both latent and active tuberculosis infection in children is difficult as there are limitations in the performance of current diagnostic methods, with diagnosis often being presumptive. However, in 2012, WHO estimated that there were approximately 530,000 cases of tuberculosis in children and 74,000 deaths from the disorder in HIV-uninfected children worldwide. Multi-drug-resistant tuberculosis is increasingly reported, with an isolate from a child infected with tuberculosis being just as likely to be drug resistant as that from an adult (WHO 2013). In one region of South Africa, tuberculosis meningitis (TBM) is now the most common form of bacterial meningitis in children (Wolzak et al. 2012). In the UK in 2012, the reported rate of tuberculosis in children under 5 years was 4.1 per 100,000. From all ages, overall rates of drug resistant isolates have shown a gradual upward trend (PHE 2014a, b). In the United States during 2005–6, the estimated rate of tuberculosis in children under 5 years of age was 2.57 per 100,000 (Pang et al. 2014). Following exposure to tuberculosis infection, in the absence of preventive treatment, infants are particularly vulnerable to tuberculosis disease, especially disseminated disease (e.g. miliary tuberculosis and TBM). Examining reports from the pre-chemotherapy era, it is estimated that following primary infection, 30–40% of children under 1 year of age progress to pulmonary disease and 10–20% progress to miliary disease or TBM. TBM was present in 30% of children who presented with tuberculosis before 2 years of age (Marais et al. 2004). It is almost universally fatal if left untreated and even with current strategies, mortality is high and neurological outcomes severe, delays in recognition and treatment being associated with worse outcome (Chiang et al. 2014).

**Pathology and pathogenesis of tuberculous meningitis**

Most cases of mycobacterial meningitis are caused by *M. tuberculosis*. A small proportion is caused by zoonotic infection with *Mycobacterium bovis*, which may be associated with ingestion of unpasteurised milk (Durr et al. 2013). Occasional cases are due to atypical mycobacteria (Flor et al. 1996). Cases have been observed attributable to disseminated Bacillus Calmette-Guérin (BCG) infection following immunisation in immunodeficient children (Tan et al. 1997). Infection with rare or unusual mycobacterial species in children should be investigated for underlying immunodeficiency including specific genetic susceptibility defects such as those involving interferon gamma and IL12 receptor defects (Levin et al. 1995; Newport et al. 1996; Al-Muhsen and Casanova 2008; Haverkamp et al. 2014).

The majority of cases of TBM are preceded by a primary focus in the lung following inhalation of the acid-fast bacillus. Progression from this primary focus then occurs, with dissemination of bacilli through lymphatics and through haematogenous routes to distant sites. The exact pathogenesis has been recently debated. For many years a two-step model of TBM pathogenesis was presumed, involving initial haematogenous spread of bacilli to the brain or meninges with a tuberculous focus known as a ‘Rich focus’ then developing and subsequently discharging into the subarachnoid space followed by caseating necrosis. This process was proposed to be separate to that involved in miliary tuberculosis (Rich and McCordock 1933; Starke 1999; Donald et al. 2005; Thwaites et al. 2013). This proposal has recently been called into question and it is currently thought that it is more likely that miliary tuberculosis and TBM (at least in children) result from the same process of haematological dissemination followed by establishment of discharging foci of tuberculosis infection in tissues, potentially including the CNS with consequent TBM. The reason why some children develop miliary tuberculosis and others TBM is yet to be elucidated (Donald et al. 2005). Occasionally, infection can spread directly from sites close to the CNS including middle ear, vertebrae or skull (Starke 1999). In adults, a polymorphism in *TLR2* has been shown to be associated with development of TBM, highlighting the possible role of innate immunity in susceptibility to and/or control of disseminated infection (Thuong et al. 2007). A relationship between *M. tuberculosis* genotype and TBM phenotype, again in adults, has also been demonstrated (Thwaites et al. 2008). However, a study in children failed to show a relationship between genotype and TBM phenotype (albeit in a different ethnic population) (Marec et al. 2007).

The infection generates a cascade of inflammatory mediators, with secondary generation of a thick exudate that settles along the base of the brain (Fig. 11.6). This in turn induces a vasculitis with secondary thrombosis of adjacent arteries and veins, resulting in embolisation and infarction, particularly in the small lenticulostriate vessels supplying the basal
ganglia, as well as in the cerebral cortex, pons and cerebellum (Poltera 1977; Starke 1999; Rock et al. 2008). Over time, the exudate fills the basal cisterns, resulting in entrapment of cranial nerves and blockage of CSF drainage pathways resulting in secondary hydrocephalus (communicating or obstructive). Rich foci can enlarge to form CNS tuberculomata (Wallace et al. 1991; Buonsenso et al. 2010) or tuberculous abscesses (du Plessis et al. 2007; Buonsenso et al. 2010). Tuberculoculous encephalopathy has previously been described associated with diffuse, predominately white matter brain injury, possibly as a result of a post or para-infectious allergic encephalitis (Dastur 1986). However, the existence of tuberculoculous encephalopathy has recently been debated (Lammie et al. 2007; Kim et al. 2011). More recent reviews of the wider literature suggest that cases previously grouped together as tuberculoculous encephalopathy may be heterogeneous in nature and that tuberculosis may be an uncommon cause of disorders such as acute disseminated encephalomyelitis (ADEM) and acute haemorrhagic leucoencephalopathy, rather than a cause of a distinct entity of tuberculoculous encephalopathy (Lammie et al. 2007).

**Vaccination**

The efficacy of BCG vaccine is highly variable, depending on age, vaccine efficacy endpoint and geographical location. A recent systematic review has looked at this in detail (Mangtani et al. 2014). Protection against pulmonary disease is variable, protection being greatest when vaccine was administered in infancy or childhood. The vaccine is more effective in settings further from the equator. Protection against TBM and miliary tuberculosis (approximately 85% efficacy) was confirmed especially in neonates and in children when stringent tuberculin testing was employed (to exclude existing tuberculosis infection) (Mangtani et al. 2014). Novel vaccination strategies are currently being investigated including strategies to boost the existing response to BCG (with viral vectored or protein adjuvant boosting) or to replace BCG (priming vaccines) (Mangtani et al. 2014).

**Clinical manifestations of tuberculoculous meningitis**

The clinical manifestations of TBM are extremely variable (Table 11.7) (Idris et al. 1976) so that the diagnosis may be very difficult. Virtually any neurological picture can be seen. TBM usually progresses over three successive stages, which if untreated results in death in 3–4 weeks. The nature of these stages is influenced by the age of the child. They have been defined by the UK Medical Research Council (MRC 1948; Starke 1999). All stages may involve fever. Stage 1 is characterised by personality change, listlessness, irritability and loss of appetite. Stage 2 involves progression to development of neurological signs and signs of raised intracranial pressure including drowsiness, neck stiffness, cranial nerve palsies, vomiting,
focal or generalised convulsions. In younger infants, stage 2 may involve increasing head circumference and bulging fontanelle. Hemiplegia and movement disorders due to involvement of the basal ganglia are often observed (Gelabert and Castro-Gago 1988). Stage 3 involves progression to severe neurological deficits including coma (MRC 1948). Tuberculoma or tuberculous abscess presents as space-occupying lesions with accompanying neurological signs depending on location, with tuberculoma abscess often having a more acute presentation than a tuberculoma (Kumar et al. 2002). Clinical features that have been shown to distinguish TBM from other forms of meningoitis in children include duration of symptoms greater than 6 days, abnormal movements and focal neurological deficits (Kumar et al. 1999).

Atypical manifestations are common. Focal neurological deficits preceding the classic meningeal irritation have been reported and include field defects, aphasia, hemiparesis, monoparesis and abnormal movements. These may be associated with cerebral infarction (Starke 1999). Isolated high fever, severe convulsions and features mimicking intracranial tumours may be observed (Udani and Bhat 1974). Tuberculosis may also affect the spinal cord, manifest as fever and meningeal signs rapidly followed by paraplegia (du Plessis et al. 2008).

**Diagnosis of Tuberculous Meningitis**

The diagnosis classically rests on a history of exposure to persons with pulmonary tuberculosis, a positive tuberculin skin test or interferon gamma release assay (IGRA; see below) in association with a compatible clinical picture, chest X-ray changes, a CSF with lymphocytosis and elevated protein, and neuroimaging revealing the classic triad of infarction, hydrocephalus and basal enhancement. However, in practice diagnosis in children is often extremely difficult.

Microscopy of CSF samples may allow detection of mycobacteria and confirm a diagnosis; however, in view of the paucibacillary nature of *M. tuberculosis*, especially in children, the diagnostic yield is low (Yaramis et al. 1998). Sensitivity can be increased through obtaining larger volumes of CSF; spending more time on microscopy (Thwaites et al. 2004) and CSF centrifugation (Stewart 1953). A modified Ziehl–Neelson staining method including a cytospin step has recently been shown to increase the sensitivity of CSF microscopy and allows clearer visualisation of the intracellular mycobacterium (Chen et al. 2012). Fluorescence staining has been shown to increase sensitivity in sputum and samples from other extrapulmonary sites (Steingart et al. 2006; Kumar and Chandra 2008) although direct evidence of its additional benefit in CSF samples is currently lacking.

Typical findings in CSF are raised protein, CSF pleocytosis with lymphocyte predominance, low glucose and raised opening pressure. Atypical findings are relatively common in children and these parameters should always be interpreted in the context of clinical history, examination findings and imaging (Starke 1999; Thwaites and Tran 2005; van Well et al. 2009). The sensitivity of tuberculosis culture of CSF in children with TBM is lower than that in adults (Yaramis et al. 1998; Starke 1999; van Well et al. 2009). Sensitivity can be increased by culturing centrifugation deposits from larger volumes of CSF; however, this is not always feasible in children (Thwaites et al. 2004). Culture times are prolonged and involve the use of both liquid and solid culture media. Mycobacterial growth indicator tubes (MGIT) can result in decreased time to detection of positive tuberculosis cultures. Microscopic observation of drug susceptibility (MODS) is a culture technique using liquid culture medium that has been demonstrated to also result in faster detection of positive cultures in adult TBM (Caws et al. 2007) and is a sensitive and more rapid technique for diagnosis of TBM in children (Tran et al. 2013). Culture from sites other than CSF, including sputum, gastric washings, bone marrow aspirate, lymph node biopsy, can also be of use in diagnosing CNS disease (Doerr et al. 1995; van Well et al. 2009).

Various non-culture techniques for detection of the presence to *M. tuberculosis* and to assess drug resistance are now available. Nucleic acid amplification tests have been shown to have a wide range of sensitivities and specificities (Pai et al. 2003) and therefore cannot be used to rule out TBM but their rapid turnaround times can be useful in rapid diagnosis of TBM (Marais and Pai 2007). Xpert MTB/RIF (Cepheid, CA, United States) is an automated nucleic acid amplification test based on real-time PCR which is increasingly being used across the globe for detection of *M. tuberculosis* and rifampicin resistance (a surrogate of multidrug resistance) in a range of clinical specimens. A study in adult patients found Xpert MTB/RIF to have a sensitivity of 59% and a specificity of 99% for diagnosis of TBM if large volumes of CSF were used (Nhu et al. 2014). A study in children comparing Xpert MTB/RIF and GenoType MTBDR plus showed a sensitivity of 33% and 26% respectively for detection of tuberculosis infection in CSF samples. Sensitivity of both assays used together in combination with culture resulted in a sensitivity of 56% with 98% specificity (Solomons et al. 2015). Measurements of adenosine deaminase and interferon gamma in CSF samples have shown some promise in distinguishing TBM from other forms of meningitis but have not yet entered widespread clinical practice (Mishra et al. 1996; Juan et al. 2006; Gupta et al. 2010a; Tuon et al. 2010).

The tuberculin skin test (Mantoux) is often negative in the context of active tuberculosis disease and interpretation may also be complicated by a history of BCG vaccination. Interferon gamma release assays (IGRA) are an in vitro method by which production of interferon gamma by lymphocytes is measured in response to stimulation with antigens that are more specific to *M. tuberculosis* than those used in the tuberculin skin test. They have good sensitivity and specificity for detection of latent tuberculosis infection in adults; however, their utility compared to tuberculin skin test in children in various contexts is controversial. A negative test should not be used to rule out active tuberculosis infection in children and they cannot be used to differentiate between latent infection and active disease (Machingaidze et al. 2011; Sollai et al. 2014). Attempts have been made to perform IGRA directly...
on CSF samples (Park et al. 2012), but the higher volumes of CSF that may be needed to achieve adequate sensitivity may reduce the potential utility of this technique in pediatric samples. The search for novel biomarkers to help diagnose tuberculosis infection and to distinguish latent tuberculosis infection from disease is ongoing (Maertzdorf et al. 2012) and results of studies investigating RNA transcriptome in whole blood, for example (Anderson et al. 2014), show promise.

CT and MRI are not essential but can be a very useful adjunct in the diagnosis and assessment of TBM. Characteristic findings that support a diagnosis of TBM include the presence of hydrocephalus (present in approximately 80% of children), basal meningeal enhancement (present in approximately 75% of children), infarctions, tuberculomata and pre-contrast basal hyper-density (Wallace et al. 1991; Andronikou et al. 2004; Marais et al. 2010) (Fig. 11.7a). MRI may be more sensitive and accurate in detecting changes associated with TBM including basal meningeal enhancement and infarctions (Pienaar et al. 2009). Diffusion-weighted imaging has confirmed that areas of ischaemia and necrosis in the brain stem (van der Merwe et al. 2009) and border-zones (Omar et al. 2011) are relatively common in children with TBM. MRI has also been used to demonstrate that a miliary pattern of leptomeningeal infection is present in a high proportion of children with TBM (Janse van Rensburg et al. 2008) (Fig. 11.7b). Magnetic resonance angiogram (MRA) can also be of use in assessing the extent of vascular involvement. A study involving adults and children with TBM found abnormalities on MRA in half of patients, with around 60% of patients having corresponding infarctions (Kalita et al. 2012).
