Tuberculomata or tuberculosis abscesses may be present in isolation or in addition to TBM and have characteristic findings on CT and MRI depending on the stage in their development at which imaging is performed (Wallace et al. 1991; Bernaerts et al. 2003; du Plessis et al. 2007). A tuberculoma appears on CT or MRI as a round mass, sometimes with a necrotic, clear centre (ring lesion). They may be polycystic in contour and behave as space-occupying lesions (Fig. 11.7). Calcification is common (Wallace et al. 1991; Bernaerts et al. 2003).

In view of the difficulties in diagnosing TBM, and in an effort to standardise disease definitions, diagnostic criteria for possible, probable and definite TBM have been proposed. This involves scoring of a number of clinical, CSF and imaging criteria which are totalled giving a cumulative score which is indicative of the likelihood of M. tuberculosis being the cause of a case of meningitis (Marais et al. 2010).

**Differential diagnosis of tuberculous meningitis**

The differential diagnosis of TBM includes a large part of the neurological pathology of childhood, in particular other lymphocytic meningitides and aseptic meningitis (see Table 11.3). Neoplastic meningitis that occurs in cases of metastatic tumours, especially germinomas, ependymomas, choroid plexus tumours, medulloblastomas and sarcomas, may mimic TBM. Partially treated bacterial meningitis may share many of the clinical features of TBM and result in similar laboratory test results. In cases where doubt exists, antituberculous drug treatment should be started and discontinued later, once an alternative diagnosis has been confirmed and tuberculosis has been excluded.

**Treatment of tuberculous meningitis**

National and international guidelines vary in terms of recommended first-line antituberculous medication combinations, duration of treatment, guidance on the use of adjunctive steroid
therapy and duration of treatment. Robust randomised controlled trial evidence to guide best practice is sparse. In general recommended treatment involves an initial short course of four antibiotics (isoniazid, rifampicin, pyrazinamide, ethambutol) for 2 months followed by an extended course of a combination of two drugs (isoniazid, rifampicin) to complete a year of therapy (WHO 2006, 2010b; Thwaites et al. 2009; NICE 2011; AAP 2012). Ethambutol can produce optic neuritis (Donald et al. 2006), so visual acuity should be monitored. Isoniazid can induce a peripheral neuropathy, and can be prevented by the administration of pyridoxine (though guidelines again vary on which groups require prophylactic pyridoxine (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; NICE 2011; AAP 2012). Some authors currently recommend 6 months of a four-drug combination including ethionamide in place of ethambutol in view of better CSF penetration of ethionamide (Moore et al. 2009; Thwaites et al. 2013). All of the major guidelines recommend use of steroids (prednisolone or dexamethasone) in the first month of therapy followed by a reducing dose over the following 2–4 weeks (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; NICE 2011; AAP 2012). Recommended dosing of antituberculous drugs also varies between guidelines with suggested regimens aiming at optimum drug concentrations in CSF (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; Donald 2010; NICE 2011; AAP 2012; Principi and Esposito 2012). Some authors currently recommend 6 months of a four-drug combination including ethionamide in place of ethambutol in view of better CSF penetration of ethionamide (Moore et al. 2009; Thwaites et al. 2013). All of the major guidelines recommend use of steroids (prednisolone or dexamethasone) in the first month of therapy followed by a reducing dose over the following 2–4 weeks (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; NICE 2011; AAP 2012).Recommended dosing of antituberculous drugs also varies between guidelines with suggested regimens aiming at optimum drug concentrations in CSF (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; Donald 2010; NICE 2011; AAP 2012; Principi and Esposito 2012). Second-line drugs that can be used in the context of suspected or confirmed resistant tuberculosis infection or when the oral route of administration is not possible include cycloserine, streptomycin, amikacin, moxifloxacin and levofloxacin (WHO 2006, 2010b; Moore et al. 2009; Thwaites et al. 2009; NICE 2011; AAP 2012; Principi and Esposito 2012). Resistance to any of these antibiotics can develop when they are given alone, and administration of several drugs simultaneously largely prevents the emergence of resistant strains (Iseman 1993). With the increasing emergence of multi-drug-resistant TB, determination of the sensitivity of the organism, if cultured, should be obtained where possible and treatment adjusted accordingly. When this information is not available, resistance information from an isolate studied in an index case can help guide empirical treatment decisions. The management of suspected or confirmed drug-resistant TBM in children is complex. Guidance on strategies for management of these cases is available, and is ideally provided by clinicians with experience in the issues involved in the use of second-line drugs in children, specifically relating to toxicities, dosing and CSF penetration (Donald 2010; Thwaites et al. 2013; Schaaf et al. 2014). Adjunctive treatment with thalidomide has demonstrated some benefit (Schoeman et al. 2006) but requires further study before recommendations can be made for routine clinical use (Buonsenso et al. 2010).

Indications for surgical treatment include hydrocephalus, or tuberculous abscess (Rock et al. 2008; Thwaites et al. 2013). Hydrocephalus is common in children especially in later stages of the disease. It can be communicating or non-communicating. Communicating hydrocephalus can often be successfully treated medically [e.g. with furosemide and acetazolamide (Schoeman et al. 2000)]. If medical treatment fails or in non-communicating hydrocephalus, ventriculoperitoneal shunting is indicated (Lamprecht et al. 2001). Tuberculomata very rarely require surgical management with current medical therapies. Tuberculous abscesses more frequently require surgery ranging from simple aspiration to total excision (Kumar et al. 2002).**

**Prognosis of Tuberculous Meningitis**
TBM in children has very poor outcomes. A systematic review and meta-analysis has compiled data on treatment outcomes.
in children with TBM between 1952 and 2012. Information on outcomes for 1636 children was analysed. Risk of death was 19.3% (95% confidence intervals 14.0–26.1) and probability of survival without neurological sequelae was 36.7% (95% confidence intervals 27.9–46.4). Risk of neurological sequelae in survivors was 53.9% (95% confidence intervals 42.6–64.9). Outcomes were poorer in TBM diagnosed in stage 3 disease than in earlier stages (Chiang et al. 2014). Multi-drug-resistant TBM is also associated with worse outcomes than fully sensitive tuberculosis (Seddon et al. 2012). Neurodevelopmental outcomes have been shown to correlate with the distribution and extent of cerebral infarction, bilateral basal ganglia infarction having a particularly poor prognosis (Springer et al. 2009).

**CHRONIC MENINGITIS**

Chronic meningitis is a syndrome characterised by various combinations of fever, headache, lethargy, confusion, neck stiffness and vomiting, along with CSF pleocytosis and elevated protein that fails to improve over four weeks (Tan 2003). The main causes of this syndrome are infective and are shown in Table 11.3, but there is a wide differential and noninfec-
tious aetiology should always be considered (Ginsberg and Kidd 2008). A careful travel and exposure history as well as examination in important in identifying the aetiologi-
al agent and should guide focused, step-wise investigation (Ssyed et al. 2009). Some of the causes of chronic lymphocytic men-
ingitis is described in the next sections. They include condi-
tions such as Lyme disease, neurobrucellosis and *Cryptococcus neoformans* meningitis. Chronic polymorphonuclear pleocytosis may be caused by infectious agents such as *Nocardia* spp. and *Actinomyces* spp., and a number of fungi (Peacock et al. 1984).

**INTRACRANIAL ABSCESS AND EMPYEMA**

**Cerebral Abscess**

Brain abscess is an uncommon but life-threatening condition in children. Any age can be affected. A recent case series of 118 children over 10 years from the UK reported a bimodal age distribution with most cases occurring in children under 2 years, or aged between 9 and 15 years (Felsenstein et al. 2013). Other case series have shown a similar age distribution (Wong et al. 1989) or a peak in early teenage years (Leotta et al. 2005). The responsible organisms gain access to the brain most commonly via the haematogenous route from a distant focus or by direct extension from a nearby focus such as otitis media, dental infection, mastoiditis or sinusitis, or a septic thrombo-
phlebitis of bridging veins. Abscesses can also complicate men-
ingitis. One major predisposing factor in children is cyanotic congenital heart disease, although this seems to be a less prom-
inent factor in more recent years (Goodkin et al. 2004; Leotta et al. 2005; Shachor-Meyouhas et al. 2010; Cole et al. 2012; Felsenstein et al. 2013). Abscesses that result from bacteraemia are often multiple, and are often found in the distribution of the middle cerebral artery and at the border between white and grey matter (Bakshi et al. 1999; Yogev and Bar-Meir 2004). Abscesses secondary to focal infections arise at adjacent sites through direct invasion (e.g. frontal, temporal, cerebellar) (Saez-Llorens 2003). Brainstem abscesses are uncommon.

A microbiological diagnosis may be achieved through direct culture or PCR from the abscess site or from culture of CSF, blood, or adjacent sites (e.g. mastoid, sinus). The most common causal organisms are streptococci (especially *Strepto-
coccus anginosus* group). A wide range of other organisms are implicated including *H. influenzae*, *S. pneumoniae*, *S. aureus, Enterococcus* spp. and *Enterobacter* spp. Mixed growth is com-
mon. *Citrobacter* spp. are associated with abscesses during the neonatal period (Chowdhyr and Cohen 2012). Anaerobes are involved in a minority of cases, but the possibility of anaerobic infection should guide empiric antibiotic therapy (Goodkin et al. 2004; Leotta et al. 2005; Shachor-Meyouhas et al. 2010; Cole et al. 2012; Felsenstein et al. 2013). A similar range of organisms is found in the context of immunodeficiency with the addition of opportunistic infections including fungi, *Toxoplasma gondii* and *Nocardia* spp. (Chow et al. 2005; Alsultan et al. 2006; Yoegle et al. 2013).

The initial stage of an abscess is septic encephalitis or cereb-
ritis, which consists of an oedematous area with softening and congestion of the brain. Neutrophils accumulate, and microg-
lial and astrocyte activation is evident with the elaboration of numerous pro-inflammatory cytokines (Kielian 2004). Over time, the centre becomes liquefied thus forming the abscess cavity, while a wall develops, initially thin, and then becoming a thick, firm capsule. Initially composed of inflammatory granul-
tissue, the capsule becomes fibrous. Marked oedema surrounds the abscess and is responsible in part for the high ICP that is prominent in cases of brain abscess (Frazier et al. 2008).

**CLINICAL MANIFESTATIONS OF CEREBRAL ABSCESS**

The clinical manifestations of brain abscess depend on a number of factors including age of child, virulence of infect-
ing organism, presence of immunodeficiency, site of abscess, source of infection and speed of progression. Symptoms are frequently nonspecific in the early stages of the disease. Head-
ache, fever, decreased consciousness, seizures and focal neuro-
logical signs are relatively common presenting features. Neck stiffness and cranial nerve signs are less common. Infants may present with increasing head circumference (Wong et al. 1989; Leotta et al. 2005; Shachor-Meyouhas et al. 2010; Felsenstein et al. 2013).

**DIAGNOSIS OF CEREBRAL ABSCESS**

Blood cultures are frequently negative (Saez-Llorens 2003; Yogev and Bar-Meir 2004; Frazier et al. 2008; Cole et al. 2012) and inflammatory markers are not always raised (Frazier et al. 2008; Cole et al. 2012). Lumbar puncture is often contra-
indicated due to clinical presentation; however, if done it
reveals nonspecific changes such as pleocytosis, raised protein and low glucose (Wong et al. 1989; Tattevin et al. 2003; Frazier et al. 2008). The diagnosis of brain abscess is confirmed on neuroimaging (Fig. 11.9). Bacterial culture of samples obtained during surgical intervention can increase the chances of identifying causative organisms, although these samples may also be culture negative. Broad-range bacterial PCR (16S ribosomal) can aid in identification of organisms from culture negative samples (Al Masalma et al. 2009).

Cranial ultrasound may be useful in the neonatal period. MRI is superior to CT and is considered the preferred imaging technique. At the initial stage, neuroimaging may show only localised ill-defined hypodensity with a mass effect. Later, a rim of contrast enhancement appears and becomes thicker with the passing of time. MRI at this stage classically reveals a round mass with strong peripheral contrast enhancement and surrounding vasogenic oedema. The capsule may be hyperintense on T1 and hypo-intense on T2-weighted images. Multiple abscesses and multilocular abscesses can be visualised. Differential diagnosis includes cavitated brain tumours, tuberculosis, focal ischaemic lesions, intracerebral cysts and Schilder disease (see Chapter 10). Diffusion-weighted MRI is a useful technique for differentiating abscess from neoplasm (Frazier et al. 2008; Nickerson et al. 2012). CT and MRI may also reveal sinus or mastoid pathology as a focus of infection. The EEG may be useful as it shows a good correlation between the location of the abscess and that of a focus of slow delta waves (Vignadndra et al. 1975).

**MANAGEMENT OF CEREBRAL ABSCESS**

There are no randomised trials of management (surgical or medical). Treatment is therefore currently based on historical case series and expert opinion. Broad spectrum antibiotic therapy is the mainstay of treatment for the majority of brain abscesses, and alone can achieve complete resolution of the abscess if commenced early (although this is possible in a minority of cases). Surgical intervention is commonly indicated. Techniques such as stereotactic aspiration, craniotomy and endoscopic drainage may be used. Third generation cephalosporins and additional anaerobic cover with metronidazole are currently recommended for empirical treatment (with vancomycin added in cases following trauma or surgery). In all cases where an organism has not been isolated from either blood or other fluids (e.g. pus from sinuses/mastoid) a diagnostic aspiration through a burr hole using CT- or MRI-guided stereotactic aspiration is recommended. Subsequent therapy is guided by antibiotic sensitivity. Antibiotics should be maintained for at least 4–6 weeks and the patients carefully monitored by repeated imaging. Follow-up scans often continue to demonstrate ring enhancement for several weeks, with or without surgical puncture. Disappearance of the capsule on CT should be verified. If antibiotic therapy is not rapidly effective, or pressure effects are causing significant concerns, again surgical drainage by tapping through a burr hole should be performed. Removal of the capsule is not generally advised and is limited to patients in whom a residual cavity or large persistent hyper-intensity is present on late scans (Saez-Llorens 2003; Yogev and Bar-Meir 2004; Frazier et al. 2008; Shachor-Meyouhas et al. 2010; Cole et al. 2012; Felsenstein et al. 2013).

**SEQUELAE OF CEREBRAL ABSCESS**

Mortality rate of brain abscess in children is currently much lower than in early case series (Brouwer et al. 2014), ranging from 3.7–10% in recent case series (Leotta et al. 2005; Shachor-Meyouhas et al. 2010; Felsenstein et al. 2013). Mortality is higher in immunodeficient children (Felsenstein et al. 2013). Neurological sequelae are relatively common including seizures, motor deficits and hydrocephalus. In case series including children and adults, approximately 70% of patients with brain abscess have no or minimal neurological sequelae (Goodkin et al. 2004; Leotta et al. 2005; Frazier et al. 2008; Felsenstein et al. 2013; Brouwer et al. 2014). Younger age and GCS ≤ 8 at presentation are associated with a worse outcome (Felsenstein et al. 2013). Neonatal abscesses are generally associated with a poor outcome, with neurological deficits being present in over two-thirds of the patients and residual epilepsy in over half the cases (Renier et al. 1988).

**Subdural Empyema**

Subdural empyema is an infectious collection of fluid accumulating between the dura and arachnoid, and most commonly occurs as a result of direct spread from sinuses (in
Epidural Abscess

Epidural abscesses can affect the head and the spinal canal. Spinal epidural abscesses are uncommon and result from either haematogenous spread of bacteria from distant sites of infection, direct spread from adjacent sites or are iatrogenic following an invasive procedure. Infection is most frequently localised to the dorsal aspect of the cord. Although *Staphylococcus aureus* is by far the predominant causal organism, more unusual organisms and opportunistic infectious agents such as fungi and atypical mycobacteria may be isolated in individuals with comorbidity or underlying risk factors such as immunosuppression. Backache is the first manifestation, followed by neurological symptoms such as radicular pain and symptoms of spinal cord compression (Pradilla et al. 2009, 2010; Hawkins and Bolton 2013). The presenting symptoms and signs may be indistinguishable from those of transverse myelitis. Gadolinium-enhanced MRI is currently the investigation of choice for diagnosis. Lesions appear iso- or hypo-intense on T1 weighted images and hyperintense on T2 weighted images (Pradilla et al. 2009, 2010; Nickerson et al. 2012).

Owing to the rarity of this condition, there are no randomised trials to guide treatment practices. Ideally, blood cultures and samples from the site of infection should be obtained prior to commencing empiric antibiotic therapy. Antibiotics should provide broad Gram-positive and Gram-negative cover initially and then be tailored, once the causative organism is isolated and its antibiotic sensitivity is known. Management depends on whether there is evidence of cord compression. If there is no evidence of cord compression, surgery can be avoided and the abscess can be managed conservatively with 4–6 weeks of appropriate intravenous antibiotic therapy. If there is any evidence of cord compression, or a large loculated abscess is present, then urgent surgery is required. Medical management alone may also be appropriate in cases where there is a high risk of complications following surgery, for example in those with complete paresis for longer than 72 hours or those with extensive infection covering many spinal levels (Pradilla et al. 2009, 2010; Hawkins and Bolton 2013).

Intracranial epidural abscesses are also rare and most commonly result from direct spread of infection from sinuses. Symptoms may include fever, headache, nausea and vomiting. Infection can be polymicrobial including Gram-positive and negative, anaerobic and aerobic organisms and can co-exist with osteomyelitis. Empiric antibiotics should therefore provide cover for these organisms. MRI is the investigation of choice, showing a collection that is iso-intense to underlying brain parenchyma on T1 sequences and hyperintense on T2 with restricted diffusion on diffusion-weighted imaging (Pradilla et al. 2009; Nickerson et al. 2012; Nicoli and Makite 2014) (Fig. 11.10). Management includes a prolonged course of antibiotics (6 weeks minimum) and surgical drainage is often necessary (Pradilla et al. 2009).
Intramédullary Abscess

Intramédullary abscess is a rare condition resulting from either haematogenous spread or more commonly through a pre-existing congenital defect in the spinal cord. A review of all reported paediatric intramedullary abscesses noted that 89% of children presented with neurological deficits (paralysis, paraesthesiae, incontinence) (Simon et al. 2003). The diagnosis is best made with MRI, and organisms are varied, with *Staphylococcus* spp., *S. pneumoniae* and other *Streptococcus* spp., *E. coli* and *Proteus* spp. accounting for the majority (Morandi et al. 1999; Simon et al. 2003). Of the cases reported by Simon et al., 55% had single organisms, 17% mixed, and 28% were sterile (prior antibiotic therapy accounted for some of these). Treatment was surgical decompression followed by antibiotic therapy for, on average, 4–6 weeks. Mortality of these patients was 28% were sterile (Brown et al. 2001). Follow-up should include plain radiographs at regular intervals for 12–18 months to ensure resolution of the destructive process (Early et al. 2003).

Infection and Inflammation of the Vertebrae and Disc Space

Vertebral osteomyelitis is often associated with a limp or other walking difficulty (Fernandez et al. 2000). Neurological complications occur in approximately 12% of patients (Fuchs et al. 2012). Discitis is an imperfectly understood condition which tends to affect younger children more than vertebral osteomyelitis. It can occur in the thoracic, lumbar or sacral spine, but is most common in the lumbar region in children under 5 years of age. Blood cultures may be positive but often these are organisms associated with ‘contaminated’ blood cultures; in many cases no organism is found and the infectious nature is not certain. Depending on the age of the child, presentation is variable, with the child either refusing to weight-bear or presenting with back, hip or abdominal pain (Fernandez et al. 2000). On examination, flexion of the spine may be limited with loss of lumbar lordosis. X-rays of the spine show narrowing of the disk-space in 80% of cases (Jansen et al. 1993). Radionuclide uptake is increased at the level of the lesion. The condition should be distinguished from vertebral tuberculosis (Pott’s disease). Most children improve with a 4–6-week course of antibiotics. Biopsy of the infected disc space is reserved for children refractory to antibiotics as cultures are usually sterile (Brown et al. 2001). Follow-up should include plain radiographs at regular intervals for 12–18 months to ensure resolution of the destructive process (Early et al. 2003).

Nonsuppurative Bacterial Infections

Syphilis

Congenital syphilis is by far the most common form of the disease in children, with acquired syphilitic meningitis being rare but nonetheless important to diagnose because of the effectiveness of therapy. Syphilis is caused by the spirochaete *Treponema pallidum*, which has the ability to invade the CNS in early and late forms of the disease and produce protein neurological manifestations. Congenital syphilis can be divided into early (under 2 years of age) and late infection. Neurological involvement is observed in approximately 20% of cases of early congenital syphilis. Neurosyphilis without neurological signs or symptoms (asymptomatic neurosyphilis) can occur and is common in children with other physical signs of congenital syphilis. Asymptomatic neurosyphilis can be diagnosed in a patient with clinical evidence of syphilis, CSF abnormalities of pleocytosis and reactive tests but no neurological signs. CNS infection can be present with normal CSF findings. Two possible forms of early neurosyphilis are observed (with some overlap): the first being acute syphilitic leptomenigitis, with classic signs of meningitis including vomiting and bulging fontanelle, and the second, chronic meningovascular neurosyphilis, presenting later in the first year of life with hydrocephalus, cranial nerve palsies and developmental regression. Ocular findings may include chorioretinitis, glaucoma and uveitis (Woods 2005).

Up to one-third of children with late congenital syphilis have asymptomatic neurosyphilis. Symptomatic neurosyphilis occurs rarely and is associated with VIIth nerve deafness, tabes dorsalis, neurovascular lesions and/or juvenile paresis (Chakraborty and Luck 2008). Juvenile paresis is characterised by altered consciousness as the initial symptom. Neurological signs set in later and include spasticity in half the cases and cerebellar signs in a quarter. Seizures occur in 30% of cases and optic atrophy in 10–15%. Deafness and multiple cranial nerve deficits may be present. Juvenile paresis should be distinguished from the much more frequent progressive metabolic or degenerative diseases.

Congenital neurosyphilis is diagnosed on the basis of a combination of clinical examination, specific (treponemal) and nonspecific (reactogenic or non-treponemal) serological tests on blood and CSF, CSF microscopy, CSF protein and glucose, neuroimaging and PCR (Michelow et al. 2002; Doroshenko et al. 2006). Treatment is with penicillin G for all stages of neurosyphilis.

Leptospirosis

Leptospirosis is a zoonotic disease caused by several spirochetes of the *Leptospira interrogans* complex. Humans acquire disease through contact with infected fluids from rodents; for example, through broken skin when swimming in contaminated fresh water. Disease can range in severity from being asymptomatic to fulminant fatal infection. Initially, there is a systemic illness with chills, conjunctivitis and occasionally jaundice, renal failure and bleeding diathesis (Weil disease) followed by signs of meningeal irritation. Neurological manifestations of leptospirosis infection are rare but can include aseptic meningitis, encephalitis, intracranial haemorrhage, cerebellitis and myelitis; CSF can show lymphocytic pleocytosis and raised protein. Pathogenesis is mainly through a vasculitic process. The diagnosis is made with serology and treatment is with penicillin. Prognosis is generally good, although long-term sequelae occasionally occur. Prognosis is
worse if there are signs of encephalitis (Panicker et al. 2001; Mathew et al. 2006).

**Borrellosis (Lyme Disease)**

Lyme disease is endemic throughout North America, Europe and Asia. It is caused by the spirochaete from the *Borrelia burgdorferi* complex, and is transmitted from animal reservoirs to humans by tick vectors of the Ixodes genus. Most cases occur in late spring and summer, and occur commonly in the 5–14; year age group (CDC 2007, Feder 2008). Infection may be asymptomatic, cause only the specific rash (erythema migrans), or disseminate to many organs, including the CNS. The disease can be divided into three stages. Neurological involvement is reported in 5–10% of Lyme borreliosis (O’Connell 2010).

The first stage occurs 7–10 days after a bite, and is characterised by a rash known as erythema chronicum migrans, located in the area of the tick bite, that expands away from the bite. Minor constitutional symptoms may be present (Nau et al. 2009; Esposito et al. 2013a). The second stage, which occurs in 5–15% of patients, results from disseminated infection some weeks or months later. Systemic symptoms (e.g. arthrits, carditis, myositis) as well as both central and peripheral neurological involvement occur. The most common neurological abnormalities are cranial nerve involvement (particularly VIIth, but also VIth nerve palsy), papilloedema and aseptic meningitis (Shah et al. 2005), but peripheral neuropathy and radiculitis may also develop (Bingham et al. 1995). Facial palsy is unilateral in most cases (Lebech and Hansen 1992); bilateral involvement 8–15 days apart is highly suggestive of borreliosis (Angerer et al. 1993). In American Lyme disease (causd by *Borrelia burgdorferi sensu stricto*), meningeal signs are frequently observed but radiculitis is uncommon (Williams et al. 1990; Belman et al. 1993). The peripheral neuritis is usually asymmetrical, motor, sensory or mixed and involves the limbs or trunk (Pachner and Steere 1985; Hansen and Lebech 1992; Christen 1993). Rare manifestations include other cranial neuropathies, ataxia, chorea, encephalitis and symmetrical nevropathy of the Guillain–Barré type (Christen 1993) (Bingham et al. 1995) or transverse myelitis (Linssen et al. 1991). Pleocytosis is present in the majority of children with CNS involvement, and the CSF protein is raised (Feder 2008). The meningeal reaction may become chronic, and Lyme disease is, with mumps, a major cause of prolonged aseptic meningitis, accounting for 11.7% of cases in the experience of Christen (1993). The spectrum of neurological disease observed in children is different from that observed in adults, facial nerve palsy and lymphocytic meningitis being the most common presentation while radiculopathy and peripheral neuropathy are relatively rare (Wilke et al. 2000; Feder 2008; Nau et al. 2009; O’Connell 2010).

The third stage of persistent infection may be observed in untreated patients from 6 months to many years after the initial infection. Skin lesions (acrodermatitis chronica atrophicans) may occur associated with peripheral neuropathy. The lesions are characteristic areas of skin thinning and prominent venous markings associated with pain, pruritis, hyperaesthesia or paraesthesia. Chronic progressive meningoencephalitis and cerebral vasculitis can occur. Joint manifestations, including chronic mono- or asymmetric oligo-arthritis, also occur in the third stage of the disease (Nau et al. 2009).

The controversial term ‘chronic Lyme disease’ has been applied to those with late stage untreated infection, those with permanent tissue damage despite adequate treatment and patients with persistent nonspecific subjective symptoms following adequate antibiotic treatment for Lyme (the latter being described as ‘post-Lyme syndrome’ by some). Due to problems with sensitivity and specificity of the laboratory diagnosis of Lyme disease, it is possible for chronic symptoms due to alternative diagnoses, following an initial incorrect diagnosis of Lyme, to be incorrectly labelled chronic Lyme disease (Hoppa and Bachur 2007; Bratton et al. 2008; Hassett et al. 2009; Hildenbrand et al. 2009).

The diagnosis of Lyme disease rests on the history (including travel and exposure history), clinical manifestations and laboratory demonstration of Borrelia infection. A history of tick bite is frequently missing, and erythema migrans occurs in only 67% of cases (Williams and Schned 1990; Williams et al. 1990). Three-quarters of cases occur from June to October. Serological diagnosis of Lyme may be made by IgG and IgM ELISA; however, the specificity is relatively low and confirmatory Western immunoblot testing is recommended as its specificity is higher. In early infection, serological assays are frequently negative (Hoppa and Bachur 2007; Bratton et al. 2008; Esposito et al. 2013a). Positive results are frequent in endemic areas but are not always related to current neurological disease (Halperin et al. 1989). PCR assay is of limited clinical use due to poor sensitivity (Pachner and Delaney 1993; Golightly 1997; Tuerlinckx et al. 2003; Hoppa and Bachur 2007; Bratton et al. 2008). Co-infection with other tick-borne infections may occur in geographical risk areas (Hoppa and Bachur 2007).

Abnormal MRI findings may include cranial nerve enhancement and punctate (or larger) areas of increased T2 signal in the white matter which may simulate multiple sclerosis (Belman et al. 1992; Hildenbrand et al. 2009). Atypical cases can masquerade as brainstem tumour (Curless et al. 1996). There is little evidence from paediatric studies on which to base treatment recommendations. Suggested treatment regimens for Lyme neuroborreliosis include intravenous ceftriaxone (for more severe disease), intravenous Penicillin G or oral doxycycline (in children >8 years) for 14–21 days (Mygland et al. 2010; O’Connell 2010; Esposito et al. 2013a). Treatment failures have resulted in a tendency for prolonged treatment (2–4 weeks), although no evidence is available to suggest that this is beneficial (Stanek and Strle 2003; Worman et al. 2003).

**Brucellosis**

*Brucella* is a genus of Gram-negative organisms transmitted to humans from domestic animals, particularly cattle, in endemic
Postnatal Extrinsic Insults

**MYCOPLASMA INFECTIONS**

*Mycoplasma pneumoniae* is a common cause of respiratory tract infection in children. Infection can cause extrapulmonary manifestations including haematological, cardiac, CNS and musculoskeletal involvement. CNS disease is reported to occur in 0.1% of mycoplasma-infected patients (Koskineniemi 1993) and in 1–7% of hospitalised patients (Guleria et al. 2005). It is a common cause of encephalitis in children. In one large case series of paediatric encephalitis from California, mycoplasma was thought to be the causative organism in around 9%. Presenting symptoms included fever, lethargy, altered consciousness, focal neurological signs, seizures and hallucinations. Laboratory findings included CSF pleocytosis, raised protein and normal glucose. MRI abnormalities were present in approximately half of patients and the majority had abnormal EEGs (Christie et al. 2007). MRI changes frequently involve the basal ganglia. (Fig. 11.11). Culture of mycoplasma is technically difficult. Diagnosis can be made by assessing mycoplasma-specific IgM or by showing a rise in mycoplasma-specific IgG titre between acute and convalescent samples. The former lacks sensitivity and specificity whereas the latter does not help with acute diagnosis. Mycoplasma PCR on respiratory samples can increase sensitivity, but it does not prove mycoplasma to be the aetiological agent in the CNS (mycoplasma carriage is common in children). PCR on CSF samples is rarely positive (Guleria et al. 2005; Tsiodras et al. 2005; Christie et al. 2007; Yis et al. 2008; Meyer Sauteur et al. 2014). Measurements of mycoplasma antibodies in CSF and also cross-reacting antibodies against host neuron-associated glycolipids (GalC, GQ1b, GM1) have recently been proposed as additional diagnostic tools (Meyer Sauteur et al. 2014). The pathogenesis of mycoplasma encephalitis is unclear. Three main mechanisms have been proposed: direct neuroinvasion, neurotoxin, immune dysfunction or dysregulation. The former may occur in early-onset disease (Bitnun and Richardson 2015); the latter is the most likely mechanism in later or...
delayed onset disease (Guleria et al. 2005; Tsiodras et al. 2005; Christie et al. 2007; Yis et al. 2008; Meyer Sauteur et al. 2014). There is limited data on treatment. Macrolide antibiotics are generally recommended, although their penetration of the blood–brain barrier is limited. In view of the proposed immune-mediated pathogenesis, immunosuppressive or immunomodulatory therapy with steroids or intravenous immunoglobulin (IVIg) respectively have also been used with variable outcomes (Guleria et al. 2005; Tsiodras et al. 2005; Christie et al. 2007; Yis et al. 2008). Long-term neurological sequelae have been reported in 20–60% of cases. Mortality is as high as 10% in some case series (Tsiodras et al. 2005).

Other neurological diseases that have been associated with mycoplasma infection include: aseptic meningitis, transverse myelitis, Guillain–Barré syndrome (GBS), cranial nerve/peripheral neuropathy, ADEM, stroke/cerebral infarction, bilateral thalamic necrosis, Bickerstaff’s brainstem encephalitis (Guleria et al. 2005; Tsiodras et al. 2005). Similar to mycoplasma encephalitis, many of these are thought to have an autoimmune component to their pathogenesis.

**LISTERIA MONOCYTOGENES INFECTION**

Infection by *L. monocytogenes* is observed mainly in neonates (early or late onset), occurring rarely in children outside of infancy unless immunocompromised (Posfay-Barbe and Wald 2009; Ben Shimol et al. 2012; Okike et al. 2013). Infection in older children should therefore prompt screening for immunodeficiency. It is transmitted through contaminated food such as milk and soft cheese. It can produce meningitis or a rhomboencephalitis with formation of multiple abscesses (Fig. 11.12). CSF examination shows a pleocytosis with often raised protein and low glucose. Diagnosis is made by direct CSF staining and culture. Recommended treatment is with ampicillin plus gentamicin (Klein et al. 1986; Ben Shimol et al. 2012).

**BARTONELLA HENSELAE INFECTION (CAT-SCRATCH DISEASE)**

Cat-scratch disease is a self-limiting illness, caused by *Bartonella henselae*, commonly affecting children and young adults. It has a worldwide distribution. In typical cat-scratch disease a cutaneous papule develops 3–10 days after exposure to a scratch or bite from a kitten or cat. Regional lymphadenopathy then develops (1–3 weeks after inoculation), with associated fever and systemic symptoms such as malaise, anorexia, nausea and abdominal pain. It is one of the infectious agents found during investigation of ‘pyrexia of unknown origin’ in children. (Jacobs and Schutze 1998). Multisystem involvement is increasingly recognised. Neurological involvement is infrequent and includes encephalopathy in the majority of cases. Headaches, altered consciousness and seizures have all been documented. CSF findings are often normal but can show pleocytosis and raised protein. Meningomyeloradiculopathy, facial nerve palsy, GBS, transverse myelitis and cerebral arteritis have all been reported. Diagnosis is by serological testing or PCR. Lymph node biopsy may help confirm the diagnosis. There are no randomised trials to guide treatment practices; choice of antibiotics is based on case series. As cat-scratch disease is often self-limiting some would not recommend antibiotics, preferring supportive care alone. If using antibiotics, antibiotics that penetrate CSF such as rifampicin or doxycycline are recommended (Florin et al. 2008). In children younger than 8 years, azithromycin or co-trimoxazole can replace doxycycline although CNS penetration is not optimal.
OTHER RARE CAUSES OF CENTRAL NERVOUS SYSTEM INVOLVEMENT ASSOCIATED WITH BACTERIAL INFECTION

These include *Legionella* infection, which has been associated with epileptic seizures, encephalopathy and peripheral neuropathy, although as with mycoplasma, whether this is a direct effect of infection or an immune-mediated process is unclear (Heath et al. 1986). Whipple disease, although usually a disorder of adults, has very rarely been observed in children (Tan et al. 1995; Duprez et al. 1996). It is caused by *Tropheryma whipplei* and it has a rare, purely neurological form which can present in two main ways: either with multiple neurological symptoms and signs and multiple lesions on CNS imaging, or with a focal mass lesion with signs associated with the location of the lesion (Tan et al. 1995; Duprez et al. 1996; Louis et al. 1996; Panegyres et al. 2006). CNS imaging may also be normal; PCR on CSF may be positive. Neurological manifestations may also occur along with gastrointestinal and rheumatological symptoms and signs. No randomised trial evidence is currently available to guide treatment. Regimens including penicillin/streptomycin or co-trimoxazole have been suggested. Intravenous meropenem or ceftriaxone have also been used (Panegyres et al. 2006). Rickettsial disorders are rare in Western countries with the exception of Rocky Mountain spotted fever, which is frequent in the eastern United States and is responsible for a meningoencephalitic picture (Bell and Lascari 1970).

**VIRAL INFECTIONS OF THE NERVOUS SYSTEM**

**ACUTE VIRAL SYNDROMES**

Over 100 viruses are associated with CNS disease in humans, causing a spectrum of disease ranging from the most benign to the most lethal conditions. The mechanisms of CNS involvement are multiple and in many cases poorly understood. Most viruses invading the CNS are carried from their original portal of entry to the body, and their original place of multiplication (e.g. lymphoid tissue), by haematogenous dissemination. The characteristics of viruses and hosts that determine penetration into the CNS have been studied extensively and are still being actively explored. Two principal clinical syndromes are commonly encountered: meningitis and encephalitis or encephalomyelitis. Meningitis results from the haematogenous spread of the virus into the CSF, often through the choroid plexus. Some viruses can then replicate in the choroid plexus and this may explain the ease with which they are isolated from the CSF. Encephalitis or encephalomyelitis results from direct or indirect involvement of the brain tissue itself by viruses. In many cases of encephalitis tissue damage is not caused by direct viral invasion but by the host-generated inflammatory response. Other acute neurological disorders occurring in the course of a proven or suspected viral infection have no inflammatory manifestations and are better regarded as para-infectious encephalopathies.

The epidemiology of viral infections is constantly evolving as novel pathogens emerge, and globalisation, migration and climate change expand the range of known agents. Arboviruses including Japanese encephalitis virus, West Nile virus and dengue are particularly important emerging infections. Other agents, including influenza A and B and enteroviruses, have the capacity to mutate into novel pathogenic strains causing local epidemics of neurological disease. Clinicians should keep abreast of local trends in formulating their differential diagnosis for children with CNS infection.

Improvements in identification of CNS viral infection have been driven by advances in molecular diagnostics, including increasingly sensitive and rapid multiplex PCR techniques, and also by MRI. In spite of these, in the majority of cases of presumed viral CNS infection no pathogenic organism can be identified. Beyond supportive care, treatment options remain unsatisfactory for most viruses. Novel approaches including viral replication inhibitors and immunomodulatory therapy are the focus of ongoing research.

Any clinical classification of viral CNS disease is difficult and, to some extent, arbitrary. Many viruses can produce the whole gamut of aseptic meningitis, post-infectious encephalitis, primary encephalitis and acute encephalopathy. In this section, we focus first on the presenting syndromes of viral-associated CNS disease – each being caused by a wide range of viral agents – and then on the features of specific organisms.

**Viral Meningitis**

Aseptic meningitis is defined as inflammation of the meninges in the absence of bacterial growth in the CSF. In the era of conjugate vaccinations, which have greatly reduced the incidence of bacterial disease (especially in older children), up to 96% of meningitis in highly immunised populations is now aseptic (Nigrovic et al. 2007). The majority of cases with an identifiable cause are due to viruses (Sadarangani et al. 2015). This section concerns viral meningitis in the absence of parenchymal involvement (encephalitis). Viral meningoencephalitis is considered separately.

**Pathophysiology of viral meningitis**

Viruses enter the body via various mechanisms but viral infection of the meninges and CSF usually occurs following haematogenous dissemination of the virus, either during primary viraemia or later following further viral replication in other organs. Penetration of the blood–brain barrier is usually via the choroid plexus. Some viruses grow in the choroid
plexus itself and so are readily isolated from the CSF (e.g. echovirus, coxsackie virus). Penetration of the CNS via retrograde transport along cranial or other nerves may also occur for some of the herpes viruses and enteroviruses. The inflammatory response to viral invasion of the meninges is dominated initially by polymorphonuclear leukocytes and later by monocytes and lymphocytes.

**Epidemiology of Viral Meningitis**

Viral infection of the CSF can occur at any age but the majority of cases occur in children younger than three years, with a substantial proportion of these in the first two months of life (Nigrovic et al. 2013). A retrospective study of 506 Greek children with aseptic meningitis reported an overall incidence of 17 per 100,000, ranging from 26 per 100,000 in 1–5-year-olds to seven per 100,000 in teenagers (Michos et al. 2007). Cases occurred more commonly in summer and there was a male preponderance of 1.8:1. A multicentre Canadian study reported 802 paediatric cases of aseptic meningitis over a two-year period, resulting in 673 hospital admissions, with a 1.5:1 male preponderance and a marked summer peak associated with an enterovirus outbreak (Lee et al. 2006).

Enteroviruses are by far the most common aetiological agent in aseptic meningitis. Enterviral RNA was found in 49% of children tested in the Greek cohort and 54% of the Canadian cohort (Lee et al. 2006; Michos et al. 2007). In the UK, enteroviruses make up 52% of all laboratory-proven viral meningoencephalitis; the proportion is 92% in those aged less than 3 months, or 77 cases per 100,000 live births (Kadambari et al. 2014). Of aseptic meningitis without encephalitis, enteroviruses account for 77–92% of cases in which a causative agent is identified (Berlin et al. 1993; Rotbart 1995; Sadarangani et al. 2015). Echoviruses (e.g. serotypes 4, 6, 9, 11, 14, 16, 18, 20 and 30) are responsible for up to two-thirds of enterovirus meningitis (Lee et al. 2006) with group B coxsackie viruses (serotypes 1–5) making up most of the remaining cases. Other causative serotypes for meningitis include coxsackie A (e.g. 7, 9 and 25) and occasionally polioviruses. Some (e.g. coxsackie B5, echovirus 6, 9 and 30) are especially associated with meningitis epidemics, while others (coxsackie A9, B3 and B4) are mostly endemic.

Other less commonly isolated viral agents include arboviruses, arenaviruses (e.g. lymphocytic choriomeningitis virus), adenoviruses, herpes viruses, retroviruses (e.g. HIV), paramyxoviruses (e.g. mumps, measles), influenza, pachorvus and parvovirus. The spectra of neurological illnesses caused by these agents are detailed in the relevant organism entries in this chapter. A recent UK study found human herpes virus 6 (HHV-6) and parvovirus to be the most common non-enteroviral causes although the overall numbers were small (Sadarangani et al. 2015). The UK Childhood Meningitis and Encephalitis Study (ChiMES) is an ongoing cohort study (UKCRN 14206) that should further expand our understanding of local epidemiology.

**Clinical Features of Viral Meningitis**

The onset of viral meningitis is usually acute. It is sometimes preceded by a short gastrointestinal or respiratory prodrome; there may be a history of similar symptoms among family members or other close contacts. In the Greek cohort (defined by CSF pleocytosis, negative bacteriology and subsequent course consistent with aseptic meningitis), the most common symptoms at admission were fever (98%), headache (94%), vomiting (67%), neck stiffness (60%), lethargy or irritability (46%), anorexia (40%), rash (9%), symptoms of upper respiratory tract infection (4%) and seizures (2%) (Michos et al. 2007). Nonspecific presentations with fever, rash, diarrhoea and/or cough occur more commonly in younger children; symptoms with greater specificity for CNS infection (headache, vomiting, neck stiffness, photophobia) were observed in only 55% of under-5s in the Canadian cohort, compared to 99% of over-5s (Lee et al. 2006). Brief episodes of obtundation or delirium may occur in a few patients but convulsions are unusual. Neurological examination is negative except for neck and back stiffness. The presence of persisting encephalopathy or neurological signs is suggestive of meningoencephalitis (see Viral Encephalitis section). Clinical features associated with specific causative agents are detailed in the relevant organism entries later in this chapter.

**Diagnosis of Viral Meningitis**

The focus of diagnostic efforts in meningitis should be on exclusion of bacterial causes. There is considerable overlap of symptomatology between viral and bacterial meningitis; clinical prediction rules are not able to reliably exclude bacterial causes on the basis of signs and symptoms alone (Kulik et al. 2013). The most important diagnostic test is the lumbar puncture and failure to undertake a lumbar puncture can significantly compromise patient management. Before embarking upon lumbar puncture, clinicians should review the contraindications listed in Table 11.1 and also consider the accompanying advice regarding pre-lumbar puncture neuroimaging in Clinical Manifestations and Diagnosis in the Acute Bacterial Meningitis in Infants and Children section.

CSF white cell count and protein are the most useful immediately available parameters for differentiating bacterial from viral causes of meningitis (Sadarangani et al. 2015), but all CSF interpretation should be undertaken in light of the overall clinical context. The typical viral picture of a lymphocytic pleocytosis with little or no elevation in protein and normal glucose does not always apply; polymorphonuclear leukocytes may predominate in the first 12–48 hours of illness (Amir et al. 1991), and protein and glucose levels may be abnormal in 45% and 84% of cases respectively (Lee et al. 2006). Nor should normal or near-normal CSF parameters (see Table 11.2 for reference values) be regarded as excluding a diagnosis of viral meningitis; up to 19% of proven enterovirus meningitis cases have normal CSF white cell counts, including up to 42% of infants aged less than 2 months (Sawyer...
C-reactive protein (Sadarangani et al. 2015), procalcitonin
stages (Michos et al. 2007); however, marked elevation in
predominantly polymorphonuclear leukocytosis in the early
stages (Michos et al. 2007); however, marked elevation in
C-reactive protein (Sadarangani et al. 2015), procalcitonin
et al. 1994). Mild elevation in serum inflammatory markers
is frequently observed in viral meningitis, and may include a
predominantly polymorphonuclear leukocytosis in the early
stages (Michos et al. 2007); however, marked elevation in
C-reactive protein (Sadarangani et al. 2015), procalcitonin
(Lee and Davies 2007) or neutrophil count should prompt
consideration of bacterial over viral meningitis.

In the absence of bacterial growth in the CSF, the differen-
tial diagnosis of aseptic meningitis is broad and includes par-
tially treated bacterial infection, atypical bacteria (e.g. Borrelia

**BOX 11.1**

Polymerase chain reaction testing for viral infections

The polymerase chain reaction (PCR), in which repeated cycles of heating and cooling facilitate selective enzymatic amplifica-
tion of a target genetic sequence, is now the mainstay of diagnostic testing in CNS viral infection. Since its widespread intro-
duction to clinical virology in the 1990s the technique has largely superseded viral culture, which is slow and lacks sensitivity,
and antibody titre analysis, which lacks specificity without paired acute and convalescent samples (Crawford 2010). PCR has
high sensitivity and specificity for most agents and is relatively fast, with more recently developed rapid assays able to provide
results within a few hours (Nigrovic et al. 2010). Laboratory turnaround in the clinical setting may be slower as samples
are often batched together to reduce laboratory costs. The increased availability of molecular diagnostic testing has led to a
seven-fold increase in laboratory diagnosis of viral meningoencephalitis in the UK over the past decade (Kadambari et al. 2014).

**Techniques used**

A number of variations on conventional PCR amplification have been developed for enhanced detection of viral nucleic acid
(Crawford 2010). Nested PCR uses double amplification with inner and outer primers to achieve higher sensitivity but takes
longer and is more susceptible to false positive results due to contamination of samples. Quantitative real-time PCR (qRT-
PCR) uses fully automated detection to quantify copy number in real time during amplification, and can be used in some
cases to infer the quantity of virus in the original sample (Dierssen et al. 2008). Loop-mediated isothermal amplification
(LAMP) PCR is another technique which uses six primers and cyclic and noncyclic steps to achieve amplification in less than
one hour without need for skilled personnel (Parida et al. 2008).

**Requesting tests**

If viruses of interest are not specified, current UK laboratory practice is to run CSF PCR for herpes simplex virus, varicella
zoster virus and enterovirus only (plus parechovirus in children under 3 years old). Inclusion of clinical details on the request
form is therefore vital in helping the virologist to select other relevant assays. Particularly important is any history of foreign
travel, unwell contacts or immunocompromise. Bear in mind that conventional PCR requires 0.1–0.2ml of CSF per reac-
tion (i.e. per virus to be detected); multiplex PCR, in which a number of virus-specific primers are used in a single reaction tube, may become more widely available in future.

**Interpreting the result**

A patient with a positive PCR result is 88 times as likely to have a definite diagnosis of viral infection of the CNS as a patient
with a negative result (positive likelihood ratio 88.2) (Jeffery et al. 1997). The likelihood ratio for a possible diagnosis of viral
infection of the CNS in a patient with a negative PCR result, relative to a positive PCR result, is 0.10. Therefore the clinician
with a positive result can be very confident in ‘ruling in’ a CNS viral infection; the clinician with a negative result can be mod-
erately confident in ‘ruling out’ an infection. Of course other factors must be considered, including those determining the pre-
test probability of disease and also those influencing the sensitivity of the assay itself; for example, the longer the time elapsed
from onset of symptoms the lower the chance of nucleic acid detection (Hukkanen and Vuorinen 2002; Huang et al. 2004).

An indication of how strongly positive the result is may be inferred from the cycle number (the number of amplification
cycles necessary to reach the detection threshold). A larger quantity of template nucleic material prior to amplification
should be associated with a smaller number of cycles required to reach threshold, i.e. a smaller cycle number could be consid-
ered a more strongly positive result. Factors including primer design and (in encephalitis especially) variable release of genetic
material into the CSF limit the comparability of cycle number between cases; however qRT-PCR can be used to provide a
longitudinal measure of response to antiviral treatment. Highly mutable viruses (especially RNA viruses) may contain muta-
tions in the probe binding region which can confound RT-PCR analysis (Hymas et al. 2008).

**Future**

In the future, point of access testing and multiplex test kits for panels of common pathogens are expected to provide faster
and cheaper PCR. Faster results will bring secondary cost benefits in reducing duration of hospital stay and unnecessary
treatments and investigations. A US study of rapid PCR in paediatric enteroviral meningitis found reporting of results in
less than 24 hours reduced hospital related expenses by 37% (Robinson et al. 2002). The eventual aim is a comprehensive
one-step multiplex PCR assay capable of rapid detection of all known neurotropic viruses in a single test (Crawford 2010).
Infectious Diseases

Chapter 11

**Meningeal Enhancement**
Meningeal enhancement is identified in half or more cases of aseptic meningitis (Sauerbrei and Wutzler 2002), although false positive rate is high in neurotropic viruses with high seroprevalence in the general population; paired acute and convalescent samples are usually required for a meaningful result. Even if analgesia and hydration can be maintained orally such children may be safely managed at home with appropriate follow up. Ventriculitis, which includes encephalitis, is a spectrum of pathology which includes encephalitis. Before lumbar puncture. Early detection of enterovirus in the CSF by rapid PCR is an alternative strategy for reducing hospitalisation, which may be employed more widely in future (Nigrovic et al. 2010).

There are no currently approved specific antiviral therapies for the enteroviruses, which comprise the bulk of viral meningitis cases (Abzug 2014). Headache duration in adults with aseptic meningitis was reduced by approximately two days in a randomised controlled trial of pleconaril, an antiviral agent with action against enteroviruses, although the benefit was relatively modest and restricted to patients with more severe disease (Desmond et al. 2006). Neuroimaging in viral meningitis is typically normal although CT abnormalities including meningeal enhancement, hydrocephalus, ventriculomegaly and focal hypodensity have been reported in up to 12% of cases (Lee et al. 2006). MRI may demonstrate diffuse T1 enhancement of the meninges.

**Management of Viral Meningitis**
In the absence of specific treatments for the majority of viruses causing meningitis, supportive management is all that is required. A short period of hospitalisation for parenteral antibiotics is often considered appropriate while awaiting bacterial culture results. However, composite scoring systems, such as the Bacterial Meningitis Score, applied to a population of children with pleocytosis before bacterial culture results become available, are capable of identifying those at very low risk of bacterial meningitis with 99.9% accuracy (Nigrovic et al. 2007). If analgesia and hydration can be maintained orally such children may be safely managed at home with appropriate follow up, although this is not appropriate for young infants, the immunocompromised, or children pre-treated with antibiotics before lumbar puncture. Early detection of enterovirus in the CSF by rapid PCR is an alternative strategy for reducing hospitalisation, which may be employed more widely in future (Nigrovic et al. 2010).

**Outcome of Viral Meningitis**
The vast majority of patients with viral meningitis have a benign course and experience a complete recovery within 7–10 days. Communicating hydrocephalus occurs as a rare complication if the arachnoid granulations are obstructed by inflammatory debris. In the Canadian cohort 2% of 802 children required intensive care admission but there were no cases of coma or raised intracranial pressure and no deaths (Lee et al. 2006). Neonates may experience a higher rate of complications, especially if meningitis occurs as part of a disseminated viral infection affecting multiple organ systems.

Uncomplicated viral meningitis (i.e. without concomitant encephalitis) rarely results in long-term sequelae. Hearing loss may occur if infection spreads to the neighbouring structures of hearing. Viral meningitis occurring in the first three months of life may be associated with subsequent subtle delays in development of receptive language (Baker et al. 1996) but the long-term outcome is generally excellent. Chronic enteroviral meningoencephalitis is described in children with inherited or acquired antibody deficiencies (see Chronic Viral Infections section).

**Viral Encephalitis**
Encephalitis is a syndrome of neurological dysfunction caused by an inflammatory process involving the brain parenchyma. In most cases the meninges are also affected, and myelitis may also be part of the process; the terms meningoencephalitis and encephalomyelitis refer to a spectrum of pathology which includes encephalitis. Recent years have seen a number of advances in the diagnosis and management of encephalitis, including an expanded repertoire of molecular and imaging tests, a small number of novel antiviral therapies, and improved consensus on aciclovir treatment schedules for herpes simplex virus (HSV) encephalitis, the most common cause of devastating encephalitic disease.
Encephalitis is the most common form of acute non-suppurative neurological disease in childhood. The majority of cases are caused by viruses. Parasitic and bacterial causes of encephalitis are considered elsewhere in this chapter. Autoimmune encephalitis characterised by the presence of anti-neuronal autoantibodies are covered in Chapter 12. Acute encephalitides of viral origin can be subdivided into those directly related to viral invasion of the CNS (primary encephalitides) and those indirectly related (para- or post-infectious encephalitides), with the presence of detectable virus within the CNS supposed to differentiate the two. There also exists a separate category of acute encephalopathy syndromes occurring in association with viral infections and producing an ‘encephalitis-like’ illness in the absence of inflammation of the brain parenchyma. These syndromes are covered separately later in this chapter (see Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses section). In clinical practice, however, a pathological distinction between primary and post-infectious encephalitis, or even between encephalitis and para-infectious encephalopathies, is rarely possible as very few cases proceed to diagnostic brain biopsy.

Subacute and chronic encephalitides require a different approach to acute encephalitis, as the differential diagnosis in such cases includes neurodegenerative metabolic conditions and other slowly evolving disorders. Those viruses causing predominantly chronic encephalitides are covered separately later in this chapter (see Chronic Viral Infections section).

**Aetiology and Mechanisms of Viral Encephalitis**

The relationship between viral infection and brain inflammation is complex. Two major mechanisms are recognised.

Primary encephalitis results from direct invasion of the brain parenchyma by virus. Active replication within neurons, glial cells and/or macrophages leads to cell death and tissue destruction. The pathology is characterised by the presence of viral genome, inflammatory infiltrates, round cells of glial nodules, neuronal necrosis, and sometimes intranuclear inclusions.

The second mechanism involves a virally initiated, host-generated autoimmune response within the CNS, similar to that observed in experimental allergic encephalitis (Johnson 1982b), and applies to para- and post-infectious encephalitis. Acute disseminated encephalomyelitis (ADEM) is a well-characterised example, in which acute encephalopathy occurs in the presence of inflammatory demyelination and is often temporally associated with a systemic infection or other triggering event such as vaccination. In many cases a trigger is not identifiable. ADEM, and the increasingly-recognised autoantibody-associated encephalitides (e.g. NMDA receptor antibody encephalitis) are discussed in detail in Chapter 12.

The mechanisms outlined above are not mutually exclusive; in many or even most cases, primary encephalitis is probably associated with activation of microglia and astrocytes within the CNS, leading to lymphocyte recruitment, blood–brain barrier breakdown and variable degrees of immune-mediated neuronal damage.

**Epidemiology of Viral Encephalitis**

Some viruses causing encephalitis are spread by human-to-human transmission only (e.g. herpes viruses, enteroviruses), others rely upon arthropod vectors for transmission (so-called arboviruses e.g. flaviviruses, alphaviruses), and a small number are transmitted from animals (e.g. henipaviruses, lymphocytic choriomeningitis virus). Incidence of the various causes of encephalitis varies significantly between countries; (due to e.g. restrictions in the range of arthropod vectors) and also within regions in a seasonal or epidemic pattern. Historically, public health measures have had an important impact on encephalitis epidemiology; vaccination against measles, mumps and rubella (MMR) substantially reduced the number of cases of encephalitis occurring in association with these agents (Koskineni and Vaheri 1989).

In Western settings the overall incidence of encephalitis in children is around 10.5–13.8 per 100 000 (Ijom et al. 2008), or roughly five to seven patients per year in the average British district general hospital. HSV varicella zoster virus (VZV) and enteroviruses are the most commonly identified causes. Younger children and neonates are at higher risk. The largest prospective study of encephalitis epidemiology in the UK to date identified 203 cases (34% children) with encephalitis, defined as encephalopathy plus two or more of: fever, seizures and/or focal neurology, CSF pleocytosis, EEG suggestive of encephalitis, and neuroimaging suggestive of encephalitis (Granerod et al. 2010). The most common causes were HSV (19%), ADEM (11%), tuberculosis (5%), VZV (5%), anti-NMDA receptor antibodies (4%), anti-VGKC antibodies (3%), and streptococci (2%). Other viruses comprised a further 4% of cases; no cause was identified in 37%. The most recent report from the California Encephalitis Project found anti-NMDA receptor antibodies to be the most commonly identified cause of suspected encephalitis in children and young adults, seen in 4% of 761 cases, ahead of enterovirus (4%), HSV-1 (1%), VZV (1%), and West Nile virus (1%) (Gable et al. 2012). The high proportion of cases without an identifiable cause and low incidence of HSV encephalitis may be explained by a referral bias toward diagnostically challenging cases. The largest exclusively paediatric prospective epidemiological study to date was in Finland in the post-MMR era (Koskineni et al. 1997). Of 175 children presenting with suspected encephalitis, likely aetiological agents were identified in 63%; the most common were VZV (22%), respiratory viruses (20%), enteroviruses (19%), adenoviruses (5%), Epstein–Barr virus (EBV) (5%), HSV (5%) and rotaviruses (5%). Other recent European paediatric cohorts have found VZV (Vial et al. 2007) and HSV (Galaknis et al. 2009) to be the most common causes. Tick-borne encephalitis virus is an important agent in Slovenia (Cizman and Jazbec 1993) and some other parts of Eastern Europe. Other arboviruses are more important in Africa, Asia and the Americas (see Arboviruses section).

The UK Childhood Meningitis and Encephalitis Study (ChiMES) is an ongoing cohort study (UKCRN 14206) that should further expand our understanding of local epidemiology.
Clinical Features of Viral Encephalitis

Some CNS viruses present with a characteristic set of signs and symptoms which are highly suggestive of the cause (e.g. rabies virus). These presentations are described in the organism-specific sections later in this chapter. However, most viral encephalitides present initially with a relatively nonspecific syndrome of which the core feature is encephalopathy, defined as altered mental status manifesting as reduced consciousness or altered cognition, personality or behaviour (Kneen et al. 2012). This usually appears acutely as confusion and drowsiness with variable deterioration in conscious level; in some cases a prodromal phase occurs with subacute onset of subtle memory and behavioural disturbances in the absence of frank obtundation. Children with immunocompromise are more likely to present subacutely (Thompson et al. 2012). Other common clinical features include fever (67–80%), seizures (61–78%), focal neurological signs (37–78%) and vomiting (57%) (Kolski et al. 1998, Kneen et al. 2010). Older children may complain of severe headache. Seizures may be generalised or more subtle focal convulsions with, for example, twitching of the fingers or face (Solomon et al. 2007).

Encephalopathy may be preceded by a brief influenza-like illness; symptoms of respiratory or gastrointestinal infection are present in over half of children with confirmed encephalitis (Wang et al. 2007). Rashes may offer further clues to the cause; for example, hand, foot, and mouth disease (enterovirus), chickenpox (VZV), slapped cheek syndrome (parvovirus B19), and roseola (HHV-6) (Thompson et al. 2012). Of viral CNS infections in newborn infants, 85% are acquired vertically during delivery (Whitley 1994); features of primary viral infection may be present in the mother, for example, genital lesions of HSV. Focal neurological signs of encephalitis involve mostly the cerebral hemispheres (e.g. hemiparesis, dysphasia) but may also affect the brainstem and cerebellum, with ataxia present in 58% of cases in one encephalitis series (Rantala et al. 1991). Additional neurological manifestations include extrapyramidal signs (basal ganglia involvement), lethargy and sleep disturbance (hypothalamic involvement), and cranial nerve palsies and dysautonomia (brainstem involvement) (Lee et al. 2013).

Early recognition of symptoms suggestive of encephalitis is of vital importance as delayed initiation of treatment can impact negatively upon the outcome. Possible pitfalls include failure to take note of family reports of abnormal behaviour, finding false reassurance in the absence of fever, and incorrect attribution of confusion to other causes (fever, non-neurological infection, drugs, alcohol, psychiatric illness). Misdiagnosis of subtle or intermittent abnormal movements as manifestations of a nonspecific febrile illness must also be avoided. Clinical features of encephalitis in the neonate are often nonspecific and encephalopathy may be more difficult to detect in this age group.

Brainstem Encephalitis

Brainstem involvement is relatively common in encephalitis, especially in ADEM and the post-infectious encephalitides. It manifests as myoclonus, tremor, ataxia, autonomic dysfunction, respiratory drive disturbance and/or oculomotor and bulbar palsies (Lee et al. 2013). Isolated brainstem encephalitis is more unusual but occurs with a number of viruses including enteroviruses (especially EV-71), flaviviruses, alphaviruses and rabies virus (Kneen et al. 2012). The clinical presentation is of fever, systemic symptoms and aseptic meningitis, in association with symptoms and signs of brainstem dysfunction. Involvement of the oculomotor nerves and lower facial nerves is prominent and may be associated with obtundation and signs of involvement of the long tracts with resulting pyramidal and cerebellar manifestations. Cranial nerve involvement and ataxia may mimic the Fisher syndrome (see Chapter 22) that has been considered by some authors to be a form of brainstem encephalitis. Bacterial infections (listeriosis, brucellosis, Lyme disease), toxoplasmosis and tuberculosis also enter the differential diagnosis for primary encephalitis of the brainstem. Locked-in syndrome should be considered in cases of encephalitis with prominent brainstem involvement in which the degree of obtundation is out of proportion to cerebral involvement on neuroimaging and EEG.

Cerebellitis

Post-infectious cerebellitis is a well-recognised and usually self-limiting condition in children following viral infection, characterised by acute onset of cerebellar signs with or without meningism, nausea, headache, altered consciousness and seizures (Kamate et al. 2009). Cerebellitis may also occur as a primary encephalitis caused by; for example, herpesviruses (particularly VZV and EBV), enteroviruses (Fig. 11.13), and mumps and measles in the unvaccinated (Amador et al. 2007). Rotavirus is also increasingly recognised as a cause of cerebellitis (see organism-specific section). The clinical course of viral cerebellitis is usually benign with complete recovery in the majority. A minority suffer fulminant cerebellitis (Kamate et al. 2009) which may require neurosurgical intervention (see Complications in the Viral Encephalitis section). Bacterial causes of cerebellitis include pertussis and diphtheria. Cerebellar lesions may also occur as part of CNS inflammatory demyelinating disease. Severe cerebellar atrophy with persistent cerebellar signs may follow the acute attack (Hayakawa and Katoh 1995).

Post-Infectious Encephalitis

Post-infectious or immune-mediated encephalitis presents with broadly similar features to primary encephalitis. In the majority of cases onset is abrupt with disturbances of consciousness and seizures. These symptoms appear on average six days (up to 21 days) after the occurrence of an upper respiratory tract infection or exanthematous infection, in most cases in a child over the age of 2 years. The range of neurological manifestations is as for any encephalitis, but a higher proportion of post-infectious encephalitides demonstrate extrapyramidal signs, and seizures are seen less frequently;

Continued
immune-mediated encephalitis tends to favour involvement of white and deep grey matter over the cortex.

### Differential diagnosis of Encephalitis

Encephalitis is a pathological diagnosis which can technically be made only on a tissue sample demonstrating inflammation of the brain parenchyma. As brain biopsy is rarely undertaken before other investigations have been exhausted, the diagnostic approach to suspected encephalitis in actual clinical practice is instead a process of narrowing the differential diagnosis of acute encephalopathy in a number of stages. Initial systematic assessment (see Table 11.8) is focused on identifying problems requiring immediate intervention and distinguishing meningoencephalitis from a range of other neurological, infectious, metabolic, vascular and toxic processes requiring alternative management. The most important diagnostic test for meningoencephalitis remains the lumbar puncture, which in the absence of contraindications should ideally take place prior to prompt commencement of empirical antimicrobial therapy. While the results of CSF analysis are awaited, neuroimaging and EEG should be arranged. Blood tests in viral encephalitis may reveal mild lymphocytosis but are otherwise useful only for exclusion of differentials, correction of electrolyte imbalance, and in some cases viral serology. Final diagnosis is guided by thorough review of the history, neurological examination, neuroimaging, EEG and laboratory studies, including results of molecular diagnostic testing.

should be given to disorders that require immediate specific therapy, especially bacterial meningitis and encephalitis, tuberculous meningitis and brain abscess. Bacterial causes of encephalitis include *Mycoplasma pneumoniae*, rickettsiae, *Coxiella burnetii*, *Bartonella* spp., *Brucella* spp., *Listeria monocytogenes*, *Borrelia* and *Treponema*. Exclusion of these may not be possible early in the course of the illness, even after results of initial CSF analysis and neuroimaging become available. Treatment with antibiotics and/or antituberculous agents may therefore be required in dubious cases, in parallel with treatment for HSV encephalitis, until the diagnosis is clarified.

Neuroimaging is required to exclude a wide range of non-infective differential diagnoses. Tumours, particularly those arising from the brainstem, may result in encephalopathy. Occasionally, an acute arterial thrombosis mimics an encephalitic process. Cerebral thrombophlebitis usually produces characteristic findings on neuroimaging. Both systemic vasculitis and primary CNS angiitis may also simulate viral encephalitis. Acute encephalitis may be fulminant but in many cases new symptoms and signs continue to appear over a few days to weeks. This is an important diagnostic feature, as in many other acute encephalopathies the full picture is abruptly completed.

Metabolic and toxic causes of encephalopathy must also be excluded. Intercurrent viral illness is a common precipitant of metabolic decompensation in children with unidentified underlying disease; therefore, the presence or absence of symptoms suggestive of a viral illness cannot be used to discriminate between metabolic encephalopathies and viral encephalitis. Features in the history which may point more toward a metabolic aetiology in the encephalopathic child include a more gradual onset, history of similar episodes in the past, and the absence of fever and pleocytosis. Features on examination favouring a metabolic over an encephalitic process include symmetrical neurological findings, myoclonus and clinical signs of liver failure. CSF pleocytosis and focal changes on MRI are usually absent in metabolic and toxic causes of encephalopathy (Kennedy 2004). Derangement of acid/base balance is a common feature of many metabolic disorders; capillary or venous blood gas analysis should be a routine part of the assessment of acute encephalopathy along with measurement of serum glucose, electrolytes and ammonia. In selected cases, amino acid and organic acid profiles should be obtained. In some patients examination of urine for toxic substances may be useful, although the course of intoxication is generally much faster and there are no focal neurological signs or meningeal involvement.

Lead intoxication can mimic encephalitis; the CSF may show elevated protein but pleocytosis is absent and other features of lead toxicity are usually present. A subacute (weeks to months) history of encephalopathy should lead to consideration of autoimmune, paraneoplastic and metabolic causes.

As with any presentation, the differential diagnosis of suspected encephalitis should be informed by the previous medical history. Children with viral encephalitis are usually previously well. Recurrent episodes of febrile encephalopathy may suggest immunocompromise, *RANBP2* mutation (see Acute Necrotising Encephalopathy section) or Aicardi-Goutières syndrome. Children with a history of hypertension and/or immunosuppression are at increased risk of posterior reversible encephalopathy syndrome. Children with a history of cardiac or renal disease may be at increased risk of venous sinus thrombosis and other vascular events.

**Lumbar puncture in encephalitis**

Lumbar puncture is essential in suspected encephalitis and failure to perform lumbar puncture is an important cause of missed diagnosis. All children with suspected encephalitis should have an lumbar puncture as soon as is safely possible following admission to hospital. Before embarking upon lumbar puncture, clinicians should review the contraindications listed in Table 11.1 and consider the accompanying advice regarding pre-lumbar puncture neuroimaging (see Clinical Manifestations and Diagnosis in the Acute Bacterial Meningitis in Infants and Children section). Lumbar puncture should not be delayed for neuroimaging unless there is a clear indication to do so, that is, clinical suspicion of raised intracranial pressure with brain shift. Such children may require further stabilisation prior to neuroimaging and any concerns should be discussed with an experienced anaesthetist. Known or suspected clotting abnormalities should be discussed with a haematologist prior to lumbar puncture.

Lumbar puncture for suspected encephalitis in children should include measurement of opening pressure (where possible), microscopy, culture and sensitivity studies, total and differential white cell count, red cell count, protein, lactate and glucose (paired with pre-lumbar puncture plasma glucose). Molecular (PCR) testing panel is determined according to local epidemiology and clinical presentation; in the UK, laboratories usually consider first-line testing for HSV-1, HSV-2, VZV, HHV-6, HHV-7, enteroviruses, parechoviruses, adenoviruses, influenza A and B and rotavirus (Solomon et al. 2007; Kneen et al. 2012). Other tests may be considered according to clinical presentation (e.g. with immunosuppression), including EBV, cytomegalovirus (CMV), measles, mumps, and parvovirus B19. Tests for arboviruses and other imported infections may be indicated by exposure and travel history. Additional CSF can be stored for further tests if required (e.g. antibody tests, see Molecular Diagnosis section) following discussion with the virologist or paediatric infectious disease specialist. Paired oligoclonal bands in CSF and serum should be examined if ADEM is part of the differential diagnosis.

The opening pressure is usually moderately raised in encephalitis. Laboratory analysis typically reveals abnormal CSF with a pleocytosis consisting of lymphocytes and mononuclear cells, a mildly elevated protein level and a normal glucose level. The CSF white cell count varies from a few to several hundred cells per cubic mm, in most cases with a majority of mononuclear cells, although polymorphonuclear cells may predominate in very acute cases with necrotic lesions, and in such cases red blood cells may also be present. CSF red cell count is elevated in approximately half of HSV encephalitis cases (Koskineni et al. 1984). Up to 10% of
patients with viral encephalitis have completely normal CSF cell counts and biochemistry, particularly early in the disease course, including some cases of proven HSV encephalitis (Whitley et al. 1989). VZV, EBV and CMV encephalitis are particularly associated with acellular CSF.

**Molecular diagnosis of encephalitis**

Isolation of specific nucleic acid in the CSF following PCR amplification is now the mainstay of diagnosis for viral infections of the CNS (Box 11.1). CSF PCR yield in suspected encephalitis is highest in the first week after disease onset (Koskineniemi et al. 2002) although false negatives occur in up to 29% of HSV encephalitis cases in the first 48–72 hours of illness (Tyler 2004; Whitley and Kimberlin 2005; To et al. 2014). In cases with a strong clinical suspicion of HSV encephalitis, in which the initial PCR is negative, it is useful to repeat the lumbar puncture 2–7 days later, even when aciclovir has been administered in the intervening period (Tunkel et al. 2008). PCR for HSV taken at day 2–10 of illness has greater than 95% sensitivity and specificity for HSV (Kneen et al. 2012). Recommendations for repeat PCR testing in established cases of HSV encephalitis at the end of treatment are discussed in Management in the Herpes Simplex Virus Encephalitis section.

Other techniques used for detection of virus in the CSF include culture, direct antigen detection, electron microscopy and antibody tests. These should be undertaken in close collaboration with specialists in microbiology, virology or infectious diseases. Antibody tests for consideration in suspected encephalitis include those against mycoplasma, chlamydophila, herpes viruses, enteroviruses, respiratory syncytial virus (RSV), parvovirus B19, adenovirus, influenza A and B, and (if travel history is suggestive) West Nile virus, tick-borne encephalitis, rabies virus and Japanese encephalitis (Kneen et al. 2012). Intrathecal antibody production to a specific virus provides strong evidence of the presence of a causative agent (Koskineniemi et al. 2002); CSF testing for HSV-specific IgG at 10–14 days of illness is particularly helpful in cases of suspected encephalitis where PCR of the CSF was not performed acutely (Kneen et al. 2012). Serological antibody positivity (demonstration of seroconversion or the presence of specific IgM) provides weaker evidence and must be interpreted in the context of background seroprevalence of the virus. Virus may also be detected in the throat, sputum, urine, rectum and any vesicles; viral isolation from these sites (especially vesicles) may be a helpful adjunct to diagnosis, but the results must be interpreted with caution.

In cases where a viral diagnosis remains elusive, testing for autoantibodies may be more cost effective than expanding the search for rarer viral agents, and more likely to result in the identification of a condition with specific treatment (i.e. immunomodulation) (Kirkham 2013; Weingarten et al. 2013). Even following autoantibody testing, 40% of suspected viral encephalitis cases remain without an identified aetiology. Brain biopsy has a diagnostic role after initial investigations have been exhausted in a small number of situations, including PCR-negative patients with suspected HSV encephalitis who deteriorate despite aciclovir (especially those with a focal lesion on imaging) (Pulhorn et al. 2008), patients with immunocompromise (Kneen et al. 2012), and patients with suspected vasculitis (Salvarani et al. 2007). One biopsy series of patients with presumed HSV encephalitis (conducted in the era before routine PCR testing) found HSV in 45%, other viruses in 9%, an alternative treatable disease in 9%, and an alternative non-treatable disease in 4% (Whitley et al. 1989).

**Neuroimaging in encephalitis**

Neuroimaging plays an important role in the diagnosis of encephalitis. MRI with diffusion-weighted imaging is the modality of choice for early identification of subtle changes, and is recommended within 24–48 hours of hospital admission in patients with suspected encephalitis in whom the diagnosis is uncertain (Kneen et al. 2012). Early CT is often normal in viral encephalitis and is used mainly as a rapid screening modality for alternative diagnoses and neurosurgical complications. Even with definitive MRI, in many cases the findings are nonspecific and must be interpreted together with the clinical history and laboratory investigations.

**Magnetic resonance imaging**

MRI is the most sensitive and specific imaging modality for viral encephalitis. Use of contrast is recommended as characteristic patterns of post-contrast enhancement may lead to identification of differential diagnoses (ADEM, suppurative abscess). The anatomical distribution of changes may in some cases be suggestive of the causative virus (Table 11.10) but there remains significant overlap among neurotropic viruses in appearance and location of changes on imaging. Of note, involvement of the cingulate gyrus and contralateral temporal lobe is highly suggestive of herpes encephalitis (Steiner et al. 2005). Imaging later in the disease course may show areas of haemorrhage. Further information on imaging findings in specific viral encephalitides is detailed in the organism-specific sections later in this chapter.

Input from an experienced neuroradiologist is invaluable in formulating the differential diagnosis of suspected viral encephalitis. Transient T2-hyperintensity and restricted diffusion of the cortical grey matter, subcortical white matter and hippocampi have been reported following status epilepticus in the absence of infection (Goyal et al. 2009; Chatzikonstantinou et al. 2011); peri-ictal changes must therefore enter the radiological differential diagnosis in cases of suspected encephalitis with seizures, and repeat imaging may be helpful after seizures resolve. In encephalopathic patients with significant white matter lesions, ADEM should enter the differential diagnosis. ADEM presents with large, patchy, ill-defined lesions of T2- and FLAIR-hyperintensity in a predominantly subcortical and periventricular distribution, with various patterns of post-contrast enhancement (Rossi 2008).
Other modalities

CT is less sensitive than MRI for viral encephalitis and is often normal in early HSV encephalitis (Behzad-Bebahani et al. 2003). The principal advantages of CT are its availability and short scan time. It is therefore well suited to rapid screening for problems requiring urgent neurosurgical intervention, including several of the differential diagnoses listed in Table 11.9, in addition to acute complications of encephalitis such as hydrocephalus and brainstem compression. However, it is inappropriate as definitive imaging for encephalitis due to its very limited sensitivity. Exposure to ionising radiation is another factor limiting the use of CT in non-urgent situations.

Cranial ultrasound is a readily available bedside test in neonates with suspected brain infection. Cortical and subcortical oedema may be seen in encephalitis but sensitivity is poor, the depiction of brain convexity obtained is incomplete and posterior fossa abnormalities are poorly visualised (reviewed in Schneider 2011).

Functional and metabolic changes in encephalitis can also be investigated using MR spectroscopy, functional MRI (fMRI), single photon emission CT (SPECT), and positron emission tomography (PET). However, there is insufficient data to support the routine diagnostic use of these techniques in children with viral encephalitis at present (reviewed in Kneen et al. 2012).

Electroencephalography in viral encephalitis

EEG abnormalities are common in viral encephalitis, occurring in up to 75% of cases (Gable et al. 2012). The most common abnormality seen is nonspecific generalised or predominately unilateral background slowing. These electrographic abnormalities may be apparent earlier than parenchymal change on MRI (Steiner et al. 2005), making EEG a useful investigation for demonstration of cerebral dysfunction early in the disease course in patients presenting only with subtle behavioural symptoms, in whom psychiatric and functional causes are in the differential diagnosis (Kneen et al. 2012). However, the severity of EEG abnormalities does not usually correlate with the extent of the disease and only rarely are specific features of the diagnosis identified. Periodic lateralised epileptiform discharges (Fig. 11.14) are often seen in HSV encephalitis, but also occur in other encephalitides (Hulihan et al. 1992; Garcia-Morales et al. 2002). EEG is also used for detection of subtle or nonconvulsive seizures or status epilepticus in encephalitis; use of continuous EEG monitoring identified seizure activity in 46% of 217 children enrolled in the California Encephalitis Project (Gold et al. 2014).

**Management of viral encephalitis**

Concerns regarding inconsistencies in the management of suspected encephalitis in children (Kneen et al. 2010), including indications for starting aciclovir and appropriate duration of treatment once started, led to the formulation of national guidelines by the Association of British Neurologists and British Paediatric Allergy Immunology and Infection Group (Kneen et al. 2012). The recommendations of the group are referred to throughout this section.

The initial assessment and stabilisation of children with suspected encephalitis is the same as that of other acute encephalopathies and is a paediatric emergency. Priority must be given to ensuring a patent airway and maintaining adequate circulation. A complete assessment of the child is then in order (see Table 11.8). Neurological examination is essential in establishing the correct diagnosis, evaluating prognosis and planning therapy. When a diagnosis cannot be established or a patient fails to improve with therapy, transfer to a paediatric neurological unit is recommended. Children with suspected infective encephalitis should be notified to the regional Consultant in Communicable Disease Control.

Antimicrobial therapy

The antimicrobial treatment of CNS viral infections remains limited. The main drugs active against viruses are shown in Table 11.11. Randomised controlled trials in adults showed administration of aciclovir reduced mortality in HSV encephalitis from 42–67% to less than 25% (Whitley et al. 1986). As HSV is the most common cause of devastating viral encephalitis in children it is accepted practice to administer intravenous aciclovir in suspected viral encephalitis prior to PCR confirmation of HSV. The dose of aciclovir is 500mg/m² intravenously 8 hourly (ages 3 months to 12 years) or 10mg/kg 8 hourly (ages over 12 years), with smaller doses in children with renal impairment (Kneen et al. 2012). Please refer to the Paediatric British National Formulary, or local guidelines, for further details on preparation or dosage. Adequate hydration should be maintained and renal function monitored while giving intravenous aciclovir as reversible nephropathy occurs in up to 20% of patients after several days of treatment (Pacheco et al. 2005).

Aciclovir should be started within 6 hours of admission in any case in which acute viral encephalitis is suspected (Kneen et al. 2012). If there are no contraindications to immediate lumbar puncture (Table 11.1) this should precede initiation of aciclovir. Treatment may be withheld pending initial CSF and neuroimaging results in relatively well children with a lower pretest suspicion of HSV encephalitis (i.e. those with a subacute to chronic history, mild encephalopathy only, absence of fever, and/or signs and symptoms suggestive of an alternative diagnosis). In cases where immediate lumbar puncture is contraindicated, aciclovir therapy should be given prior to lumbar puncture if the anticipated delay in arranging and interpreting urgent neuroimaging is greater than six hours, or if the child is clinically unwell or deteriorating. If bacterial sepsis, meningitis, encephalitis or cerebral abscess are suspected, broad spectrum antibiotics should also be given. The only other empirical antiviral treatment which might be considered in previously well UK children with negative contact and travel history is oseltamivir in flu season (Thompson et al. 2012). Treatment of established (i.e. PCR proven) viral encephalitis is discussed in the relevant organism-specific sections later in this chapter.

If any bacterial or tropical cause of encephalitis is suspected, treatment should be discussed with an expert in infectious diseases, virology or microbiology. It is reasonable to start empirical antimalarial treatment in encephalopathic children returning from malarial areas, in whom cerebral malaria is suspected, if delays in obtaining results of laboratory tests for malaria are anticipated (WHO 2010a).

Decision to stop aciclovir

A common clinical dilemma occurs when a patient presenting with febrile encephalitis and treated initially with aciclovir is found to have a negative CSF PCR for HSV. Once started, can aciclovir be stopped early, especially as three weeks of intravenous treatment is quite onerous in small children? Caution is required as false negative results are not uncommon in CSF samples taken in the first 72 hours of illness (Tyler 2004; Whitley and Kimberlin 2005; To et al. 2014). Aciclovir can be stopped in an immunocompetent child if there is no ongoing clinical suspicion of HSV encephalitis; i.e. if an alternative diagnosis has been made, or a negative PCR has been obtained at more than 72 hours post onset
of neurological symptoms in a recovered child with normal neuroimaging, normal CSF white cell count and normal conscious level (Thompson et al. 2012). A still more cautious approach might include normal EEG and normal neuroimaging at more than 96 hours post onset of neurological symptoms in these criteria. A repeat lumbar puncture should be undertaken in patients with an ongoing clinical suspicion of HSV encephalitis if the first was taken at less than 72 hours post onset of neurological symptoms; HSV encephalitis is very unlikely if two CSF samples obtained 24–48 hours apart are PCR negative (Kneen et al. 2012). Treatment should otherwise be continued for at least 10 days. If HSV encephalitis is strongly suspected; for example, if imaging or EEG demonstrates a focal abnormality, then a full 21 days of aciclovir should be completed.

Immunomodulation
Adjunctive corticosteroid therapy has been tried in HSV encephalitis to reduce deleterious neuroinflammation, but the risks of immunosuppression in active infection may be significant; evidence is not yet sufficient to recommend this as standard practice (Ramos-Estebanez et al. 2014). However, children with neuroimaging and other features supporting a diagnosis of ADEM over viral encephalitis should be treated with steroids as first-line treatment (see Chapter 12). Children with antibody-mediated encephalitis often require steroids and other immunomodulatory treatments (see Chapter 12). Steroids may be tried in cerebellitis if symptoms are severe. Future treatments for viral encephalitis may incorporate targeted blocks of interleukin-1 and other pro-inflammatory mediators.

Supportive care
Children with encephalitis should be monitored closely on a neurological ward or high dependency unit. Critically ill children with a very depressed or falling level of consciousness are best treated in intensive care units and this applies particularly to those with signs of raised ICP. Maintenance of an adequate cardiac output to support effective cerebral perfusion is essential, alongside close monitoring of respiration, blood pressure and body temperature to maintain homeostasis. Nasogastric or parenteral feeding may be required. Electrolyte imbalances are common and should be carefully monitored and corrected. Hyperthermia and seizures must be kept under control as far as possible; uncontrolled seizures lead to increased metabolic activity, acidosis and intracranial vasodilatation, exacerbating risk of raised intracranial pressure (Solomon et al. 2007). Continuous EEG monitoring is extremely useful in detecting subclinical seizure activity and evaluating the degree of brain...

**Antiretroviral therapy (ART):** Three classes of first-line drugs used in specific combinations (see HIV/HTLV-1 treatment guidelines); the only ART drugs available for intravenous use are zidovudine and enfuvirtide

- Nucleoside reverse transcriptase inhibitors (NRTIs): zidovudine, lamivudine, abacavir, stavudine, didanosine, emtricitabine, tenofovir
- Non-nucleoside reverse transcriptase inhibitors (NNRTIs): nevirapine, efavirenz
- Protease inhibitors (PIs): lopinavir/ritonavir, nelfinavir, saquinavir/ritonavir, atazanavir/ritonavir

The NRTIs and NNRTIs have good CNS penetration, while the PIs generally do not

dysfunction, and is superior to routine EEG in both ruling in and ruling out seizure events (Gold et al. 2014). One study of critically ill children with acute encephalopathy showed continuous EEG monitoring led to changes in the clinical management (anti-convulsant initiation/escalation/discontinuation; urgent neuroimaging) in 59% of cases (Abend et al. 2011). Continuous ICP monitoring is not generally required in acute encephalitis but may be required in some related conditions such as Reye syndrome (see Reye Syndrome section).

Rehabilitation
Consideration of physical, psychological and educational rehabilitation should begin during convalescence (Thompson et al. 2012). Multidisciplinary input from occupational therapy, speech and language therapy, physiotherapy, neuropsychology, child psychiatry and other teams may be required. Spasticity, dystonia and epilepsy may require pharmacological management. Referral to specialist brain injury rehabilitation services should be considered for complex or severe cases. Up to 96% of families report ongoing symptoms at discharge (Easton et al. 2007); details of voluntary sector organisations should be provided to parents, and outpatient followup should be offered. Referral to community paediatrics may be required for developmental follow-up.

Complications of Viral Encephalitis

Neurosurgical Complications
Raised ICP can occur in viral encephalitis as a consequence of brainstem involvement and/or cerebral oedema. Management of raised intracranial pressure is discussed in Chapter 7; measures such as 30 degree head-up positioning, maintenance of low-normal pCO2, osmotic agents and corticosteroids may be required (Solomon et al. 2007). Decompressive craniectomy may be considered in encephalitis patients with clinical and imaging evidence of brainstem compression. Adult case series suggest surgical management of brainstem compression may be superior to medical management alone (Perez-Bovet et al. 2012). Excellent recovery of neurological function is possible in some cases (Adamo and Deshaies 2008).

Fulminant cerebellitis may cause marked swelling of the cerebellum with obstructive hydrocephalus requiring external ventricular drainage or even posterior fossa decompression (Amador et al. 2007). The course may be fatal, particularly when associated with brainstem compression or transtentorial and/or transforaminal herniation (Levy et al. 2001; Gamanagatti and Nayaz 2008).

Status Epilepticus
Status epilepticus is reported in 15% of encephalitis cases of all ages and aetiologies (Solomon et al. 2002) and is probably more common in the paediatric group. Management of status epilepticus is discussed in Chapter 16. In the California Encephalitis Project, 4% of cases (including adults and non-infective aetiologies) suffered treatment-refractory status epilepticus which required induction of anaesthetic coma to terminate; the risk was higher in children, those with infective symptoms, and those with normal initial neuroimaging (Glaser et al. 2008). Non-convulsive status epilepticus should be considered as a cause of persisting encephalopathy in viral encephalitis.

Other Complications
Lacunar infarcts in the central grey matter or internal capsule may result from vascular occlusion or focal cerebritis. Some viruses (e.g. VZV) are associated with vasculitis; magnetic resonance angiography should be performed if vasculitis is suspected (Nagel et al. 2008). The syndrome of inappropriate antidiuretic hormone (SIADH) is common in encephalitis (Solomon et al. 2007) and diabetes insipidus may also occur (Steiner et al. 2005). Patients with encephalitis are at risk of developing aspiration pneumonia. Postencephalitic Parkinsonism is unusual in children but is associated with some flaviviruses (Solomon et al. 2007).

Outcome of Viral Encephalitis
In UK children, 2–3% of viral encephalitis cases are fatal (Davison et al. 2003). Mortality is associated with younger age and particularly with HSV encephalitis. Post-infectious encephalitis usually runs a more benign course, with low mortality, and recovery in less than two weeks in three-quarters of cases.

Survivors of encephalitis often suffer physical, cognitive, emotional, behavioural, and social difficulties following the acute illness (Clarke et al. 2006). Outcome of viral encephalitis in children has not been extensively studied; some known prognostic factors for neurological outcome in children and adults with encephalitis are listed in Table 11.12.

</table>
Of children with HSV encephalitis, 63–79% suffer long-term sequelae including developmental delay, motor deficits, neuropsychiatric problems and seizures (Ito et al. 1998; Elbers et al. 2007; Wärd et al. 2012). Neuropsychiatric problems in viral encephalitis include anxiety, depression, obsessive behaviours, hyperactivity/concentration difficulties and memory problems (Kneen et al. 2012). Outcome in encephalitis with an identified causative agent is detailed in the organism-specific sections later in this chapter. Even children with apparently favourable initial outcome may be at risk of developing problems in later life; research suggests exposure to CNS infection and neuroinflammation in early life leads to altered immunological phenotypes with increased susceptibility to secondary CNS insults and increased risk for a range of disorders including cerebral palsy, epilepsy, autism, multiple sclerosis, schizophrenia and adult-onset neurological diseases (Hagberg et al. 2012).

**ACUTE ENCEPHALOPATHY SYNDROMES OCCURRING IN ASSOCIATION WITH VIRAL ILLNESSES**

Several specific syndromes of CNS disease are described, which occur in close temporal relationship to a defined or undetermined viral infection, in the absence of direct viral invasion of the CNS. These acute para-infectious encephalopathies (see Table 11.13) present as secondary deteriorations in consciousness in the context of a viral illness. Seizures and vomiting commonly accompany the encephalopathy, which can range from mild to profound. The extent to which these syndromes represent a spectrum of related conditions is not yet clear; the pathological mechanisms are heterogeneous and poorly understood, although in several syndromes pathogenesis is related to abnormal host cytokine response (cytokine storm) and culminates in a final common pathway of malignant brain oedema. Neuroinflammation may play a role in some of these syndromes but is not widespread and fulminating as in acute disseminated encephalomyelitis. Although a range of viruses may cause these presentations, influenza A and B (and to a lesser extent HHV-6 and HHV-7) are particularly common triggers. Genetic differences in host response may explain the increased incidence of several of these syndromes in Asian children.

Further to the syndromes listed in Table 11.13 and outlined in greater detail below, there are a number of other causes of encephalopathy in the context of viral illness which should be considered in the differential diagnosis. Acute decompensation of a pre-existing mitochondrial or other metabolic abnormality (see Table 11.14) may be triggered by intercurrent viral infection; serum ammonia, serum amino acids and urine organic acids are recommended in any child with severe encephalopathy of unclear aetiology. These investigations should be normal in the conditions listed in Table 11.13, with the exception of Reye syndrome, which may be associated with hyperammonaemia. Some encephalopathies may be caused by status epilepticus or its complications (e.g. aspiration). Others may be the consequence of shock or circulatory failure occurring as part of a severe viral infection (Kirkham 2013). Raised ICP must be considered in any acute presentation of encephalopathy. Derangements of fluid and electrolyte balance may occur in viral illness; hyponatraemia is a common finding in clinically mild encephalitis/encephalopathy with a reversible splenial lesion (MERS) (Takanashi 2009). Posterior reversible encephalopathy syndrome is sometimes associated with influenza infection. Viruses leading to acute anaemia and hypoxia in children with pre-existing haemoglobinopathies may also cause encephalopathy (Wierenga et al. 2001).

**Reye Syndrome**

Reye syndrome is a rare, severe, acute, noninflammatory encephalopathy occurring in association with hepatic dysfunction. Most cases are associated with antecedent viral illness (Singh et al. 2011). Occurrence is closely linked to ingestion of aspirin during the antecedent illness (Starko et al. 1980; Glasgow 2006). The pathogenesis remains unclear and may comprise a group of heterogeneous disorders (Casteels-Van Daele et al. 2000). Pathologically the disease is characterised by microvascular fatty degeneration of the liver and sometimes kidneys (Devivo and Keating 1976) with or without brain oedema. Multiple causes have been identified but in most cases there is a clear association with a viral illness. Implicated agents include varicella (Hurwitz et al. 1982), influenza A (Starko et al. 1980), influenza B (Norman 1968), adenovirus and cytomegalovirus (Qi et al. 2013). The association of Reye syndrome with administration of aspirin was first suggested by epidemiological studies and later confirmed as a dose-dependent effect of aspirin administration in children with viral infection (Starko et al. 1980). Following subsequent advice to avoid salicylate use in febrile children there was a dramatic decrease in incidence in the 1980s (Bhutta et al. 2003). Most hypothesised mechanisms are based on the presence of biochemical and pathological changes suggestive of generalised mitochondrial dysfunction. Direct mitochondrial involvement by a virus is conceivable but no virus has ever been isolated from the liver or brain. Another possibility would be the decompensation of a latent innate metabolic abnormality precipitated by viral infection and/or cofactors such as aspirin; in vitro studies show the drug acts on the mitochondrial long-chain hydroxyacyl-CoA dehydrogenase enzyme (Glasgow 2006).

**Clinical features of reye syndrome**

The clinical manifestations of Reye syndrome appear after the symptoms of the premonitory disease have subsided and in the absence of fever. Initial symptoms include repeated vomiting with progressive deterioration of consciousness to stupor and coma in severe cases (Ozdoba et al. 1997). Convulsions may occur and changes in muscle tone in the form of opisthotonus.
or decorticate or decerebrate rigidity are common. Central neurogenic hyperventilation can be seen in the later stages. The liver is enlarged in about half of cases. The clinical picture is conspicuous for the absence of focal neurological signs and absence of icterus. Clinical manifestations of raised ICP may be prominent, including papilloedema and signs such as mydriasis and decerebrate attitude that indicate brainstem dysfunction. Elevated liver enzymes (aspartate transaminase and alanine transaminase) are an early feature. Bilirubin rarely rises above 50mmol/L. Hyperammonaemia is typical but may be transient and occurs relatively late in the course of the illness. Hypoglycaemia is present in about half of cases and is more common in infants. Prolonged prothrombin time and elevated creatine kinase are sometimes observed. CSF is under high pressure but laboratory analysis is normal. MRI may show T2-weighted abnormalities in the thalamus, midbrain and pons, with or without diffuse brain oedema (Ozdoba et al. 1997; Singh et al. 2011). As the oedema is usually cytotoxic, restricted diffusion may be observed. Watershed involvement in the subcortical white matter and parasagittal cortex may reflect hypoperfusion injury (Singh et al. 2011). As Reye syndrome is now very rare, any infant or child suspected of having the disorder should undergo extensive investigation to rule out inborn metabolic disorders that may mimic it (see Table 11.14).

---

**Management and Outcome of Reye Syndrome**

The management of Reye syndrome is supportive. Careful attention to metabolic and physiological disturbances including hypoglycaemia, hypoxia-ischaemia, electrolyte imbalance and bleeding diathesis may suffice in many early cases. In more severe cases, an aggressive therapeutic approach seems justified given the high mortality rate. Intensive care, mechanical ventilation, correction of metabolic abnormalities as well as monitoring and treatment of intracranial hypertension are essential. Mortality in children was 50–60% in the early 1970s but has now improved with earlier recognition and superior supportive care. Mortality is now very rare.
Chapter 11 Infectious Diseases

Acute Infantile Bilateral Striatal Necrosis

Acute infantile bilateral striatal necrosis (IBSN) is a rare neurological syndrome occurring following a nonspecific febrile illness in infants. The aetiology of the syndrome remains unclear. Implicated organisms include *M. pneumoniae* (Larsen and Crisp 1996), echovirus 25 (Peters et al. 1979), mumps (Goutières and Aicardi 1982), measles (Cambonie et al. 2000) and others (Zevit et al. 2007). Acute IBSN is differentiated from these by its acute onset, temporal relationship to a triggering infective event, and non-progressive, typically more benign course. The differential diagnosis includes acute bilateral infarction of the striatum, which may occur following trauma or spontaneously (Bogousslavsky et al. 1988), but lacks the inflammatory features of IBSN.

**Clinical features of IBSN**

Initial symptoms are of altered consciousness (mutism, apathy, abnormal cry) with or without seizures and vomiting, followed within a few days by the appearance of extrapyramidal rigidity and dystonia, exacerbated intermittently by stereotyped episodes of paroxysmal tonic contractions, usually in flexion, with facial grimacing, head nodding and protracted monotonous whining (Goutières and Aicardi 1982). Truncal hypotonia and ataxia are also described. CSF often demonstrates pleocytosis. CT and MRI show bilateral hypodensities involving predominantly the putamina in a fairly symmetrical distribution (Fig. 11.15) consistent with striatal necrosis (Zevit et al. 2007). Solitary striatal lesions occur subacutely in a range of degenerative conditions including Leigh disease, Wilson disease, Huntington disease, status marmoratus, Hallervorden-Spatz disease, mitochondrial disorders and other familial cases (Basel-Vanagaite et al. 2006; Zevit et al. 2007). Acute IBSN is differentiated from these by its acute onset, temporal relationship to a triggering infective event, and non-progressive, typically more benign course. The differential diagnosis includes acute bilateral infarction of the striatum, which may occur following trauma or spontaneously (Bogousslavsky et al. 1988), but lacks the inflammatory features of IBSN.

**Management and outcome of IBSN**

Favourable response to corticosteroid therapy has been reported (Yamamoto et al. 1997), although even without treatment the natural course is of resolution over weeks to months without recurrence. However, extrapyramidal sequelae occur in most cases (Goutières and Aicardi 1982; Rosemberg et al. 1992) with persisting striatal lesions up to 5 years after the acute insult (Roig et al. 1990). Behavioural problems and learning difficulties may also occur, although milder cases with full recovery are described (Kim et al. 1995).
Haemorrhagic Shock and Encephalopathy Syndrome

Haemorrhagic shock and encephalopathy syndrome (HSES) was first described in 1983 (Levin et al. 1983). The alternative term acute shock with encephalopathy and multi-organ failure (ASEM) has been proposed (Goenka et al. 2014). The pathogenesis of this devastating disease remains unclear but onset is associated with viral infection in most cases; viruses isolated from peripheral sites include influenza, human herpes virus 6, norovirus, adenovirus, rotavirus and bocavirus (Gefen et al. 2008; Goenka et al. 2014; Kuki et al. 2015). Hyperpyrexia, hypoxia, oxidative injury, aberrant cytokine response, defective synthesis/reuptake of protease inhibitors and acute dysfunction of the cerebral perfusion regulatory system have been proposed as pathophysiological mechanisms (Jardine and Bratton 1995; Gefen et al. 2008; Kuki et al. 2015).

Clinical features of HSES

The median age at onset is 15 months (Kuki et al. 2015). Presentation is typically with acute onset of watery diarrhoea (Gefen et al. 2008) followed rapidly by shock and encephalopathy with unresponsiveness and seizures. Fever of 39.5°C or higher is typical. Profound hypotension leads to skin mottling and other signs of hypoperfusion. Oozing of blood occurs at puncture sites due to disseminated intravascular coagulopathy. Multi-organ failure with hepatic and renal involvement follows. Diagnosis is based on clinical criteria (Levin et al. 1989): shock, convulsive coma, fever and oliguria are mandatory features; diarrhoea and haemorrhage are supportive. The CSF is normal. The characteristic imaging finding is of widespread ischaemia affecting the watershed zones of the cortex with sparing of the thalamus and brainstem. CT is usually normal in the first 24 hours but subsequently shows loss of grey/white differentiation and watershed hypodensity with progression to widespread brain oedema. MRI shows swollen, T2-intense cerebral cortex and ischaemic changes in watershed zones. Diffusion-weighted MRI may detect cytotoxic oedema early in the disease course.

The overall picture has been compared to changes seen in shaken baby syndrome (but without subdural haematoma) (Kuki et al. 2015). The EEG shows early focal or multifocal spikes with diffuse slowing (Tsai and Baker 2013). An extensive search for infective causes is required as the differential diagnosis includes haemolytic uraemic syndrome secondary to *E. coli* O157:H7, Ekkiri syndrome secondary to *Shigella*, staphylococcal toxic shock syndrome and viral haemorrhagic fever (Ebola, Lassa, Marburg) (Gefen et al. 2008; Kuki et al. 2015).

Management and outcome of HSES

Treatment is supportive and often requires an intensive care setting for fluid replacement, vasopressors, intracranial pressure depressants and mechanical ventilation. There is no proven specific therapy although many patients are treated with steroids. Plasmapheresis (Roth et al. 1987) and therapeutic hypothermia (Kuki et al. 2015) have also been tried. Recovery from multi-organ failure can be relatively rapid but the acute illness is fatal in 37–60% of patients and neurological sequelae are present in 30–100% of survivors (Thebaud et al. 1999; Kuki et al. 2015). Absence of disseminated intravascular coagulation is associated with better prognosis. Poorer prognosis is associated with biphasic course, status epilepticus, longer duration of coma, and loss of grey/white differentiation on CT (Gefen et al. 2008; Kuki et al. 2015).

Acute Necrotising Encephalopathy

Acute necrotising encephalopathy (ANE) is a rare, severe and often fatal condition, also termed symmetrical thalamic necrosis (Yagishita et al. 1995; Mizuguchi 1997). It is triggered by a range of viral infections, particularly influenza A (Grose 2004; Tsai and Baker 2013) but also influenza B (Youdris et al. 2001; Grose 2004; Huang et al. 2004b), parainfluenza, human herpes virus 6 (Oki et al. 1995), mumps (Watanabe et al. 2013), varicella zoster virus, rotavirus (Hoshino et al. 2012) and nonviral triggers including *M. pneumoniae* and vaccinations (Neilson 2010). Host predisposition to an aberrant inflammatory response is proposed to be the main pathophysiological mechanism and susceptibility is partly genetically conferred; the condition occurs more often in Japanese children, and a familial form (ANE1) is caused by missense mutations in the *RANBP2* gene (Neilson et al. 2009; Goenka et al. 2014; Singh et al. 2015). Younger children are more susceptible.

Clinical features of ANE

The clinical presentation is with fulminant encephalopathy and coma occurring 1–5 days following onset of a febrile illness. Polifocal neurological signs are typically accompanied by seizures, which may be treatment-refractory (Tsai and Baker 2013). CSF commonly shows elevated protein (Goenka et al. 2014) and may show mild pleocytosis (Tsai and Baker 2013). Hepatic involvement ranges from elevated serum transaminases to overt liver failure. Neuroimaging reveals symmetrical, multifocal lesions affecting primarily the bilateral thalamus and brainstem, appearing as hypodensity on CT and T2-hyperintensity on MRI (Wong et al. 2006) (Fig. 11.16). Diffusion imaging reveals lamellar thalamic change with vasogenic oedema on the outside and cytotoxic oedema reflecting haemorrhage and necrosis on the inside (Albayram et al. 2004). Other areas of involvement may include the cerebellum, hippocampus, putamen, internal and external capsule, medial temporal lobes and periventricular white matter (Kneen et al. 2012); cases may initially be misdiagnosed as acute disseminated encephalomyelitis (Singh et al. 2015). The differential diagnosis also includes arboviruses and rabies (Tsai and Baker 2013).

Management and outcome of ANE

Prompt treatment with steroids is recommended; administration in the first 24 hours of illness is associated with better outcome (Okumura et al. 2009). Further immunomodulation may be required for recurrent encephalopathy in those with *RANBP2* mutations (Singh et al. 2015). Around one-third of
cases are fatal and another third are left with severe cognitive and motor impairment (Okumura et al. 2009). Prognosis is poorer in those with pontine involvement (Kneen et al. 2012) or haemorrhagic/cavitating lesions (Wong et al. 2006) on neuroimaging. However, full recovery has been reported, including in some children who did not receive steroid treatment (Loh and Appleton 2010).

Acute Encephalopathy with Biphasic Seizures and Late Reduced Diffusion

Acute encephalopathy with biphasic seizures and late reduced diffusion (AESD) is a recently described syndrome (Takanashi et al. 2006) associated with various viral infections including influenza A and B, HHV-6, HHV-7 and rotavirus (Takanashi et al. 2009; Hoshino et al. 2012). Theophylline may also be a trigger. There is probably overlap with a previously described syndrome termed acute infantile encephalopathy predominantly affecting the frontal lobes (Yamanouchi and Mizuguchi 2006; Goenka et al. 2014). Cases described to date have mostly been in Asian children. Magnetic resonance spectroscopic findings of decreased N-acetylaspartate and elevated glutamine/glutamate complex suggest excitotoxic neuronal damage as a possible pathogenic mechanism (Takanashi et al. 2009).

The syndrome is characterised by a prolonged (>30 minutes) febrile seizure as the initial neurological symptom, followed by a seizure-free interlude in which the patient may be encephalopathic or apparently symptom free. Seizures return on days 4–6, occurring as clusters of complex partial seizures with secondary generalisation with or without fever (Tsai and Baker 2013), accompanied by deterioration in consciousness. As seizures resolve frontal lobe dysfunction (e.g. speech regression) and stereotyped movements predominate. CSF shows normal white cell count and protein. Serum aminotransferase may be elevated but ammonia level is normal. EEG is acutely abnormal with slowing and/or epileptic discharges. Early MRI is normal. Diffusion-weighted imaging on days 3–9 reveals subcortical hyperintense lesions, evolving into cortical hyperintensity later in the disease course, with mostly symmetrical lesion distribution in the frontal and fronto-parietal regions (Takanashi 2009).

Management is symptomatic; immunomodulation and therapeutic hypothermia have been tried but there is no evidence for efficacy. Mortality is less than 5% (Mizuguchi et al. 2007) but sequelae including cognitive impairment, epilepsy and cerebral atrophy are common. However, the clinical spectrum is wide and many children have a milder course with full recovery.

Clinically Mild Encephalitis/Encephalopathy with Reversible Splenial Lesion

Clinically mild encephalitis/encephalopathy with reversible splenial lesion (MERS) is another relatively recently described syndrome (Tada et al. 2004; Takanashi 2009; Takanashi et al. 2009) associated with viral infections including influenza A and B (Ganapathy et al. 2008; Tsai and Baker 2013), mumps, adenovirus and rotavirus. Cases following infection with streptococci and E. coli have also been reported. The pathogenesis is not clear but may relate to focal cerebral oedema secondary to electrolyte/fluid imbalance or inflammatory infiltration.

The history is of a prodromal febrile illness followed 1–3 days later by encephalopathy characterised by delirium, abnormal behaviour and/or seizures. CSF may show pleocytosis (Tsai and Baker 2013). Hyponatraemia is a typical finding (mean 131.8mmol/L). EEG shows diffuse slow waves in around half
of cases. MRI reveals T2 hyperintensity with restricted diffusion in the corpus callosum in all cases, mostly limited to the splenium. Around one-fifth of cases have involvement of nearby white matter bilaterally (Takanashi 2009).

Patients are often treated with steroids but the natural course is of complete recovery and resolution of neuroimaging abnormalities within one month (Ganapathy et al. 2008; Takanashi 2009).

ACUTE VIRAL AGENTS

HUMAN HERPES VIRUSES

Viruses of the family *Herpesviridae* cause a range of CNS infections and are the most common cause of encephalitis in children. The name ‘herpes’ is derived from the Greek *herpein*, meaning ‘to creep’, reflecting the insidious character of this ubiquitous family of neurotropic viruses, which are capable of causing lifelong latent infection in the host and reactivating in later life. Reactivation sometimes occurs during a period of relative immunosuppression, and may occur many years after primary infection, which is usually mild and self-limiting.

Of some 130 herpesviruses, six are well known as agents of CNS infection in humans (see Table 11.15); human herpes virus 7 (HHV-7) has less frequently been associated with CNS infection but is also included. All herpesviruses have large double-stranded DNA genomes which are transcribed to mRNA within the host cell’s nucleus. During acute infection, transcription of lytic genes leads to viral replication. During latency, different viral genes are expressed leading to persistence of virus in the host cell, potentially indefinitely, or until reactivation leads to transcription of lytic genes once more.

The alpha-herpesviruses (HSV-1, HSV-2, VZV) have relatively short replication cycles and tend to infect and destroy a broad range of host cells, establishing latent infection in the sensory ganglia. The gamma-herpesvirus EBV is specific for B lymphocytes and remains latent in lymphoid tissue. The beta-herpesviruses (CMV, HHV-6, HHV-7) have relatively long replication cycles, tend to cause enlargement of affected cells, and establish latency in secretory glands and lymphoreticular cells.

Herpes Simplex Virus

HSV is one of the most common (Galanakis et al. 2009; Granerod et al. 2010) and most devastating causes of encephalitis in Western countries. One population-based study found HSV infection of the CNS accounted for 23% of all serious neurological infections in children aged 2–11 months and 4.5% in older children (Ward et al. 2012). HSV comprises serotypes HSV-1 and HSV-2. In this section four presentations are considered in turn: HSV encephalitis in children and adolescents, which is usually caused by reactivation of HSV-1; HSV meningitis in children and adolescents, which is usually caused by HSV-2; perinatally-acquired HSV meningoencephalitis, which is usually caused by primary infection with HSV-2; and HSV in immunocompromised children.

</table>
of autopsies following road traffic accidents suggests reactivation of virus already established in the CNS in a significant proportion of encephalitis cases. Regardless of the latent site, the cause or trigger of HSV reactivation is not known (Thompson et al. 2012). Recent research suggests susceptibility to HSV encephalitis may be inherited as an autosomal recessive defect in the TLR3-interferon innate immune response, which confers CNS protection against primary HSV-1 infection in healthy children (Rozenberg 2013; Zhang et al. 2013).

Neurotropism in HSV encephalitis for the basal frontal, mesial temporal, cingulate and insular cortex may be explained by proximity of these cortical areas to the termination of the olfactory fibres. HSV encephalitis is highly cytopathic, pathologically characterised by necrotic lesions, which are often haemorrhagic with gross softening, and in severe cases, loss of all neural and glial elements (Barnes and Whitley 1986). Intranuclear eosinophilic inclusions (Cowdry type A bodies) are recognised in neurons and glia.

**Clinical features of HSV encephalitis**

HSV encephalitis classically presents as an acute illness characterised by fever and encephalopathy together with behavioural disturbances and/or motor deficits and/or convulsions (Ward et al. 2012). However, in many cases the clinical features of HSV encephalitis are not characteristic; the disease cannot be reliably distinguished, on clinical presentation alone, from other less severe infections. The full clinical picture is preceded in 60% of cases by prodromal symptoms that may be purely systemic, such as fever and malaise, or may be more characteristic of encephalitis, with disturbances of behaviour. Subtle changes in speech, memory or sensation may precede the more severe neurological signs by several days. Labial herpetic lesions (cold sores) are observed in 7–25% of children (Elbers et al. 2007).

The end of the prodromal phase is marked by worsening symptoms of reduced consciousness, abnormal behaviour and high fever. The full-blown picture includes symptoms common to many encephalitides, that is, lethargy, obtundation or coma and convulsive seizures. Seizures are particularly frequent and often recurrent in HSV, and they are almost always focal, manifesting especially in the face and upper limbs. Unilateral status epilepticus may also occur. In infants and young children febrile seizures are often the dominant symptom; children below the age of 3 years had convulsive seizures in every case of HSV encephalitis in one series, while older children demonstrated a broader range of presentations (Ward et al. 2012). In some younger children, febrile seizures may be the only symptom for several days. Such cases pose a significant diagnostic challenge.

Other neurological manifestations include hemiplegia and aphasia, which can be a prominent and early finding in older children and adolescents. An acute opercular syndrome has been described, in which bilateral disturbance of facio-linguo-glossopharyngeal control leads to orofacial palsy, dysarthria and dysphagia (Garcia-Ribes et al. 2007). Changes pointing to focal necrosis of the temporobasal structures such as anosmia, olfactory hallucinations and disordered behaviour may be prominent (Whitley et al. 1981). Raised intracranial pressure is a common complication of HSV encephalitis and papilloedema is present in approximately 15% of cases. Atypical presentations of HSV include a brainstem encephalitis variant with cranial nerve involvement (Duarte et al. 1994) and acute myelitis (Wiley et al. 1987). The latter is seen mainly with HSV-2. Cases of severe temporal lobe epilepsy have also been attributed to smouldering HSV-2 infection (Cornford and McCormick 1997).

Mild HSV encephalitis has been reported in a few children who presented with fever and seizures or other neurological symptoms in the absence of encephalopathy, and enjoyed a favourable outcome (Elbers et al. 2007). However, such cases are rare.

**Diagnosis of HSV encephalitis**

The detection of herpes simplex virus DNA in the CSF by PCR is the mainstay of HSV encephalitis diagnosis. One series of biopsy-proven cases found PCR diagnosed HSV encephalitis with 96% specificity and 99% sensitivity (Lakeman and Whitley 1995). The initial approach to diagnosis in suspected viral encephalitis, including considerations regarding timing of lumbar puncture and early neuroimaging, and guidance regarding interpretation of a negative PCR result, is covered in Diagnosis in the Viral Encephalitis section.

Other investigations may support the clinical diagnosis of HSV encephalitis before the PCR result is available. CSF pleocytosis is usually observed, but the CSF is normal in 20–25% of patients, particularly in samples taken in the first few days of illness. In most cases, CSF is under moderately increased pressure and contains an excess number of cells, usually lymphocytes, from tens to hundreds per mm³. The CSF is frequently haemorrhagic or xanthochromic, with an elevation of red cells in 50% of cases (Novak 1984), usually in younger children (Ward et al. 2012). CSF protein is typically mildly elevated with normal glucose (Kennedy 2004).

EEG is abnormal in 86% of children with HSV encephalitis (Lahat et al. 1999). EEG commonly demonstrates periodic lateralised epileptiform discharges between the second and fifteenth day of disease (Schauseil-Zipf et al. 1982) (Fig. 11.14). These were once thought diagnostic of HSV encephalitis but are now known to occur in other encephalitides also (Hulihan et al. 1992, Garcia-Morales et al. 2002). Other nonspecific EEG abnormalities in HSV encephalitis include generalised and focal high amplitude slow waves and temporal spike-and-wave activity. Low amplitude may be observed in one or more regions. Tracings are usually very asymmetrical.

Neuroimaging may appear normal in the first 24–48 hours after disease onset. Early CT is abnormal in 25–80% of patients (Raschilas et al. 2002), showing reduced attenuation in one or both frontal or temporal lobes, and sensitivity is increased with use of intravenous contrast; however, CT alone is inadequate for diagnostic imaging in HSV encephalitis. Diffusion-weighted MRI is the most sensitive modality for early
Part V  Postnatal Extrinsic Insults

600

The main pattern is of bilateral, asymmetrical changes (gyral oedema on T1-weighted imaging and hyperintensity on T2-weighted imaging) in the medial temporal lobe and other limbic structures, the inferior frontal lobes, insula and cingulate gyrus (Fig. 11.17). The parietal lobes and other extra-temporal regions may be involved in up to 59% of cases (To et al. 2014), particularly in younger children (Ward et al. 2012). The lentiform nucleus, and basal ganglia more generally, are characteristically spared. The differential diagnosis of bilateral temporal lobe hyperintensity includes neurosyphilis, mesial temporal sclerosis, and mitochondrial encephalopathy, lactic acidosis and stroke-like episodes (MELAS) (Sureka and Jakkani 2012). Involvement of the cingulate gyrus and contralateral temporal lobe is highly suggestive of HSV encephalitis (Steiner et al. 2005). Diffusion-weighted MRI may demonstrate restricted diffusion in areas appearing normal on conventional MRI (Kuker et al. 2004). Early findings of focal gyral oedema on T1-weighted imaging progress to extensive cortical necrosis, with or without haemorrhagic changes, and later atrophy of affected areas. Focal HSV encephalitis with pseudotumoural features has been reported (Counsell et al. 1994). Additional MRI sequences may be useful in some cases, including susceptibility-weighted imaging for early haemorrhagic foci, post-gadolinium imaging for gyriform enhancement, and magnetic resonance spectroscopy for metabolic changes of neuronal death (Sureka and Jakkani 2012). Resolution of the latter with time has been proposed as a marker of treatment efficacy (Steiner et al. 2005).

In patients without a PCR sample taken in the first 10–12 days of illness, demonstration of a four-fold rise of antibody titre against HSV-1 in the CSF may be considered supportive of the diagnosis of HSV encephalitis in the correct clinical context. However, the change in antibody titre takes at least 10–14 days to appear (Koskineni et al. 1984). The antibodies initially belong to the IgM class and later switch to IgG type. They are associated with the presence of an oligoclonal protein pattern in the CSF (Mathiesen et al. 1988). The antibodies and oligoclonal pattern may persist for years following the acute infection (Tardieu and Lapresle 1980).

Management of HSV encephalitis

The initial and supportive management, including commencement of aciclovir and dosing, is covered in Management in the Viral Encephalitis section. This section concerns management of PCR-confirmed HSV encephalitis. Aciclovir remains the treatment of choice for HSV encephalitis, with significant benefits in reducing both mortality and morbidity (James et al. 2009). Its mechanism of action, requiring phosphorylation to the active form by viral thymidine kinase before competitive inhibition of viral DNA polymerase can occur, means that it works most efficiently during early viral replication (Crawford 2010). It is therefore important to start treatment promptly when HSV encephalitis is suspected.

Axiclovir-resistant strains of HSV are rarely encountered in children, except in those with multiple previous exposures to the drug. In general, children tolerate aciclovir very well, although at high doses aciclovir may cause renal toxicity if the patient is not well hydrated. A course of at least 14–21 days intravenous aciclovir is required in proven HSV encephalitis (Kneen et al. 2012). Shorter courses are associated with up to 26–29% relapse rate: younger children and infants appear to be at greatest risk (Ito et al. 2000; Love et al. 2004; Valencia et al. 2004). Some advocate a 21-day course for children younger than 12 years (Thompson et al. 2012). Switching to
oral valaciclovir, a prodrug with superior bioavailability compared to oral aciclovir, may be considered after at least 10–14 days of intravenous treatment (Chan et al. 2000). Repeat lumbar puncture at end of treatment is recommended to demonstrate treatment efficacy with a negative PCR result; if the CSF remains HSV positive, aciclovir should be continued with weekly CSF PCR until the result is negative (Cinque et al. 1996; Tunkel et al. 2008; Kneen et al. 2012). Discussion with a specialist in virology or infectious diseases is also suggested in such cases to consider revised antiviral therapy (Tyler 2004).

Experimental and clinical observations suggest a benefit from adjunctive corticosteroid therapy in HSV encephalitis but evidence is not yet sufficient to recommend this as standard practice (Ramos-Estebanez et al. 2014). Corticosteroids may be used by specialists for specific circumstances including marked cerebral oedema, brain shift or raised intracranial pressure (Kneen et al. 2012). The Corticosteroids in HSV Encephalitis (COHESIVE) randomised controlled trial started recruiting British adults in 2014 and the outcome of the European GACHE trial is also awaited (Martinez-Torres et al. 2008).

Relapse of HSV encephalitis
Clinical relapse may occur in up to a quarter of HSV encephalitis cases (De Tiege et al. 2003) and has been described up to 8.5 years after the initial episode (Spiegel et al. 2008). In some cases relapse is due to continuing viral replication in the CNS, for example associated with absence of HSV antibody production in the CSF (De Tiege et al. 2006) However, in most cases there is no molecular evidence of viral reactivation (Hacohen et al. 2014), suggesting an immune-mediated mechanism may be responsible (De Tiege et al. 2003; Skoldenberg et al. 2006). A characteristic clinical picture of encephalopathic relapse with prominent choreothetoid movement disorder and seizures, associated with white matter changes on MRI and poor prognosis, is well recognised following HSV encephalitis (Barthez et al. 1987; Shanks et al. 1991; Wang et al. 1994; De Tiege et al. 2003; Valencia et al. 2004; Kullnat and Morse 2008); more recently, anti-NMDA receptor antibodies have been detected in some cases (Leyboldt et al. 2013, Pruss 2013, Hacohen et al. 2014). Immunomodulation plus empirical antiviral therapy may maximise neurorehabilitation potential in such patients. An approach to management has been proposed in which cases negative for ongoing HSV replication (as determined by CSF with or without blood PCR) are treated with IVIg or plasmapheresis. Steroids and other immunosuppressive drugs may be used as second-line therapy, with careful surveillance for virological reactivation (Bamford et al. 2014).

Outcome of HSV encephalitis
In the pre-aciclovir era, mortality from HSV encephalitis was greater than 70%, and less than 3% survived without severe sequelae. In the aciclovir era, mortality in children is 6–8% (Whitley et al. 1986; Ito et al. 1998; Lahat et al. 1999) but morbidity remains high, with 36–79% of survivors suffering long-term sequelae (Ito et al. 1998; Lahat et al. 1999; Elbers et al. 2007; Ward et al. 2012). Common sequelae include developmental delay and cognitive impairment (15–58%), seizures (15–44%), motor deficits (19–37%), visual loss (21%), personality change and behavioural problems (5–15%) and speech difficulties (5–7%) (Lahat et al. 1999; Elbers et al. 2007; Ward et al. 2012). Severe epilepsy in infants may manifest as infantile spasms.

Outcome is difficult to predict during the acute illness. Table 11.12 summarises some of the reported prognostic factors. Sequelae are more common in younger children (Ito et al. 1998; Lahat et al. 1999; Whitley and Kimberlin 2005; Ward et al. 2012) and in those with greater impairment of consciousness at presentation (Whitley et al. 1986; Lahat et al. 1999). One study found mean GCS at presentation in patients later suffering neurological sequelae was 7.7, compared to 11 in those without sequelae (Lahat et al. 1999). Late administration of aciclovir (McGrath et al. 1997; Raschilas et al. 2002) and status epilepticus during the acute illness (Herrmann et al. 2006) are also associated with poorer outcome. High viral load in the CSF has also been proposed as a negative prognostic feature (Domingues et al. 1998), but a direct relationship between HSV DNA copies per millilitre of CSF and CNS damage has not so far been established (Tyler 2004).

Herpes simplex virus meningoencephalitis
Aseptic meningitis without encephalitis is more commonly caused by HSV-2 than HSV-1. It is rare in children. HSV-2 meningoencephalitis may be a manifestation of primary infection in the sexually active adolescent; in younger children the possibility of sexual abuse should be considered. Rarely, mild cases of HSV-1 infection can manifest only with meningeal irritation (Whitley et al. 1982), with recovery in 7–14 days. Around 20% of HSV-2 meningitis patients develop recurrent episodes termed Mollaret meningitis. This rare, benign meningitis is characterised by multiple episodes of aseptic, lymphocytic meningitis separated by symptom free periods. Transient neurological symptoms are described but no permanent neurological sequelae. Treatment of Mollaret meningitis is with intravenous aciclovir followed by oral valaciclovir prophylaxis. Indomethacin has also been tried to speed recovery.

Perinatally-acquired herpes simplex virus
Neonates with HSV infection usually acquire it by vertical transmission during birth; hence, HSV-2 (which causes genital herpes) has been the predominant cause of disseminated HSV infection and meningoencephalitis in this age group (Kennedy and Chaudhuri 2002), although HSV-1 is becoming more important in some developed settings (Jones et al. 2014). The disease is devastating in the neonatal period. In 70% of cases infection is acquired from an asymptomatic mother, and occasionally from other caregivers in close contact with the child during the neonatal period (Brown 2004). Risk factors for vertical transmission include maternal primary infection during the third trimester, invasive monitoring
during labour, vaginal delivery, gestation less than 38 weeks, and maternal age less than 21 years (Whitley 2004). Maternal seropositivity to HSV-1 or HSV-2 is protective. Vertical transmission may be decreased by prophylactic antiviral treatment (Berardi et al. 2011).

Presentation may be delayed until 2–4 weeks after birth. CNS involvement occurs in 30% of all infected neonates, rising to 70% in those with disseminated infection (Berger and Houff 2008). Presentation is typically with seizures (focal or generalised), irritability, lethargy and/or fever (Baskin and Hedlund 2007). Skin lesions are observed in two-thirds of infants.

**Diagnosis of perinatally-acquired HSV infection**

Basic principles of initial investigation and management are as outlined in Management in the Viral Encephalitis section. Laboratory results in disseminated disease often show abnormal liver function and disseminated intravascular coagulation. CSF typically shows a lymphocytic pleocytosis, increased protein levels, and PCR positivity for HSV-2 (Berger and Houff 2008). The presence of a multifocal periodic pattern on the EEG, together with an inflammatory CSF, is highly suggestive of herpetic encephalitis and may occur before any abnormality is visible on CT or MRI. Neuroimaging changes in perinatally-acquired HSV are more diffuse and widespread than in older children (Steiner et al. 2005), presumably due to haematogenous rather than neuronal mechanism of CNS penetration. The temporal and frontal lobes may be spared with lesions seen instead in the deep grey and periventricular white matter. Lesions show nonspecific diffuse hypointensity on T1-weighted imaging and hyperintensity on T2, and are rarely haemorrhagic (Schneider 2011). Restricted diffusion in the periventricular area is a sensitive marker of early disease (Dhawan et al. 2006).

**Management of perinatally-acquired HSV infection**

Randomised controlled trial evidence in neonatal HSV encephalitis shows high-dose intravenous aciclovir (20mg/kg 8 hourly) for 21 days decreases mortality and morbidity (Kimberlin et al. 2001) and is the recommended treatment regimen (Thompson et al. 2012). This high dose of aciclovir is associated with a mild degree of neutropenia in most patients, which if more severe could be supported by granulocyte colony stimulating factor. In view of the more extensive and diffuse CNS infection and less mature immune response in neonates, repeat CSF PCR at the end of intravenous treatment is strongly advised to confirm viral clearance (Kimberlin 2004). Quantitative PCR (see Box 11.1) can be used as a guide to treatment efficacy (Thompson et al. 2012). Prolonged oral suppression therapy may have a role in reducing the incidence of recurrent disease (Tiffany et al. 2005). However, aciclovir resistance has been reported in some cases of prolonged therapy (Thompson et al. 2012).

**Outcome of perinatally-acquired HSV infection**

Mortality in neonatal HSV encephalitis has reduced from 50% in the pre-aciclovir era to 4% with high-dose aciclovir (James et al. 2009). Unfortunately neurodevelopmental outcomes remain devastating with two-thirds suffering sequelae including diffuse cystic encephalomalacia, microcephaly, seizures, cerebral palsy and cognitive impairment (Schneider 2011). Prognosis is better in HSV-1 than HSV-2.

**Herpes simplex virus in immunocompromised children**

Primary HSV infection in the immunocompromised may be life threatening. The mouth, skin, lungs and gut are most often affected; the CNS is rarely specifically involved. However, a high index of suspicion is required; an atypical subacute presentation is described in immunocompromised children (Kleinschmidt-DeMasters and Gilden 2001) and CSF pleocytosis may be absent. CSF PCR is therefore crucial in diagnosis and monitoring of treatment (Cinque et al. 1998). High-dose intravenous aciclovir should be effective, although resistance may be problematic for immunocompromised patients (Wilson et al. 2009), especially those with repeated exposure to oral treatment. Such cases may require treatment with other antivirals such as foscarnet or cidovir (Whitley 2002).

**Varicella Zoster Virus**

VZV infection is transmitted by droplets entering the body via the respiratory tract or conjunctiva. Primary infection is associated with a range of CNS complications occurring in around one to two per 10000 childhood cases (Stahl et al. 2011), with a particular tendency to cause large and small vessel vasculopathy. Quantification of VZV DNA in the CSF has demonstrated higher levels in those with more severe disease (Aberle et al. 2005). As with other alphaherpesviruses, latent infection is established in the sensory ganglia; however, CNS manifestations of reactivated VZV are rare in children, with the exception of the immunocompromised (Koskiniemi et al. 2002).

Neurological manifestations may occur simultaneously with chickenpox or many months later; in some cases they may precede vesicular eruption, or even occur in patients with no rash (Gnann 2002). Four distinct CNS presentations are recognised: acute aseptic meningitis, acute encephalitis, post-infective cerebellitis, and post-infective focal arteritis manifesting as stroke. It has been argued that all CNS presentations of VZV are best thought of as variable manifestations of a common pathogenic mechanism of vasculopathy (Baskin and Hedlund 2007). VZV may also cause ventriculitis, benign idiopathic intracranial hypertension (Ravid et al. 2012) and Reye syndrome (see Reye Syndrome section) (Hurwitz et al. 1982). Superadded bacterial infection should be considered in the differential diagnosis of VZV-associated CNS disease, as the virus is known to cause transient immunosuppression.

**Aseptic meningitis**

VZV not uncommonly causes symptoms evocative of meningitis (photophobia, headache) without any evidence of CNS involvement (Stahl et al. 2011). Lumbar puncture may
reveal the presence of VZV by PCR, with or without pleocytosis and/or elevated protein. Acellular CSF occurs more commonly in patients with immunocompromise (Studahl et al. 2000). In immunocompetent children VZV meningitis is largely self-limiting. Aciclovir may be considered in PCR-positive cases with ongoing symptoms.

**VZV-associated acute encephalitis**

Although commonly referred to as an encephalitis, the acute encephalopathy occurring in association with VZV infection may be more properly described as a multifocal vasculopathy or leukoencephalopathy (Gilden 2002; Baskin and Hedlund 2007). The clinical features are those of a nonspecific viral encephalitis, ranging in severity from mild confusion and headache to seizures, reduced consciousness and focal neurological deficits (Baskin and Hedlund 2007). Onset may be acute or subacute (Kneen et al. 2012). Onset prior to eruption of vesicles has also been described (Maguire and Meissner 1985; Wagner et al. 1998). The immunocompromised are particularly susceptible (Koskineniemi et al. 2002), and it may occur as part of a VZV reactivation with cranial dermatome involvement (shingles) and/or disseminated infection. Stroke and myelitis may complicate the picture further.

MRI demonstrates diffuse, multifocal cortical and subcortical hypointensity on T1-weighted imaging with high signal on T2 (Baskin and Hedlund 2007). In immunocompromised children the distribution may be more clearly arterial. MRA should be performed to look for evidence of vasculitis (Nagel et al. 2008). CSF should be sent for PCR; CSF IgG detection can be useful in cases where PCR result is negative or not available.

VZV encephalitis should be treated with intravenous aciclovir at a dose of 500mg/m² (ages 3 months to 12 years) or 10–15mg/kg (age >12 years) three times daily for up to 14 days (Kneen et al. 2012). Adjunctive corticosteroids may be given (Solomon et al. 2007).

**VZV-associated post-infective cerebellitis**

VZV-associated cerebellitis is usually mild, presenting as acute ataxia in a younger child with a history of recent chickenpox infection. Although described as post-infective, ataxia may in fact occur prior to eruption of chickenpox vesicles (Dangond et al. 1993). Most cases show full recovery within a few weeks and no specific treatment is required (Kneen et al. 2012). Hydrocephalus may occur secondary to cerebellar swelling in severe cases (Shkalim et al. 2009). Where neuroimaging is performed this should include MRA for vasculopathy.

**VZV-associated post-infective vasculopathy**

There is a four-fold increased risk of arterial ischaemic stroke in the 0–6 months after chickenpox (Thomas et al. 2014). VZV is thought to account for up to one-third of all arterial ischaemic stroke in children (Kneen et al. 2012). Children are usually immunocompetent and previously well (Baskin and Hedlund 2007). Median interval between chickenpox and stroke is 4 months. Infarction typically occurs in the middle cerebral artery territory secondary to abnormalities in the M1 segment of that vessel (Miravet et al. 2007). There is probably more than one mechanism for these post-infectious events, and inflammatory changes in arterial tissue as well as increased secretion of procoagulants such as anticardiolipin may be important in some cases (Kurugol et al. 2000, 2001). In addition, the host immune response to VZV includes antibodies that may cross-react with and inactivate the important host anticoagulant factor protein S. This may lead to a hypercoagulable state with development of purpura fulminans as well as post-VZV ischaemic stroke (Josephson et al. 2001; Thomson et al. 2010). Haemorrhagic infarcts are also reported (Gilden et al. 2009).

Presentation is usually with acute onset of hemiparesis, chorea or facial weakness (Kneen et al. 2012). MRI with angiogram is usually diagnostic of a focal or multifocal arteriopathy with irregularity, segmental narrowing, beading, or stenosis of the anterior and middle cerebral arteries and their branches. Isolated basal ganglia ischaemia is also described and may be unilateral or bilateral (Baskin and Hedlund 2007) (Fig. 11.18). Extensive investigation for causes of arterial ischaemic stroke should be carried out as detailed in Chapter 15; treatable risk factors may co-exist with VZV arteriopathy in some patients (Miravet et al. 2007). Workup should also include lumbar puncture; detection of anti-VZV IgG in the CSF (positive in 93% of cases) is more sensitive than VZV PCR, which is only positive in 30%. CSF pleocytosis is usually absent. Intrathecal synthesis of IgG can be confirmed by reduced serum/CSF ratio (Nagel et al. 2008). One-quarter of patients suffer recurrence which is usually associated with progressive arteriopathy (Miravet et al. 2007).

**Epstein–Barr Virus**

Infection with Epstein–Barr virus (EBV) occurs mainly via the oropharyngeal route. Most children are infected asymptotically in early life; those infected later may present symptomatically with infectious mononucleosis. Various neurological complications of infection with this B-cell lymphotropic herpesvirus are reported and may be less rare than previously thought, occurring in up to 5% of infectious mononucleosis cases in teenagers and young adults (Junker 2005). CNS manifestations range from aseptic meningitis and cranial neuropathies to fulminant encephalitis which can mimic HSV encephalitis (Whitley et al. 1989). EBV encephalitis in the immunocompetent occurs mainly as an immune-mediated complication of primary infection (Stahl et al. 2011). The virus may be implicated in up to 10% of all acute encephalitides and co-infection with other agents (particularly *Mycoplasma pneumoniae*) is common (Weinberg et al. 2005; Doja et al. 2006). Neurological presentations also occur in the context of reactivated infection, with serious long-term complications including hippocampal atrophy and sclerosis (Hauser et al. 2002).
EBV ACUTE ENCEPHALITIS
EBV encephalitis in the immunocompetent is most common in teenagers, with a median age of 13 years. Only 5–18% of patients have a clear preceding history of infectious mononucleosis but nonspecific prodromal symptoms of fever and headache are common (Doja et al. 2006). Neurological illness classically presents 1–3 weeks after the prodromal illness (Schnell et al. 1966; Greco et al. 2014) although some patients go on to develop symptoms of infectious mononucleosis following initial presentation with isolated neurological symptoms (Booss and Esiri 2003). Encephalopathy may be profound. Around half of children suffer seizures; presentation may be with acute status epilepticus (Connelly and DeWitt 1994). Nonconvulsive status epilepticus is also reported (Greco et al. 2014). Other neurological features include focal motor deficits and hallucinations. Transverse myelitis and optic neuritis may be associated in some cases (Doja et al. 2006). Cerebellar involvement is common and may rarely result in obstructive hydrocephalus. Brainstem involvement is rarely observed (Baskin and Hedlund 2007) and can present with signs and symptoms mimicking a tumour (Angelini et al. 2000).

Diagnosis of EBV encephalitis
CSF pleocytosis is usually observed with variable patterns of neutrophil and lymphocyte predominance (Bathoorn et al. 2011). EBV DNA is detectable by PCR in around half of cases. Acute and convalescent serology may be helpful in PCR-negative cases; detection of anti-EBV IgM or rising IgG is more sensitive and specific than heterophile antibodies. EEG may show generalised or focal slowing, epileptiform discharges and focal intermittent rhythmic delta activity (Doja et al. 2006). Neuroradiological findings are observed in up to 80% of cases (Doja et al. 2006). The characteristic pattern is of increased T2-weighted signal in the bilateral thalami and basal ganglia. Multifocal lesions may also be seen in the cerebral cortex, brainstem and cerebellum. Diffusion is not restricted. Magnetic resonance spectroscopy may be helpful especially in cases with basal ganglia involvement (Baskin and Hedlund 2007). White matter involvement with demyelination is a feature in some cases (Doja et al. 2006).

MANAGEMENT AND OUTCOME OF EBV ENCEPHALITIS
Management of EBV encephalitis remains largely supportive. Antiviral therapy with aciclovir or ganciclovir has been tried, as these agents show activity against the virus in vitro (Doja et al. 2006), but there is little clinical evidence to support this (Baskin and Hedlund 2007). Corticosteroids have been used in ADEM-like presentations and fulminant infectious mononucleosis (Andersson and Ernberg 1988). EBV encephalitis may be fatal, particularly in those with status epilepticus, but the majority of patients make a full recovery (Doja et al. 2006). Thalamic and limbic involvement is associated with poorer outcome (Abul-Kasim et al. 2009). Convalescence may be prolonged (weeks to months) and fatigue is a common persisting symptom. Other sequelae include behavioural change and focal motor deficits (Domachowske et al. 1996).

OTHER CENTRAL NERVOUS SYSTEM PRESENTATIONS OF EBV INFECTION
EBV may cause aseptic meningitis with or without cranial nerve involvement (Hausler et al. 2002), affecting primarily the VIth nerve (Bell’s palsy) but also the optic and hypoglossal nerves. EBV-associated optic neuritis may be unilateral or bilateral; it is usually retrobulbar, but may also involve the chiasma (Beiran et al. 2000; Baskin and Hedlund 2007). The ‘Alice in Wonderland’ syndrome (Todd 1955) of perceptual distortions regarding the size, shape and colour of objects

Chapter 11 Infectious Diseases

Epstein–Barr virus in immunocompromised children

Viral reactivation is the likely aetiology when EBV CNS disease occurs in the immunocompromised. CSF is more likely to be acellular (Studahl et al. 2000). Very high levels of EBV DNA may be detected in the CSF in immunocompromised patients with CNS lymphoma (Weinberg et al. 2002). EBV-driven lymphoma is particularly associated with advanced HIV disease and may present as isolated CNS involvement or multi-system disease (Nadal et al. 1994). More effective treatments for EBV-driven lymphoma in HIV, including antiretroviral therapy, chemotherapy and immune modulators such as rituximab are now available.

EBV infection may be responsible for a severe and often fatal illness in certain families in which host susceptibility to EBV is transmitted as an X-linked character. This disease is known as the X-linked lymphoproliferative (XLP) syndrome (Grierson and Purtilo 1987) and variously features fatal infectious mononucleosis, malignant lymphoma, acquired hypo- or agammaglobulaemia, and virus-associated haemophagocytic syndrome (Tiab et al. 2000; Gilmour and Gaspar 2003). The gene defective in XLP has been identified and designated SH2D1A. It encodes an adaptor protein SAP [signalling lymphocytic activation molecule-associated (SLAM-associated) protein] and measurement of this protein can be used to diagnose the condition (Gilmour et al. 2000). XLP is associated with a high morbidity, and overall outcome is poor. At present, allogeneic stem cell transplantation is the only curative treatment (Lankester et al. 2005).

A similar syndrome of mono- or poly-clonal lymphocyte proliferation driven by EBV, known as post-transplant lymphoproliferative disease (PTLD), may occur in immunosuppressed patients, especially in transplant recipients (Randhawa et al. 1992). Post-transplant lymphoproliferative disease may present with multi-organ involvement, infrequently including the CNS. Brain involvement in transplant recipients with post-transplant lymphoproliferative disease carries a poor prognosis; however, isolated CNS involvement has a better prognosis than CNS plus extracranial involvement (Buell et al. 2005). It has been demonstrated, in a study of paediatric liver transplant patients, that monitoring of EBV viral load with early intervention can reduce the incidence of post-transplant lymphoproliferative disease (Lee et al. 2005). Combination treatment with antiviral therapy and the anti-B-cell monoclonal antibody rituximab has some efficacy (Nozzoli et al. 2006) and immunosuppression is reduced where possible.

Cytomegalovirus

Cytomegalovirus (CMV) is a major cause of congenital CNS infection, as described in Chapter 1. Postnatally acquired CMV is highly prevalent with 50–80% of the population seropositive in adulthood (Stahl et al. 2011). Primary infection is usually asymptomatic although an infectious mononucleosis-type illness may occur. The most important postnatally acquired CNS manifestation is encephalitis, which occurs almost exclusively in the immunocompromised (Arribas et al. 1996), in the context of systemic CMV reactivation. There is usually a high viral load in the blood, and end organ disease may occur in the brain, retina, lungs, bone marrow, liver and gut. Encephalitis may be generalised, with fever, headache and altered consciousness, or focal, with ventriculo-encephalitis, cerebral mass lesions and cranial neuropathies, especially in patients with HIV (Baskin and Hedlund 2007). CSF may be neutrophilic with low glucose, or acellular (Studahl et al. 2000); diagnosis relies on detection of cytomegalovirus DNA in the CSF by PCR. Neuroimaging may show cortical and subcortical areas of T2 hypertensity in the frontal and parietal lobes (Baskin and Hedlund 2007). Subependymal gadolinium enhancement is sometimes observed (Crawford 2010).

Other CNS manifestations of CMV in the immunocompromised host include cranial nerve palsies, transverse myelitis, radiculitis and retinitis. CMV retinitis is well recognised in advanced HIV infection; where this occurs in infants in contrast to adults or older children, the macula rather than the peripheral retina is first affected, causing immediate risk to central vision (Wren et al. 2004). CMV disease in the CNS, including retinitis, may become acutely symptomatic in patients with HIV once they start antiretroviral therapy as a manifestation of immune reconstitution inflammatory syndrome (IRIS). IRIS is more common in patients who start treatment with advanced disease and very low CD4 counts, and it requires careful management with treatment of the CMV, HIV and immune modulation to reduce symptoms (Griffiths 2004). There is also increasing interest in the role of CMV in neuro-oncogenesis following detection of the virus in a high proportion of glioblastomas (Baryawno et al. 2011) and medulloblastomas (Miller 2009; Lucas et al. 2011), with possible implications for pathogenesis and treatment (Soderberg-Naucler and Johnsen 2015).

Treatment of CNS cytomegalovirus with ganciclovir, foscamet or cidofovir may be effective (Avila-Aguero et al. 2003); however, these are toxic agents and require close monitoring. Ganciclovir is the first-line compound used, followed by foscamet and cidofovir; longer-term oral maintenance suppressive therapy can be considered with oral valganciclovir (Kimberlin 2002; Griffiths 2004). Success of therapy is monitored by end organ response as well as blood viremia level. Prognosis is guarded without improved immune function.
Rare cases of meningoencephalitis in immunocompetent children are usually self-limiting.

**Human Herpes Viruses 6 and 7**

The overwhelming majority of children around the world become infected with human herpes viruses 6 (HHV-6) and 7 (HHV-7) in the first two years of life (Caserta et al. 2001). Viral entry and shedding is via the salivary glands and latency is established in the salivary glands, T lymphocytes and brain. Primary infection is symptomatic in many children (Stahl et al. 2011). HHV-6 comprises two closely related species, HHV-6A and HHV-6B; the latter is well known as the cause of exanthem subitum (roseola infantum), and is also a major cause of febrile convulsions in children under two years of age. A small proportion of children infected with HHV-6 develop meningoencephalitis as an acute or (rarely) post-infective complication of primary infection. The natural history of primary infection with HHV-7 is less well understood, but may also be associated with exanthem subitum and CNS involvement (Ward 2005).

**HHV-6 Meningoencephalitis**

HHV-6 is implicated as a cause of viral encephalitis (Yao et al. 2009). Disease can be severe with ataxia and prolonged convulsions (Mannone et al. 2007). Diagnosis is challenging because HHV-6 is able to integrate into chromosomes in a significant proportion of the population, leading to chronic presence of high levels of viral DNA in CSF and other body fluids (Kneen et al. 2012), which may need to be excluded in suspected cases of HHV-6 meningoencephalitis. Quantitative PCR in blood and CSF can help distinguish acute infection from chromosomal integration (Ward et al. 2007). HHV-6 antibody reactivity in the CSF and peripheral seroconversion also support acute over latent infection. Neuroimaging may be normal or demonstrate abnormalities in the frontal lobes, medial temporal lobes, hippocampi and limbic system. Changes include oedema and increased T2 signal on MRI, usually without restricted diffusion (Baskin and Hedlund 2007). Treatment with ganciclovir or foscarin may be effective for confirmed cases (Solomon et al. 2007; Tunkel et al. 2008). Sequelae include persistent volume loss in the medial temporal lobes. HHV-6 has been frequently associated with parainfectious encephalopathy syndromes including acute necrotising encephalopathy (see section Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses); changes affecting the basal ganglia, striatum, thalami and brainstem have been described (Baskin and Hedlund 2007).

Febrile convulsions occur in up to 36% of primary HHV-6 infection in younger children (Hall et al. 1994). A UK prospective study of children under 3 years of age presenting with febrile convulsions found 17% had primary infection with either HHV-6 or HHV-7 (Ward et al. 2005). HHV-6B is particularly associated with febrile convulsions and in some cases is isolated from the CSF (Theodore et al. 2008). HHV-6B is also implicated in mesial temporal lobe epilepsy; one series of children undergoing surgical resection for mesial temporal lobe epilepsy found evidence of active HHV-6B replication in almost half the samples (Fotheringham et al. 2007).

**Human herpes viruses 6 and 7 in immunocompromised children**

HHV-6 reactivation occurs commonly in the immunocompromised, including nearly 50% of bone marrow recipients and 20–30% of solid organ transplant recipients. Complications appearing 2–3 weeks following the procedure may include fever, rash, pneumonia, bone marrow suppression, graft rejection (Yoshikawa 2003) and, rarely, encephalitis. Symptoms of the latter include altered consciousness, seizures and headache. Prompt treatment with ganciclovir or foscarnet reduces mortality (Singh and Paterson 2000). HHV-6 is the major cause of post-transplant acute limbic encephalitis (PALE) (Seeley et al. 2007). Development of limbic encephalitis is associated with high viral load post-transplant (Ogata et al. 2006). HHV-7 viraemia after stem cell transplant has also been associated with encephalitis (Chan et al. 2004).

**Enteroviruses**

Enteroviruses are small, single-stranded RNA viruses in the Picornavirus family. Most enterovirus infections are asymptomatic but they also cause a range of common and mostly benign illnesses in children worldwide. Neurological involvement occurs in a small proportion of cases, ranging from self-limiting aseptic meningitis to poliomyelitis and brainstem encephalitis with significant morbidity and mortality.

A revised taxonomy of enteroviruses based on genomic analysis names 12 species (enteroviruses A to J and rhinoviruses A to C) within the genus. However, the 90 plus serotypes identified to date (Abzug 2014) are usually organised for clinical purposes into the traditional groupings of coxsackie viruses (A and B), echoviruses, polioviruses and the numbered enteroviruses. The spectrum of tropism for each enterovirus is considerable and many can cause neurological disease (Rhoades et al. 2011).

Transmission of enteroviruses is usually via the faecal–oral route although respiratory transmission also occurs. Neonates can acquire infection perinatally via the ascending or transplacental routes, during delivery, and possibly postpartum from breast milk (Tebruegge and Curtis 2009). Enteroviruses can survive on household surfaces at room temperature for several days. After replication in the gastrointestinal or respiratory lymphatic tissue during an incubation period lasting 3–10 days, the virus may cause one or more periods of viraemia, leading to biphasic illness in some cases. Further replication in other organs (depending on serotype) can be damaging to the host leading to myocarditis, hepatitis, pneumonitis and other manifestations. Enterovirus serotypes vary in their neurovirulence. CNS infection is thought to occur via haematogenous
spread, either by direct viral penetration of the blood–brain barrier or via ‘Trojan horse’ infection of immune cells (Rhoades et al. 2011). Certainly enteroviruses tend to preferentially affect the more vascular parts of the brain, especially the brainstem. An alternate mechanism for the brainstem and anterior horn cell tropisms demonstrated by enteroviruses may be retrograde axonal transport of virus through the cranial and spinal nerves from infected muscle (Gromeier and Wimmer 1998). Once inside the CNS, enteroviruses can have a highly cytotoxic effect on host cells, inducing transcriptional shutdown and apoptosis (Rhoades et al. 2011). In addition to their direct cytotoxic effect, enteroviruses have also been reported as triggers of an ADEM presentation (Agin et al. 2010; Pillai et al. 2015).

Host factors are important in determining the severity of infection. Immunocompromised children with X-linked hypogammaglobulinaemia and T cell disorders are especially susceptible. Infants are another at-risk group; transplacental enterovirus-neutralising antibodies confer some protection to neonates encountering serotypes their mothers have previously been exposed to, but the range of circulating serotypes is large and changeable (RNA viruses demonstrate high rates of mutability and rapid antigen divergence) and maternally-derived enterovirus antibody levels fall to undetectable levels in 99% of infants by the age of 6 months (Luo et al. 2009). There have been rare cases of enterovirus encephalitis following therapeutic B-lymphocyte depletion therapy with rituximab (Quartier et al. 2003). Genetic factors may influence host susceptibility to enterovirus infection even in otherwise immunocompetent individuals. The HLA-A33 haplotype, which is more common in Asian people, confers increased susceptibility to enterovirus 71 infection (Chang et al. 2008). Enterovirus infection of the CNS occurs more often in boys than in girls.

**Nonpolio enteroviruses** comprise over half of all laboratory-proven viral meningoencephalitis in the UK (Kadambari et al. 2014). The majority of children present with self-limiting meningitis only. However, in vulnerable groups (i.e. infants and the immunocompromised), enteroviruses may cause life-threatening neurological infection, and certain strains (e.g. enterovirus 71) are increasingly recognised as causes of life-threatening encephalitides even in the immunocompetent. The present section concerns those patients presenting with neurological disease other than simple meningitis, the features and management of which are discussed in the Viral Meningitis section.

**Clinical features of enterovirus infections**

Enteroviruses cause a wide range of non-neurological clinical manifestations including gastrointestinal and respiratory illness and nonspecific febrile illness. Several serotypes are associated with a maculopapular exanthem (e.g. echovirus 4, 9 and 16; coxsackie viruses A9 and A23) and petechial rashes have also been reported. Hand, foot, and mouth disease, outbreaks of which occur sporadically in many parts of the developed and developing world, is caused mostly by coxsackie viruses A6, A10, A16 and enterovirus 71. Several strains are associated with acute and persistent diarrhoea in young children (Rao et al. 2014). Other manifestations of enteroviral infection include haemorrhagic conjunctivitis (enterovirus 70); herpangina, parotitis (enterovirus 71, group A coxsackie viruses) and pleurodynia and myocarditis (group B coxsackie viruses). Enterovirus 68 has re-emerged as a cause of fatal paediatric respiratory infections in Asia, Europe (CDC 2011) and recently North America (Stephenson 2014). Enteroviruses are an important cause of neonatal sepsis, mostly causing a benign febrile illness, but in a proportion leading to disseminated infection and multisystem manifestations including meningoencephalitis, myocarditis, pneumonia and coagulopathy (reviewed in Abzug 2014). Neonates at risk for severe disease include those with (1) onset in the first few days of life, (2) maternal illness at or before delivery, and (3) infection by echovirus 11 or coxsackie B viruses. Immunocompromised older children may present in a similar manner to neonates with disseminated multisystem infection.

Neurological manifestations of nonpolio enteroviruses include a poliomyelitis-like acute flaccid paralysis (coxsackie A4, A7, A9, A24, B5; echovirus 9, 11, 18; enterovirus 68, 70, 71, 75) (Kelly et al. 2006; Pfeiffer et al. 2015); GBS and transverse myelitis (coxsackie A9, B1, B4; echovirus 6; enterovirus 70); and cerebellar ataxia (coxsackie A4, A7, A9, B3, B4; echovirus 6, 9; enterovirus 71) (Fig. 11.13). Many serotypes – especially the coxsackie viruses and enterovirus 70, 71 and 75 – also cause meningoencephalitis, with a spectrum of disease ranging from ‘pure’ encephalitic disease to ‘pure’ meningitis. These frequently occur in outbreaks where only a small proportion of individuals have the more severe encephalitic presentation (Huang et al. 2003). Encephalitis accounts for only 3% of neurological enterovirus infections (Stahl et al. 2011) but a much larger proportion of the morbidity and mortality.

Enterovirus 70 and 71 have a particularly strong neurotropism. The latter (EV71) may present with neurological manifestations including meningoencephalitis, transverse myelitis, opsoclonus–myoclonus, cerebellitis and GBS in up to one-third of children with hand, foot and mouth disease (Tyler 2009), although most series report a neurological complication rate of 9–15% (Prager et al. 2003; Lee et al. 2013) and severe disease in less than 1% (Ho et al. 1999). Variations in neurovirulence may be due to different genetic subtypes. Since first being isolated in 1969, EV71 has steadily expanded its range (Tyler 2009) with major paediatric outbreaks in Bulgaria, Hungary, Taiwan, Japan, Korea, Singapore, Australia, Vietnam, Brunei, India, Malaysia and Cambodia (Wilson 2013; Abzug 2014). The largest known epidemics in recent years have been in China, where EV71 is the most common enterovirus serotype isolated from the stools of healthy children of anterior horn cell disease. Respiratory failure (Wu et al. 2013), and annual outbreaks caused 876 deaths from 2008 to 2010 (Tan et al. 2011). Smaller pockets of disease have occurred in North America, Western Europe and the UK (reviewed in Abzug 2014).

The most devastating manifestation of EV71 is a brainstem syndrome with high fatality characterised by rhomboencephalitis with associated cardiac failure, neurogenic pulmonary oedema and/or acute flaccid paralysis (Chen et al. 2007).
Preschool children are most commonly affected. Pathological findings are of cavitating lesions in the brainstem with direct invasion of virus. Cardiorespiratory failure is not due to direct viral invasion in most cases (Fu et al. 2004); the pathogenesis is not fully understood but is thought to result from some combination of systemic cytokine response and damage to the respiratory and vasomotor centres in the brainstem, leading to increased pulmonary permeability and systemic vasconstriction, with subsequent pulmonary oedema and left ventricular dysfunction (Solomon et al. 2010). Pulmonary complications can appear as early as day 2–3 of illness (Prager et al. 2003). The neurological features are those of a brainstem encephalitis syndrome (see Brainstem Encephalitis in the Viral Encephalitis section). Recurrent or sustained seizures are unusual and may indicate involvement of brain regions other than the brainstem, such as the hippocampus, cerebral cortex, thalamus, putamen and subcortical white matter (Lee et al. 2013).

**Diagnosis of Enterovirus Infections**

Enterovirus may be detected in a range of specimens including CSF, serum, urine, stool, vesicle fluid and swabs of the rectum, throat and nasopharynx. Detection of virus by real-time PCR is quicker and more sensitive than by culture (Abzug 2014) and can be used for strain-specific genotyping (Mirand et al. 2008). Although detection of virus in the CSF or brain is the criterion standard for diagnosis of enterovirus meningoencephalitis, the diagnostic yield may be higher from other sites including the throat, rectum and vesicles (Lee et al. 2006). If available, vesicle fluid is an especially useful sample, as it is always indicative of acute infection, unlike virus in the throat or gastrointestinal tract which may represent chronic viral carriage (Ooi et al. 2010). Serum IgM is of little value in diagnosing enterovirus encephalitis (Fowlkes et al. 2008).

In EV71 encephalitis, the CSF typically shows ten to 100 white blood cells per mm$^3$, predominantly lymphocytes, although pleocytosis may be absent. MRI typically shows characteristic T2- and FLAIR-hyperintensity in the dorsal pons and medulla, with changes also reported in the midbrain and dentate nuclei of the cerebellum (Shen et al. 1999) (Fig. 11.18). In some cases of EV71 brainstem syndrome, the neuroimaging is normal (Lee et al. 2013). Those with a poliomyelitis-like acute flaccid paralysis may show anterior horn cell hyperintensity and T1 enhancement in the ventral spinal roots (Abzug 2014).

**Management of Enterovirus Infections**

In the absence of any currently approved specific antiviral therapy (Abzug 2014), the mainstay of care is supportive. Intensive care therapies are often required to manage the EV71 brainstem syndrome, with particular focus on management of cardiac and pulmonary involvement, which can progress rapidly to cardiorespiratory collapse (Prager et al. 2003).

Treatment with pleconaril and IVIg has been tried in paediatric EV71 encephalitis (Nolan et al. 2003). Pleconaril is a drug that integrates into the capsid of enteroviruses, preventing the virus from attaching to cellular receptors and releasing viral RNA into the cell. There is some randomised controlled trial evidence for its efficacy in aseptic meningitis in adults (Desmond et al. 2006) but there have been no trials assessing its role in enterovirus encephalitis and it is not widely available (Kneen et al. 2012). Enteroviruses require neutralising antibodies to clear so it is reasonable to consider the use of IVIg in the moribund patient. Although there is no randomised controlled trial evidence to support this, there was a suggestion of benefit in a recent Taiwanese outbreak (Ooi et al. 2010). Clinical trials of a hyperimmune IVIg from Chinese donors with high titres of EV71 antibody are in progress (Cao et al. 2011) and several other candidate drugs have been identified for development (Abzug 2014). The success of the global poliovirus vaccination effort has prompted consideration of vaccination programmes against other enteroviruses. The large number of circulating strains presents a considerable challenge for vaccine design (Rhoades et al. 2011). Recently three candidate vaccines for enterovirus 71 have shown efficacy in phase 3 clinical trials, and two have subsequently been approved by regulatory authorities in China (reviewed in Reed and Cardosa 2016).

**Outcome of Enterovirus Infections**

Focal enterovirus encephalitis is particularly associated with the EV71 brainstem syndrome (Fowlkes et al. 2008). Peak mortality is in those aged 6–12 months (Ho 2000). The majority of fatal cases are associated with left ventricular failure, pulmonary oedema or haemorrhage (Ho et al. 1999; Fu et al. 2004).

Survivors of EV71 brainstem encephalitis with cardiopulmonary failure have a high rate of sequelae including limb weakness, swallowing difficulties, developmental delay and reduced cognitive function. Children with enterovirus 71 meningoencephalitis without cardiopulmonary involvement had a much better outcome, with developmental delay in only 5% of cases (Chang et al. 2007).

Imported poliomyelitis should be considered in Western travellers returning from these regions (Stewardson et al. 2009).

Cases of paralytic poliomyelitis following immunisation with the oral live vaccine (Sabin type) have been reported in immunodeficient patients; for example, those with T cell disorders or X-linked hypogammaglobulinaemia, and in immunodeficient contacts of vaccine recipients (CDC 2012a). Such individuals may develop neurological symptoms many years after exposure due to genetic reversion of vaccine virus to neurovirulence (DeVries et al. 2011). Nonimmunocompromised children can also rarely be affected by vaccine-derived paralytic poliomyelitis and some strains with reacquired neurovirulence have the capacity to circulate and infect others. Most industrialised countries now use inactivated polio vaccine in their routine immunisation schedules to avoid the problem, termed vaccine-associated paralytic poliomyelitis (Abzug 2014).

The pathological lesions in poliomyelitis involve the anterior horn cells, the motor and sensory cranial nuclei of the medulla,
the reticular formation, the cerebellar vermis and, to a lesser extent, the thalamus and layers III and V of the motor cortex. An isolated bulbar form rarely occurs. Neurons undergo degenerative changes accompanied by an initially polymorphonuclear reaction, which later becomes mononuclear.

The clinical manifestations of poliomyelitis appear after an incubation period of 3–35 days. Initial symptoms consist of headache, vomiting and fever, followed, within 2–5 days, by signs of meningeal irritation and severe pain in the lower back and limbs. Asymmetrical flaccid paralysis appears during the first two days of the major illness and involves the legs, arms and/or trunk, with absent tendon reflexes. All cranially innervated muscles may be affected. Urinary retention is present at onset in 20–30% of cases. Sensory loss is unusual. The polioviruses have a broad range of neurotropisms (Rhoades et al. 2011) and can infect most parts of the CNS; hence, poliovirus may present with features of encephalitis in addition to those of anterior horn cell disease. Respiratory failure may be secondary to brainstem involvement or paralysis of the diaphragmatic and intercostal muscles.

Examination of the CSF typically shows 30–200 white cells per mm³. Initially, these are predominantly polymorphonuclear cells, followed after 5–7 days by a lymphocytic pleocytosis. The protein content rises late, reaching a maximum around the twenty-fifth day of illness. MRI changes in the anterior horn of the spinal cord and bilateral substantia nigra have been reported (Choudhary et al. 2010). Before clinical onset the virus can be isolated from the stools and oropharynx as early as 19 days and as late as 3 months after the first clinical features (mean 5 weeks). Typing of the virus shows one of the three types of poliovirus. Serological diagnosis is made by demonstration of an elevation of the titre of neutralising or complement-fixing antibodies.

The differential diagnosis includes GBS, although this is usually easily distinguished due to its differing pattern of onset, symmetrical distribution of weakness and CSF findings. Other enteroviruses have also been reported to cause a polio-like illness (Kelly et al. 2006). Arboviral infection with West Nile virus (see West Nile Virus section) or tick-borne encephalitis virus (see Tick-Borne Encephalitis Virus section) can also present as acute flaccid paresis. Cases of intoxication by chemicals may clinically mimic the condition (Gear 1984). Infant botulism (see Botulism section) should also be considered as a cause of acute flaccid paralysis (Kelly et al. 2006).

There are no effective antiviral treatments for poliovirus. Supportive management may include mechanical ventilation in cases of paralytic poliomyelitis with respiratory failure. The prognosis of paralytic poliomyelitis depends on the extent of involvement, with death from respiratory muscle paralysis in 5–10% (McFee 2013). Recovery in some affected muscles is observed for up to one year or more, but muscles remaining completely paralysed after one month usually remain so indefinitely. A progressive motor neuron disease (post-polio syndrome) resembling amyotrophic sclerosis is sometimes observed in adults 20 or more years after an acute attack (Dalakas et al. 1986).

Parechoviruses

Although assigned to a different genus in 1999 (formerly echovirus 22 and 23), the parechoviruses are included here due to their clinical similarity to the enteroviruses. They share with enteroviruses a faecal–oral/respiratory mode of transmission. Rates of infection vary significantly year by year; in outbreak years, parechovirus may be more common than enterovirus as a cause of CNS infection in at-risk groups such as young infants (Harvala et al. 2009). Like the enteroviruses their neurological presentation is mostly with aseptic meningitis, although encephalopathy can occur in the context of a disseminated infection. CSF pleocytosis is unusual. Three-quarters of meningitis and/or encephalitis cases occur in infants; human parechovirus type 3 is implicated in severe neonatal disease with sepsis, encephalitis and hepatitis (Harvala et al. 2010). Parechoviruses can also cause white matter injury in infants (Verboon-Maciolek et al. 2008; Gupta et al. 2010b). Parechovirus testing should be considered in all children less than 3 years of age presenting with suspected meningitis and/or encephalitis. There is no specific antiviral treatment.

Respiratory Viruses

Respiratory infections are a common antecedent to encephalitis in children. Some cases are caused by *Mycoplasma pneumoniae* and streptococcal species but the majority are viral infections including the influenza viruses, adenoviruses and respiratory syncytial virus (see Paramyxoviruses section for the latter). Respiratory-virus-associated encephalitis shows a predilection for the thalami and basal ganglia on neuroimaging, accounting for 44% of such findings among cases in the California Encephalitis Project (Beattie et al. 2013). Many respiratory viruses – particularly the influenza viruses – are also associated with a range of para-infectious encephalopathies (see Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses section). Encephalopathy occurring in the context of recent or concomitant respiratory tract infection should prompt PCR testing for respiratory viruses in the CSF and respiratory tract, which may include samples of the sputum, nasopharyngeal aspirates, tracheal aspirates and throat or nasal swabs as appropriate (Kneen et al. 2012). PCR detection of aerosolised respiratory viruses in air is also possible and may become more widely available in future (Perrott et al. 2009).
Influenza A and B

Influenza A and B are the main disease-causing genera of RNA virus of the family Orthomyxoviridae. Although the majority of infants and children infected with influenza have a mild respiratory illness only, more severe manifestations of disease with encephalopathy are increasingly recognised. Encephalitis with direct invasion of the CNS is unusual as influenza has no known neurotropism. More common is influenza-associated encephalopathy in the absence of detectable virus in the CSF (Stahl et al. 2011). A spectrum of specific para-infectious acute encephalopathy syndromes has now been identified (see Table 11.13 and accompanying section). These are triggered by various viral infections but are especially associated with influenza, particularly acute necrotising encephalopathy (see Acute Necrotising Encephalopathy section) (Tsai and Baker 2013; Goenka et al. 2014). Pathogenic mechanisms are not well understood but there is evidence of increased pro-inflammatory cytokines in the serum and CSF of some children with neurological manifestations of influenza, with higher levels in those with fatal outcome (Ichiyama et al. 2004; Tokashi et al. 2004; Hosoya et al. 2005; Nunoi et al. 2005).

The encephalopathies present as acute deteriorations in consciousness in the context of influenza infection, ranging in severity from mild (febrile seizures, delirium) to devastating (coma with malignant brain oedema and haemorrhagic necrosis) (Goenka et al. 2014). Seizures occur in up to two-thirds of cases (Surana et al. 2011, Ekstrand 2012). Influenza infection precedes neurological symptom onset by 1–14 days (median 3) (Amin et al. 2008). Japanese children appear to be particularly susceptible (Sugaya 2002). The emergence of influenza A(H1N1) in 2009 heralded an increased rate of neurological complications; even outside Japan, 6–19% of children hospitalised with H1N1 suffered neurological manifestations (Ekstrand et al. 2010; Farooq et al. 2012; Khandaker et al. 2012), although this still represents only 1.2 per 100 000 infections (Glaser et al. 2012). Interestingly, a 17-fold increase in incidence of paediatric necrolysis was observed in Finland in 2010 following H1N1 pandemic vaccination in 2009 (Partinen et al. 2012). The seasonal influenza vaccine is considered safe (Tsai and Baker 2013).

A recent British population-based study reported 12 children with influenza-associated encephalopathy and 8 with encephalitis over 2 years surveillance (Goenka et al. 2014). Median age was 4 years and 28% of children had pre-existing neurological conditions. Eighty per cent of patients required admission to an intensive care unit; 84% of patients had influenza A in their respiratory secretions, of which 95% was the H1N1 subtype. CSF pleocytosis was observed in three patients only. Two-thirds of patients had abnormal EEGs. Neuroimaging was diagnostic of a specific acute encephalopathy syndrome in five children and nonspecifically abnormal in a further five.

Initial investigation is as for any acute encephalopathy (Table 11.8). Virological diagnosis is based on virus isolation or antigen detection from respiratory secretions, or seroconversion (Studahl 2003). Laboratory investigations should also include coagulation, hepatic and renal profile, with a low threshold for metabolic screening including serum ammonia, and urine amino- and organic acids. T1, T2 and diffusion-weighted magnetic resonance sequences are recommended for identification of acute encephalopathy syndromes with specific clinical and prognostic implications (see Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses section). Recurrent or familial cases of AFE should be tested for RANBP2 mutations (see Acute Necrotising Encephalopathy section) (Singh et al. 2015).

In the absence of any proven specific therapies (Goenka et al. 2014), management of influenza-associated encephalopathy is largely supportive, although treatment with the neuraminidase inhibitor oseltamivir may be helpful if started promptly in H1N1 infection (within 48–72 hours of symptom onset) (Straumannis et al. 2002; Crawford 2010). CSF penetration is poor but severity of systemic disease may be reduced. Oselatamivir-resistant H1N1 may be treated with zanamivir (van der Vries et al. 2010). Early administration of steroids may be beneficial in AFE (Okumura et al. 2009). IVlg is sometimes given in the severely unwell but the benefits have not been proven. Plasma exchange (Kawashima et al. 2005) and therapeutic hypothermia (Yokota et al. 2000) have also been tried. Overall outcome in the British series of influenza-associated encephalitis and encephalopathy was poor in two-thirds, including death in 16% of cases (Goenka et al. 2014). A smaller European series reported full recovery in two of five cases (Surana et al. 2011).

Adenoviruses

The genus Mastadenovirus (family Adenoviridae) includes more than 50 serotypes of double-stranded DNA virus known to cause disease in humans, ranging from mild respiratory, gastrointestinal, pharyngo-conjunctival and urinary tract infections to hepatitis, pancreatitis, nephritis, myocarditis and disseminated infection with multi-organ failure (Goncalves and de Vries 2006; Lynch et al. 2011). They are included in this section as respiratory viruses as this is the most common presentation in children. CNS manifestations of adenovirus infection also vary widely and include aseptic meningitis (de Ory et al. 2013), myelitis, subacute focal encephalitis, and acute encephalopathy syndromes ranging from transient and mild (Strausberg et al. 2001) – for example, clinically mild encephalitis/encephalopathy with reversible splenial lesion (MERS) (see Clinically Mild Encephalitis/Encephalopathy with Reversible Splenial Lesion section) (Takanashi 2009) – to severe, including Reye syndrome and haemorrhagic shock and encephalopathy syndrome (HSES) (see Haemorrhagic Shock and Encephalopathy Syndrome section) (Gefen et al. 2008). CNS involvement is relatively rare in immunocompetent children. Serotypes vary in their neurotropism. CNS involvement is more commonly reported with serogroup B1, followed by serogroup A and serogroup C (Reyes-Andrade et al. 2014). Serotype 7 is associated with meningoencephalitis with a rather severe course.
Chapter 11 Infectious Diseases

Most children with CNS involvement are younger than 5 years and present with co-existing respiratory symptoms (Reyes-Andrade et al. 2014). Severe adenovirus infection in the immunocompetent may mimic bacterial sepsis with significantly elevated acute phase reactants (Chuang et al. 2003) and petechial rash (Schneider et al. 2013). Neurological features are highly variable but may include seizures, encephalopathy, irritability, psychosis and hallucinations, meningism and weakness. Cerebral infarction is reported in some cases. Diagnosis is most commonly by detection of virus in samples from the nasopharynx, throat, sputum or stool. Viral detection by CSF PCR is diagnostic of meningoencephalitis and absent in para-infectious encephalopathies.

Management is largely supportive in immunocompetent children. Children with disseminated infection should be evaluated for immunocompromise and considered for treatment with cidofovir or ribavirin (Lynch et al. 2011; Reyes-Andrade et al. 2014). Novel therapeutic options include CMX001 (Tebruegge and Curtis 2012) and administration of antiviral-specific cytotoxic T lymphocytes (Leen et al. 2009). CNS manifestations of adenovirus are often reversible and follow a benign course (Straussberg et al. 2001). One series reported full recovery in 91% of cases (Huang et al. 2013). However, some cases are associated with permanent sequelae (Chuang et al. 2003), especially HSES (Gefen et al. 2008).

Respiratory Syncytial Virus

Respiratory syncytial virus (RSV) is a common cause of seasonal respiratory tract infection in infants and is associated with apnoea in up to 21% of cases, particularly in younger infants, which may be of central origin (Kneyber et al. 1998). Older children may present with febrile convulsions (Millichap and Millichap 2006). Encephalopathy has been reported in 0.3–1.8% of cases (Ng et al. 2001; Sweetman et al. 2005; Millichap and Wainwright 2009) although encephalitis is rare (Hirayama et al. 1999). Rates of neurological complications in children admitted to intensive care units with respiratory syncytial virus may be as high as 36.4% (Kho et al. 2004) and largely relate to hypoxic-ischaemic events and requirement for extracorporeal membrane oxygenation (Millichap and Wainwright 2009). EEG abnormalities are common and focal neurological deficits are also reported. Long-term sequelae occurred in 37% of cases in one intensive care unit series of respiratory syncytial virus with neurological manifestations (Millichap and Wainwright 2009).

Arboviruses as Emerging Infections

Arboviruses have a strong propensity to become emerging infections, that is, infections which acquire new hosts, spread into new territories, alter characteristics of their pathogenesis, or are caused by agents not previously recognised as pathogenic (Tyler 2009). Eighty per cent of emergent viruses are zoonotic and 40% of these are arboviruses (Taylor et al. 2001). Factors promoting the emergence of arboviruses include intensification of agriculture, close contact between animals and humans, and increasing population density (Tyler 2009). Novel viral infections are most likely to arise in Africa, Latin America and Asia (Jones et al. 2008). But the rapid spread of West Nile virus (WNV) across North America in 2002–3 (reviewed in Tyler 2009), and to a lesser extent the spread of Toscana virus in Europe, demonstrate the capacity for arboviruses to expand into new territories even in the West if amplifying hosts and vectors are available. Japanese encephalitis virus, tick-borne encephalitis virus, dengue and Chikungunya have also all re-emerged to some extent in recent years. Climate change, which has a major impact on the geographic range of arthropods, may push emerging arbovirus infections further into northerly latitudes in future (Patz et al. 2005). Up-to-date knowledge of local epidemiology and outbreaks is, therefore, essential for early identification of arbovirus infection, which may be easily missed in the UK and other countries where disease is not endemic. ArboZoonet is an EU-based international collaborative network that

**ARBOVIRUSES**

The arboviruses (arthropod-borne viruses) are the most important causes of encephalitis globally. The group is defined by the vector-borne mode of transmission (via mosquito, tick or sandfly bite) rather than by taxonomy, although all but one are RNA viruses belonging to one of four families: **Flaviviridae**, **Togaviridae**, **Bunyaviridae** and **Reoviridae**. Most are transmitted from vertebrate animals to humans (zoonotic), with bird or mammal reservoirs acting as amplifying hosts and humans usually dead-end hosts (Stahl et al. 2011). Dengue and Chikungunya are exceptions in which humans are the principal reservoir host. Seasonality of arboviral infection in endemic areas varies by vector and region; in addition, epidemics of infection across a larger geographical area may lead to significant year-to-year variations in incidence. Infection with arboviruses is usually asymptomatic or results in mild non-specific disease only; neurological manifestations occur even less commonly, ranging from aseptic meningitis and transient encephalopathy to severe and sometimes fatal encephalitis. For all arboviruses the presumed route of entry to the CNS is via penetration of the BBB. This is supported by an established predilection for the midbrain, thalamus and basal ganglia (suggesting haematogenous spread) (Beattie et al. 2013; Wilson 2013). Diagnosis of arboviral infection is more often achieved by detection of virus-specific IgM in serum or CSF rather than by PCR (Gaensbauer et al. 2014). Cross-reactivity between viruses is common and species-specific viral-neutralisation assays—that is, demonstrating the biological activity of patient-derived antibodies to reduce viral infectivity—are usually required to confirm the diagnosis, especially for flaviviruses (Stahl et al. 2011). Acute and convalescent blood samples are recommended in all cases of suspected arboviral infection (Kneen et al. 2012). There are no effective specific treatments currently available for any of the arboviral infections. Management is, therefore, supportive.

**Respiratory Syncytial Virus**

Respiratory syncytial virus is a common cause of seasonal respiratory tract infection in infants and is associated with apnoea in up to 21% of cases, particularly in younger infants, which may be of central origin (Kneyber et al. 1998). Older children may present with febrile convulsions (Millichap and Millichap 2006). Encephalopathy has been reported in 0.3–1.8% of cases (Ng et al. 2001; Sweetman et al. 2005; Millichap and Wainwright 2009) although encephalitis is rare (Hirayama et al. 1999). Rates of neurological complications in children admitted to intensive care units with respiratory syncytial virus may be as high as 36.4% (Kho et al. 2004) and largely relate to hypoxic-ischaemic events and requirement for extracorporeal membrane oxygenation (Millichap and Wainwright 2009). EEG abnormalities are common and focal neurological deficits are also reported. Long-term sequelae occurred in 37% of cases in one intensive care unit series of respiratory syncytial virus with neurological manifestations (Millichap and Wainwright 2009).
has been established to help monitor and control emerging arboviruses in future (Ahmed et al. 2009).

FLAVIVIRUSES

Japanese Encephalitis Virus

Japanese encephalitis virus (JEV) is the most common single cause of viral encephalitis worldwide, with at least 68,000 cases per year (Campbell et al. 2011) and some 15,000 deaths (Erlanger et al. 2009), mostly in children. The natural cycle of JEV has water birds as the principal host and Culex spp. mosquitoes as vectors. Pigs are an important amplifying host. In endemic areas, exposure of humans is ubiquitous by early adulthood, but only one in 300 exposures are symptomatic.

Pathophysiology of JEV

After the bite of an infected mosquito the incubation period is 6–16 days, during which time the virus amplifies peripherally in the skin and regional lymph nodes. Primary viraemia leads to seeding in extraneural tissues (muscle, lymphoreticular, endocrine, exocrine) and, in less than 1% of cases (Campbell et al. 2011), penetration of the CNS by haematogenous spread, involving especially the more vascular parts of the brain (thalami, basal ganglia and brainstem). Autopsy reveals an inflammatory response to widespread neuronal infection, predominantly affecting the grey matter, with foci of haemorrhage (Tiwari et al. 2012). Susceptibility factors for CNS involvement in JEV infection are not well understood but may include reduced blood–brain barrier integrity, for example, due to neurocysticercosis (Solomon et al. 2000a). Elevated CSF levels of pro-inflammatory cytokines and chemokines are associated with poor outcome; the extent to which the host immune response is directly pathogenic is not well understood (Winter et al. 2004).

Epidemiology of JEV

JEV has expanded its range west across the Indian subcontinent and south into Papua New Guinea and Northern Australia in recent decades. Nearly half the world’s population now lives in the region where JEV occurs (Erlanger et al. 2009), which is approximately bound by eastern Russia in the north, Australia in the south and Pakistan in the west (Stahl et al. 2011). Around half the total number of cases currently occur in China (Campbell et al. 2011) where the incidence is falling, but incidence is increasing elsewhere including Bangladesh, Northern India, Nepal and Vietnam (Jmor et al. 2008; Tiwari et al. 2012). Infection is endemic throughout the year in the tropical regions with summer epidemics further north. Most acute infections occur in the nonimmune (younger children or recent immigrants) with peak incidence at ages 3–6 years (Tiwari et al. 2012). Areas of rice cultivation and pig farming are high risk; intensification of agriculture is expected to contribute to increased transmission in a number of resource-limited Asian countries in future, including Cambodia, Laos, Burma and North Korea (Erlanger et al. 2009). Bird migration, irrigation projects, global warming and animal smuggling may also contribute toward future geographical expansion of JEV (Tiwari et al. 2012). Mass vaccination has proven highly effective at reducing disease incidence in Japan, Korea, Taiwan and Thailand; cost and competing healthcare priorities limit vaccination availability in poorer Asian countries, despite the strong case that has been made for the expansion of such programmes (Solomon 2006).

Clinical features

Symptomatic infections follow a series of clinical stages. A febrile prodrome of 2–3 days with headache (70%), abdominal pain and vomiting is succeeded by an encephalitic phase (5–7 days) with seizures (80%) and coma (80%) (Ooi et al. 2008); this is followed by a subacute phase (10–12 days) with dystonia (43%) and movement disorders including parkinsonism (45%) (Kumar et al. 2006; Basumatary et al. 2013). The final phase of gradual convalesence in survivors can take weeks to months. Other presentations include focal limb weakness (25%), cranial nerve palsies, status epilepticus and a poliomyelitis-like acute flaccid paralysis (Solomon et al. 1998; Gould and Solomon 2008). Older children may present with abnormal behaviour leading to misdiagnosis of primary psychiatric illness (Gould and Solomon 2008). Japanese encephalitis is more severe in younger children. Fatality peaks in the encephalitic phase and is associated with prolonged coma, status epilepticus and cerebral and/or pulmonary oedema (Tiwari et al. 2012).

Diagnosis of JEV

JEV may be isolated by viral culture of the peripheral blood in the first week of symptoms, although the relatively low viraemia limits sensitivity. In practice, diagnosis is more often achieved by detection of IgM in the serum and/or CSF. Presence of specific IgM in the CSF, and/or detection of virus by CSF PCR, is regarded as diagnostic. CSF rapid antigen detection using reverse passive haemagglutination, immunofluorescence and staphylococcal coagglutination is also available for both CSF and serum (Tiwari et al. 2012). CSF pleocytosis is observed in up to 82% of cases (Basumatary et al. 2013).

Brain MRI is abnormal in 90% of cases (Kastrup et al. 2008), bithalamic oedema with or without haemorrhage being the most common abnormality in children (Dung et al. 2009) (Fig. 11.19). Abnormalities may also be observed in the basal ganglia, brainstem, hippocampi, cerebral cortex and white matter (Nickerson et al. 2012). Atypical imaging findings may overlap with those of herpes simplex encephalitis (Basumatary et al. 2013).

Management and outcome of JEV

In the absence of any currently available curative treatments, management is focused on supportive care. Randomised
controlled trial of interferon alfa-2a in children with Japanese encephalitis failed to demonstrate improvement in outcome (Solomon et al. 2003), and nor is there any convincing evidence to support the use of ribavirin or dithiol. Trials of IVIg are in progress. Vaccination is effective in preventing the disease but availability in many affected countries is limited. Japanese encephalitis confers high mortality with rates of 20–30% (Solomon 2006; Campbell et al. 2011). Up to half of survivors suffer severe neuropsychiatric sequelae (Kumar et al. 2006) including seizures, tremors, ataxia and paralysis, or more subtle sequelae such as learning difficulties and behavioural problems (Lam et al. 2005).

Dengue

The four dengue virus subtypes are spread by the *Aedes aegypti* mosquito in tropical and subtropical regions worldwide. Dengue is unusual among flaviviruses in that humans are the principal vertebrate host. Infection is symptomatic in around a quarter of cases, causing fever, arthralgia and rash, with neurological involvement in 1–5% and encephalitis in less than 1% of symptomatic cases. A 30-fold increase in incidence over the past 50 years has led the WHO to declare it the world’s fastest growing vector-borne disease and warn of its pandemic potential (WHO 2012b).

**PATHOPHYSIOLOGY OF DENGUE ENCEPHALOPATHY**

Encephalopathy occurring in association with dengue can be caused by complications of systemic infection including shock; metabolic derangements such as hyponatraemia; hepatic failure; and intracranial haemorrhage (Carod-Artal et al. 2013). However in recent years evidence of direct neurotropism has accumulated. Dengue virus was isolated from the CSF in half of those with systemic dengue infection in one series (Araujo et al. 2012). Virus has been repeatedly isolated from brain tissue in fatal cases (Carod-Artal et al. 2013). Sequential infection with different serotypes increases the risk of severe disease.

**EPIDEMIOLOGY OF DENGUE**

Increasing urbanisation, international travel and climate change have led to the emergence or re-emergence of dengue across Asia and the Americas in recent decades. It is now endemic to over 125 countries with epidemics reported in Australia and North America (Misra et al. 2006); 96 million symptomatic infections occur annually, with the greatest numbers in the Indian subcontinent, Indonesia, Burma, Nigeria, China and Brazil (Bhatt et al. 2013). The rate of neuroinvasive disease may be increasing in recent years.

**CLINICAL FEATURES OF DENGUE**

In younger children dengue can produce an undifferentiated fever, but in older children and adults the typical dengue fever is accompanied by arthralgia and rash. Retro-orbital headache and photophobia may also occur. Symptoms usually last 2–7 days following an incubation period of 4–10 days; 1–10% of patients develop haemorrhagic fever with petechiae, gastrointestinal and gum bleeding, thrombocytopenia and increased vascular permeability. In dengue shock syndrome leads to circulatory failure.

CNS complications of dengue include dengue encephalopathy, encephalitis, and immune-mediated phenomena. Neurological features may be observed in as many as 21% of cases but most paediatric series report neurological manifestations in 0.5–5.4% (Solomon et al. 2000b; Cam et al. 2001; Panchareon and Thisyakorn 2001). Impairment of consciousness...
is the most common neurological manifestation and is probably more often caused by complications of systemic infection than by encephalitis. Other manifestations include headache, dizziness, disorientation, seizures and behavioural symptoms (Carod-Artal et al. 2013). Intracranial haemorrhage may occur in dengue haemorrhagic fever. Less common presentations include a fully reversible acute flaccid quadriparesis due to hypokalaemia (Gupta et al. 2011), and ischaemic stroke caused by cerebral vasculitis (Nanda et al. 2014). Dengue has also been linked to a range of post-infectious immune-mediated illnesses including transverse myelitis, acute disseminated encephalomyelitis, GBS and various mononeuropathies. Neuromuscular and neuro-ophthalmic complications also occur (Carod-Artal et al. 2013).

**Diagnosis of dengue**

Diagnosis of dengue fever can be confirmed by viral isolation (viral nucleic acid by PCR or viral proteins [NS1 antigen]) from peripheral blood in the first few days of illness or by elevated IgM thereafter. Definite categorisation into dengue encephalopathy or encephalitis is often challenging. The combination of pleocytosis and detectable virus in the CSF (by RNA, IgM or antigen detection) is helpful for diagnosis of the latter, although normal CSF cellularity does not exclude dengue encephalitis and the sensitivity of viral detection in the CSF is low (Carod-Artal et al. 2013). The presence of causative systemic complications is helpful for diagnosis of dengue encephalopathy. Neuroimaging in dengue may show cerebral oedema, but there are no specific neuroimaging features for dengue encephalitis and imaging is of limited use in diagnosis (Nickerson et al. 2012). EEG abnormalities (typically slowing) are present in up to half of patients with neurological symptoms (Kalita and Misra 2006) but these also do not discriminate between encephalopathy and encephalitis.

**Management and outcome of dengue**

There are as yet no effective antiviral therapies for treatment of dengue infection and management remains supportive. Patients with neurological involvement should be carefully assessed for correctable complications of systemic illness. At least six candidate vaccines are currently in clinical development and the Dengue Vaccine Initiative is coordinating efforts in developing countries. The outcome of dengue encephalopathy depends on the cause. The outcome of dengue encephalitis is variable but can be fatal.

**West Nile Virus**

West Nile virus (WNV) is another mosquito-borne flavivirus which has expanded its range in recent years, notably spreading across North America since 1999. Birds are the amplifying vertebrate host and *Culex* spp. mosquitoes are the principal vectors (Tyler 2009). Transmission has also been reported from organ donation (Iwamoto et al. 2003) and transplacentally (CDC 2002). Around 80% of infections are asymptomatic, 20% cause a nonspecific flu-like illness only, and less than 1% lead to neuroinvasive disease (Tyler 2009).

**Pathophysiology of WNV**

Animal models suggest haematogenous spread across the blood–brain barrier is the most likely route of entry to the CNS (Xiao et al. 2001). The mechanisms of CNS invasion in humans are incompletely understood. It is known that host genetic factors contribute to the risk of developing neuroinvasive disease (Glass et al. 2006). Direct viral invasion of neurons leads to damage by a combination of viral-mediated and immune-mediated mechanisms (Smith et al. 2014).

**Epidemiology of WNV**

WNV caused relatively mild outbreaks of febrile illness in Africa, the Middle East and Asia until the mid-1990s, when more severe outbreaks with higher rates of neuroinvasion began to occur in the Middle East and Eastern Europe (Smith et al. 2014). The virus first arrived in North America in 1999 and from New York spread rapidly across the continent in 2002–3. It has since spread to Latin America and the Caribbean. The virus is now considered endemic in the United States (Stahl et al. 2011); 5674 cases were reported in 2012, the highest since 2003 (Wilson 2013). Younger children are less likely to suffer symptomatic WNV infection than teenagers and adults, and the rate of neuroinvasive disease is also lower in children, although at least 505 paediatric cases occurred in the United States between 2003 and 2012 (Gaensbauer et al. 2014). Peak age of incidence for neuroinvasive WNV in children is 15–17 years. Incidence is highest in the North Central and Mountain regions. Smaller outbreaks continue to occur in Southern Europe including Romania, Bulgaria, Italy, France and Greece.

**Clinical features of WNV**

After an incubation period of 2–15 days WNV causes a nonspecific illness lasting 3–7 days characterised by high fever, headache, myalgia and fatigue (Smith et al. 2014). Vomiting and diarrhoea are prominent in around a quarter of patients. Physical examination may reveal a macular rash and lymphadenopathy. Fatigue can persist for several months.

Neuroinvasive WNV can cause the full spectrum of meningoencephalitis from pure encephalitis to pure meningitis. Onset of neurological symptoms may be during the febrile phase or delayed. Meningitis is the more common presentation in children and produces the usual symptoms of aseptic meningitis (see Viral Meningitis section) in addition to cranial nerve palsies (particularly the facial nerve) in around 20% of cases (Tyler 2009). WNV encephalitis is more serious, characterised by the usual fever, headache and encephalopathy, plus a range of movement disorders including myoclonus, tremor, parkinsonism and ataxia (Tyler 2009). Seizures are rare (Smith et al. 2014).

A poliomyelitis-like acute flaccid paralysis is also observed in 5–10% of patients with neuroinvasive disease (Sejvar et al. 2013).
2006), tending to occur either very early in the febrile phase of the infection or several weeks later (Smith et al. 2014). Weakness usually affects a single limb only but may be accompanied by facial weakness and/or respiratory muscle involvement. There may be associated pain but no sensory loss.

Other neurological complications of WNV include retinitis and retinal vasculitis is a common accompaniment to all manifestations of WNV neurological disease (Koevary 2005).

**Diagnosis of WNV**

Across the entire spectrum of WNV neurological disease the CSF is characterised by pleocytosis (initially polymorphonuclear in half of cases) and associated with elevated CSF protein in 70% of cases (Tyler et al. 2006). Molecular diagnosis of WNV infection is by antibody detection in CSF or serum, or by PCR detection of viral nucleic acid in CSF, blood or tissues. WNV IgM is detectable from day 3–8 of illness until around day 30–90. Detection of IgM in the CSF is indicative of intrathecal synthesis and therefore diagnostic of neuroinvasive disease. CSF:serum antibody ratio can be calculated. IgG seroconversion is supportive of recent WNV infection. Sensitivity of PCR reduces with increasing duration of illness; a negative result does not exclude WNV (Smith et al. 2014).

The neuroimaging findings in WNV encephalitis are nonspecific. CT is usually normal. T2-hyperintensity is observed on MRI in around half of cases, with changes in the basal ganglia, brainstem, cerebellum, mesial temporal lobe and periventricular white matter (Davis et al. 2006). Diffusion-weighted imaging is the most sensitive modality in early infection, demonstrating cortical and subcortical lesions with restricted diffusion (Kastrup et al. 2008). In cases of acute flaccid paralysis the anterior horns of the spinal cord may demonstrate T2-hyperintensity on MRI. Initial nerve conduction studies demonstrate reduced compound muscle action potential with preserved sensory potentials; later EMG may show evidence of denervation (Tyler 2009).

**Management and outcome of WNV**

No specific treatment is currently available beyond supportive care (Smith et al. 2014). Ribavirin and IVIg show promise but are yet to be supported by clinical trial evidence in adults or children. Prevention depends on vector mosquito control and public education. WNV encephalitis in adults has a mortality of 10–15% (Smith et al. 2014) but children appear to be less severely affected; mortality in a US cohort comprising roughly equal numbers of paediatric meningitis and encephalitis cases was only 1% (Gaensbauer et al. 2014). As many as 80% of WNV encephalitis survivors suffer long-term sequelae (Klee et al. 2004). The flaccid paralysis caused by WNV has a mortality of 10–50% and only one-third of survivors make a full or near-full recovery (Smith et al. 2014).

**Tick-Borne Encephalitis Virus**

Tick-borne encephalitis virus (TBEV) is endemic across much of Eastern Europe and Russia with a range extending from eastern France to Siberia and Japan. There are three main subtypes, all of which circulate in Europe, although the most severe strain occurs mainly in East Asia. The vectors of TBEV are ticks of the *Ixodes* genus. Humans are accidental hosts; rodents are the natural reservoir. Humans can also be infected by consumption of unpasteurised dairy products although this mode of transmission is not reported to cause encephalitis (Stahl et al. 2011). As with most arboviruses, the majority (70–95%) of infections are asymptomatic (Gritsun et al. 2003).

**Pathophysiology of TBEV**

The virus is transmitted from the salivary glands of the tick to the skin during the first few minutes of a blood meal. Initial replication occurs in the subcutaneous tissue and regional lymph nodes. Further replication occurs within circulating leukocytes during viraemia and the virus seeds numerous extraneural sites. CNS invasion occurs during viraemia via incompletely understood vascular mechanisms (Ruzek et al. 2010). Within the CNS, neuronal infection by TBEV induces an inflammatory reaction involving cytotoxic T cells (Gelpi et al. 2006) in which tissue and meningeal infiltration, perivascular cuffing, and (less commonly) infiltration of the nerve roots are observed (Jellinger 1981). Tissue necrosis occurs in affected areas in fatal cases.

**Epidemiology of TBEV**

In some regions of Russia, Latvia, Lithuania and Estonia, TBEV is the most common infection of the CNS, with incidence as high as 51 per 100,000 (Centre for Communicable Diseases and AIDS 2010). TBE also occurs in Germany, Austria, Czech Republic, Poland, Switzerland, Slovakia and Hungary (Kollaritsch et al. 2011). The ticks live in the moist undergrowth of forest floors and feed during spring and summer; hence, childhood presentation with TBE is more common during the summer months. The number of cases in Europe has increased by 400% in recent decades due to climate change and other factors (Suss 2008); around 2500 cases of TBE are recorded annually across the continent.

**Clinical features of TBEV**

TBEV in children is generally milder than in adults, although severe illness can occur, especially in vulnerable groups such as young infants (Leistner and Dahlem 2011). Less than half of cases present with a clear history of a preceding tick bite. An incubation period of 3 days to 3 weeks precedes onset of non-specific flu-like symptoms including fever, myalgia, arthralgia and headache. After up to a week of symptoms most patients then make a full recovery; however, 20–30% have a biphasic course with recurrence of fever after 2–10 days accompanied by neurological symptoms (Dumpis et al. 1999). Neurological disease is usually restricted to aseptic meningitis but encephalitis...
occurs in around one-third of children. The virus has a cerebellar tropism; ataxia is commonly seen in both the meningitic and meningoencephalitic presentations. Cerebral cortical involvement is usually restricted to the motor areas. Myelitis and meningoaraciduloneuritis are also reported, presenting with, for example, flaccid paresis of one or more limbs (classically upper). The more severe strains may have slower onset of neurological symptoms (Gould and Solomon 2008). Marked lethargy and sleepiness are described during recovery (Ruzek et al. 2010).

**Diagnosis of TBEV**

Diagnosis is by demonstration of anti-TBEV IgM in the CSF and/or serum, four-fold elevation in IgG across paired samples, or direct viral detection by PCR (Kollaritsch et al. 2011). The differential diagnosis of neurological symptoms following a tick bite in Europe includes ehrlichiosis and Lyme borreliosis (Cizman et al. 2000).

**Management and outcome of TBEV**

There is no specific treatment for TBEV (Ruzek et al. 2010). TBEV is a vaccine-preventable disease and immunisation should be offered to all children living in or travelling to endemic areas. Post-exposure immunisation is not capable of producing effective concentrations of neutralising antibodies and is not recommended, although completion of an incomplete course started prior to exposure may be considered (Broker and Kollaritsch 2008). Mortality is reported as 1–2% for the Western subtype but may be as high as 40% for the Far Eastern subtype (Mansfield et al. 2009). Persistent epilepsy, weakness and/or neuropsychiatric sequelae occur in around 10% of children affected by European strains (Haglund and Gunther 2003) and up to 60% of survivors of Far Eastern strains (Gould and Solomon 2008). Persisting neurological signs may represent chronic infection.

**Other Flaviviruses**

*St Louis encephalitis* virus is related to JEV and WNV but is only found in the Americas. Around 50 cases are reported annually in North America although epidemics affecting up to 800 per 100,000 people arise every 5–15 years (Gould and Solomon 2008). From 2003 to 2012 there were only four reported paediatric cases in the United States (Gaensbauer et al. 2014). *Culex* spp. mosquitoes are the vectors and birds are the reservoir host. The flu-like illness may be complicated by meningitis or encephalitis. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) is reported to occur in one-third of cases (Stahl et al. 2011). Mortality is less than 10%.

Powassan virus also causes CNS infection in North America where it is the only tick-borne flavivirus cause of encephalitis. It is closely related to the severe strains of TBEV that occur in eastern Russia. It is exceptionally rare with only eight reported paediatric neuroinvasive cases in the United States from 2003 to 2012 (Gaensbauer et al. 2014) but has a high fatality rate with severe sequelae in survivors (Stahl et al. 2011).

Louping ill virus is a UK relative of TBEV found in ticks of the Irish, Scottish, Welsh and English moorlands (Gould and Solomon 2008). It causes encephalomyelitis in sheep and very rarely in humans with one documented fatality (Davidson et al. 1991). Local TBEV lineages also occur rarely in forested regions of Spain, Norway, Turkey, Greece, Siberia and India (Gould and Solomon 2008).

Murray Valley encephalitis virus is transmitted by mosquitoes in Australia and New Guinea. It rarely produces a similar illness to JEV with mortality of up to 30% (MacKenzie 2005).

Zika virus, first documented in Uganda in 1947, was regarded as a relatively unimportant pathogen for many years. However, from 2007 it increased its geographical range to 52 new countries (Brouet et al. 2016) and became the focus of global media attention in 2015 when it was linked to a marked increase in congenital microcephaly in Brazil. The putative link between prenatal Zika virus infection and congenital brain anomalies (reviewed in Rasmussen et al. 2016; de Fatima Vasco Aragao et al. 2016) is beyond the scope of this chapter. Postnatally, Zika is transmitted to humans by mosquitoes mainly of the genus *Aedes*, or by human sexual contact. Symptoms are usually mild and nonspecific, including fever, rash, conjunctivitis, myalgia, malaise and headache, lasting for 2–7 days. The virus is neurotropic in animal models but its link to neurological disorders in humans remains controversial (Brouet et al. 2016). A case-control study of 42 adults presenting with GBS during a 2013–14 Zika outbreak in French Polynesia found serological evidence of Zika infection in all GBS cases versus 56% of controls, and evidence of recent infection (positive anti-Zika IgM) in 93% of cases versus 17% of controls. At population level, the peak incidence of GBS was found to follow the peak incidence of Zika by an interval of around 3 weeks (Cao-Lormeau et al. 2016). All other literature linking postnatally acquired Zika to neurological disorders is based on individual cases. Zika virus was detected by PCR in the CSF of a 15-year-old girl with acute hemiparesis and lesions in the cerebral and thoracic cord on MRI. She was given a short course of intravenous methylprednisolone and had reasonable recovery of neurological function (Mécharles et al. 2016). A case of meningoencephalitis associated with Zika infection was described in an 81-year-old man (Carteaux et al. 2016). Our understanding of Zika-associated neurological disease is expected to be refined in future following the WHO’s declaration of a Public Health Emergency of International Concern in February 2016.

**Togaviridae**

All togaviridae causing disease in humans are found in the genus *Alphavirus*.

*Eastern equine encephalitis virus* (EEEV) is the most neurovirulent of these. It is widespread in the eastern parts of Central and South America and is also found along the Atlantic and Gulf coasts of North America. Birds are the reservoir host in North America, while rodents and marsupials are the reservoir
in South America (Stahl et al. 2011). Throughout the Americas, mosquitoes are the vectors and both humans and horses are dead-end hosts. Most infections are asymptomatic but encephalitis caused by EEEV can be severe. In the United States it caused at least 30 paediatric encephalitis cases from 2003 to 2012, half of which occurred in children younger than 4 years (Gaensbauer et al. 2014). 90% of cases occurred in summer. Case fatality rate was 33% and disabling sequelae are reported in survivors.

Western equine encephalitis virus is a similar agent affecting the western half of the Americas. It previously caused more cases of encephalitis than EEEV (Arpino et al. 2009) but appears to have declined in recent years (Stahl et al. 2011) and is less neurovirulent with a fatality rate of 3–10%.

Venezuelan equine encephalitis virus is the third major alphavirus of the Americas. It is the least neurovirulent but is re-emerging in Brazil and other South American countries (Stahl et al. 2011). Rodents are the reservoir and new strains emerge frequently as large outbreaks in horses and humans, transmitted by various vectors (Powers et al. 1997).

Chikungunya is a mosquito-borne alphavirus endemic to sub-Saharan Africa and tropical Asia. Humans and other primates are the vertebrate reservoir host. A major re-emergence in 2004 began in Kenya and spread rapidly around the Indian Ocean to infect some 6 million people (reviewed in Das et al. 2010). The virus is now endemic in the Indian subcontinent (Pialoux et al. 2007). Cases have subsequently been exported to the UK and mainland Europe (Das et al. 2010) including a small outbreak in northern Italy (Rezza et al. 2007). Unusually for an arbovirus, infection results in symptomatic illness in more than 85% of cases (Stahl et al. 2011), with fever, rash, myalgia, headache, photophobia and a distinctively severe arthralgia. The fever is described as subsiding and recurring in a 'saddleback' pattern similar to dengue (Rajapakse et al. 2010). Fever resolves over weeks but arthralgia can persist for many months. Neurological manifestations, occurring in up to 61% of children aged more than 3 years (less in younger children) (Ernould et al. 2008), include acute encephalopathy, meningism, seizures, encephalitis and GBS (Wielanek et al. 2007; Robin et al. 2008). Excepting GBS, neurological manifestations begin in the first few days of illness, and CSF is usually unremarkable (Arpino et al. 2009). Diagnosis is by PCR identification of virus, elevated IgM or rising IgG. CNS co-infection has been described, particularly with dengue. CT and MRI are usually normal but may show generalised cerebral oedema; haemorrhages, white matter changes and ring-enhancing lesions have also been described (Rajapakse et al. 2010). EEG is usually abnormal in children, demonstrating frontal slowing, burst-suppression and paroxysmal polyspikes (Robin et al. 2008). Long-term sequelae including cognitive impairment and disorders of behaviour and communication occur in 10–25% of cases (Robin et al. 2008; Lewhrwaite et al. 2009). Death can occur, particularly in haemorrhagic cases, and in neonates affected by vertical transmission.

**BUNYAVIRIDAE**

La Crosse virus (LACV) is the most common neuroinvasive arboviral infection of children in North America with at least 665 cases from 2003 to 2012 – more than WNV (Gaensbauer et al. 2014). It is transmitted by the *Aedes triseriatus* mosquito; squirrels and chipmunks are amplifying hosts. Peak age of incidence is 5–9 years. Most infections occur in summer in forested areas of the Midwest and Appalachian regions. 78% of children present with encephalitis, 20% with meningitis and 2% with acute flaccid paralysis. The encephalitis has a mortality around 1% and results in epilepsy in some survivors. Related viruses to La Crosse virus include Jamestown Canyon and California encephalitis virus in the United States and Tähyna virus in Europe (Stahl et al. 2011).

The most important Bunyavirus in Europe is the Toscana virus, first isolated in 1971 (Tyler 2009). Sandflies are the vectors and possibly also the reservoir host (Stahl et al. 2011). Infections occur in Spain, Portugal, France and especially central Italy, where it is the most common cause of viral meningitis in the summer months (Charrel et al. 2005). Most infections cause a mild febrile illness only but the virus also has a neurotropism, causing mostly meningitis with associated tremors and myalgia (Tyler 2009). CSF typically shows a lymphocytic pleocytosis with elevated protein and normal glucose (diNicuolo et al. 2005). Encephalitis is rare and most patients make a full recovery. Related viruses to Toscana in Europe include the Sicilian and Naples viruses (Stahl et al. 2011).

**REOVIRIDAE**

The family *Reoviridae* includes coltiviruses and seadornaviruses. The most important of the former is Colorado tick fever virus, which is transmitted by high altitude ticks in North America. Squirrels and chipmunks are the reservoir hosts. Cases in humans occur in summer and cause encephalitis in 5–10% of symptomatic infections (more in children). Eyach virus is a related coltivirus implicated in similar presentations in France and Germany. The only important seadornavirus in humans is Banna virus, which is transmitted by mosquitoes in Southeast Asia. It is reported to cause encephalitis and may be misdiagnosed as JEV (Attoui et al. 2005).

**PARAMYXOVIRUSES**

Several single-stranded RNA viruses of the family *paramyxovi-rides* are associated with acute CNS disease in children.

**Measles Virus**

Primary infection with measles causes respiratory tract infection and the characteristic exanthem. The virus spreads by aerosolised droplets and is highly contagious. It causes over 145,000 deaths globally per year (Perry et al. 2014), largely due to pneumonia. There has been an increase in measles cases
across the UK and Europe in recent years due to reduced vaccination uptake; around 5% of 10–16-year-olds in England are currently unvaccinated (Simone et al. 2014). Neurological complications occur in a small proportion of cases, including two chronic encephalitides (measles inclusion body encephalitis and subacute sclerosing panencephalitis) which are discussed in the Chronic Viral Infections section. It is also the most common exanthematos cause of acute encephalitis.

**ACUTE PRIMARY MEASLES ENCEPHALITIS**

From the epithelial cells of the respiratory tract the virus spreads to local lymph nodes where secondary replication occurs, followed by invasion of the blood and other organs. Slight pleocytosis is sometimes observed during primary infection in the absence of neurological signs or symptoms. 1–3 per 1000 cases are complicated by direct CNS invasion of virus, i.e. primary encephalitis (Hosoya 2006). This typically occurs during the exanthematous stage of infection, although in some cases rash follows neurological involvement (Johnson et al. 1984), or does not occur at all (Wairagkar et al. 2001), especially in children with T cell immunodeficiencies (Sábella 2010). Neurological features include headache, encephalopathy, seizures, ataxia and weakness (Buchanan and Bonthius 2012). CSF analysis reveals marked lymphocytic pleocytosis with mild elevation of protein. PCR detection of measles virus in the CSF is diagnostic of primary meningoencephalitis. Detection of measles virus in urine by culture or PCR may be supportive in the absence of positive CSF (Kneen et al. 2012). MRI reveals focal hyperintensities on T2-weighted imaging. EEG may show diffuse slowing and focal or generalised epileptiform discharges. Raised intracranial pressure may occur as a result of brain oedema and lead to secondary brain injury (Bonthius and Karacay 2002). Treatment is supportive in the absence of any proven antiviral treatment, although ribavirin is effective against measles virus in vitro (Buchanan and Bonthius 2012). The course is often severe and may be fatal in up to 10–15% of cases (Perry and Halsey 2004). Learning difficulties, seizures and behavioural disturbances are common in survivors.

**ACUTE DISSEMINATED MEASLES ENCEPHALOMYELITIS**

Measles also causes post-infectious acute disseminated encephalomyelitis (ADEM) in 1 per 1000 cases, making it one of the most common causes of ADEM worldwide (Chowdhary et al. 2009; Reuter and Schneider-Schaullies 2010). Presentation is during the resolution phase or several weeks later (Buchanan and Bonthius 2012). Virus is not detected in the CSF. Clinical features and management of ADEM are discussed in Chapter 12. Outcome of measles-associated ADEM is better than for primary measles encephalitis. ADEM is also described following measles immunisation, albeit extremely rarely (one to two per million vaccinations) and usually in a milder presentation (Tenembaum et al. 2007).

---

**Mumps Virus**

Mumps virus is transmitted by inhalation of, or oral contact with, aerosolised droplets. Its principal primary manifestation is parotitis; it also causes orchitis and pancreatitis. Around one-third of infections are asymptomatic (Philip et al. 1959). The virus is highly neurotropic, accessing the CNS via the choroid plexus or transiting mononuclear cells (Rubin et al. 2015). CNS infection is the most common extrasalivary-gland manifestation of mumps (Hvïid et al. 2008) and it is one of the most common causes of aseptic meningitis in unimmunised populations. It is less commonly associated with encephalitis and para-infectious encephalopathy. The differential diagnosis of parotitis with CNS involvement includes EBV, influenza, para-influenza, HHV-6, coxsackievirus, adenovirus, parvovirus B19, lymphocytic choriomeningitis virus, HIV, bacterial infection, drugs and tumours (Davidkin et al. 2005; Hvïid et al. 2008).

Diagnosis of mumps meningoencephalitis is most reliably achieved by CSF PCR. Viral culture or PCR of buccal or parotid gland duct swabs (following 30 seconds of parotid gland massage) may detect the virus within 9 days of symptom onset, and urine samples for a further 5 days (Kneen et al. 2012). Infection may also be diagnosed serologically by measurement of specific IgM (Hvïid et al. 2008). Elevated serum amylase is commonly seen in acute mumps infection (Solomon et al. 2007).

**MUMPS VIRUS MENINGITIS**

Mild degrees of CSF pleocytosis are observed in up to half of all cases of mumps (Russell and Donald 1958), with clinical meningitis occurring in up to 10% (Rubin et al. 2015) and marked elevation of lymphocyte count in 0.5–2%. Onset of symptoms including headache, vomiting, neck stiffness and lethargy is typically 5 days after onset of parotitis, although parotitis may precede meningitis by up to 3 weeks, follow it by up to 1 week, or be completely absent (30–40% of cases) (Levitt et al. 1970). Symptoms peak at around 48 hours and resolve in 7–10 days (Hvïid et al. 2008). CSF lymphocyte count may be as high as several hundreds of cells per mm³. The glucose content may be reduced (Wilfert 1969). Mumps meningitis is a benign, self-limiting illness without mortality or long-term sequelae (Hvïid et al. 2008; Stahl et al. 2011), although obstructive hydrocephalus is reported as a rare complication (Yanofsky et al. 1981; Lahat et al. 1993). Pleocytosis may last for several months and there is protracted persistence of specific intrathecale-produced oligoclonal IgG (Vandvik et al. 1978a).

**MUMPS ENCEPHALITIS AND PARA-INFECTIONOUS ENCEPHALOPATHY**

Encephalitis occurs in up to 0.5% of mumps cases (Rubin et al. 2015) although severe disease is rare, occurring in one per 6000 cases or less (Cooper et al. 2007). Symptoms include seizures, alterations of consciousness and focal neurological signs (Koskineni et al. 1983). Predominant involvement of
the cerebellum is frequently observed (Cohen et al. 1992). Multifocal seizures are described (Parain and Boulloche 1988). Pathological findings include oedema and congestion throughout the brain with haemorrhage, lymphocytic perivascular infiltration and demyelination (Johnson 1982a; Rubin et al. 2015). Outcome is generally favourable in children and mortality is less than 1.5% (Hviid et al. 2008). Chronic infection may become established in some cases (Ito et al. 1991). Sequelae include sensorineural hearing loss (Hviid et al. 2008), ataxia and opsoclonus (Ichiba et al. 1988), vestibular neuritis (Thomke and Hopf 1992) and vertigo (Willfert 1969).

Mumps virus is occasionally associated with rapid onset of progressive coma and/or seizures early in the febrile illness with normal CSF, suggesting a para-infectious encephalopathy. CSF cytokine profile is similar to that seen in influenza-associated encephalopathy (Watanabe et al. 2013). Specific syndromes described include acute infantile bilateral striatal necrosis (IBSN) (Goutieres and Aicardi 1982), acute necrotising encephalopathy (Watanabe et al. 2013) and clinically mild encephalitisencephalopathy with reversible splenial lesion (MERS) (Takanashi 2009) (see section Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses). The latter is also described following mumps vaccination (Takanashi et al. 2015).

Henipaviruses

Nipah virus and Hendra virus are two zoonotic paramyxoviruses that emerged as causes of encephalitis in the 1990s and were classified together in a relatively recently identified genus called Henipavirus. In both viruses, bats are the reservoir and mammals are amplifying hosts (horses for Hendra virus, pigs for Nipah virus). For humans the principal groups at risk are those working closely with the amplifying hosts. Hendra virus has so far occurred only in Australia. Nipah virus emerged in Malaysia but has now spread throughout Southeast Asia where outbreaks occur annually, particularly in India and Bangladesh (Wilson 2013). A recent outbreak demonstrated human-to-human transmission via respiratory droplets (Sazzad et al. 2013) and the virus can present with respiratory symptoms. Both viruses cause a devastating encephalitis characterised by CNS vasculitis and brainstem involvement, with mortality of 40–75% (Eaton et al. 2006). Acute neuroimaging may reveal multiple small T2-hyperintensities throughout the cerebral white matter (Kastrup et al. 2008). Survivors suffer motor deficits (Goh et al. 2000) and chronic intraneuronal infection is described as a cause of relapse. A recent review of emerging infections flagged Nipah virus as a special threat in view of its high mortality rate, wide host range and ability to spread from human to human (Wilson 2013). Other henipaviruses circulate widely in African fruit bat populations and the continent is considered high risk for future emergence of henipaviruses infecting humans.

OTHER VIRUSES

Rabies Virus

Rabies is caused by several species or genotypes of Lysavirus, the most important of which in humans is genotype 1, also known as rabies virus. It is rare in industrialised countries but causes an estimated 50 000 deaths per year in Africa and Asia (Stahl et al. 2011). It is a non-arthropod-borne zoonotic virus transmitted to humans in the saliva of infected mammals (e.g. bats, dogs, foxes, cats, raccoons, etc.) via a bite or skin abrasion, and occasionally through intact skin or mucous membranes. A history of animal bite is absent in many cases (Fishbein and Robinson 1993). A small number of infections have been acquired via organ donation (Burton et al. 2005).

Viral replication in the skin is followed by retrograde axonal transport of virus along the peripheral nerve and eventually CNS invasion. The incubation period lasts between 10 days and 8 months. Severe bites to the face and neck are associated with shorter incubation time (Dimaano et al. 2011). A brief prodrome of fever and malaise precedes onset of neurological symptoms. In classic furious rabies (two-thirds of cases) the predominant feature is altered mental status (fluctuating delirium with intermittent agitation). Characteristic symptoms such as hydrophobia, aerophobia, hypersalivation, hyperacusis and pharyngeal spasms are striking but may be absent in some cases. Paralysis and respiratory failure may follow on from furious rabies, or may be the presenting neurological features in paralytic rabies (one-third of cases) (Hemachudha et al. 2013). Disease progression to coma and death is almost universal in symptomatic patients, although occasional cases of survival have been reported using modern intensive care support (Willoughby et al. 2005). Survival may be associated with the presence of neutralising antibodies in the CSF and non-Lysavirus 1 disease ( Wilde et al. 2008). In cases following organ donation, CSF analysis revealed mild pleocytosis, and MRI revealed T2-hyperintensity in the hippocampi, brainstem, temporal lobes and basal ganglia (Burton et al. 2005). Characteristic viral inclusions (Negri bodies) are found in the neurons, especially in the pyramidal cells of the hippocampus. PCR amplification and/or antigen detection can also be undertaken on brain biopsy, which should be considered in cases of encephalopathy where exposure may have occurred (Hughes et al. 2004).

When a suspected exposure has occurred, prevention of rabies may be achieved by rapid post-exposure prophylaxis, either passively with human rabies immunoglobulin, or actively with serial vaccination on days 0, 3, 7, 14 and 28 (Willoughby and Hammarin 2005). Pre-exposure prophylaxis is indicated in certain circumstances (occupational, travel).

Human Immunodeficiency Virus

Primary HIV-1 infection can present with an acute meningoencephalitis during seroconversion (Apoola et al. 2002), although it is unusual in children. HIV should be considered in
the differential diagnosis of aseptic meningitis if there are risk factors in the history. The effects of chronic HIV infection on the brain are discussed in the Chronic Viral Infections section.

**Parvovirus B19**

Parvovirus B19 is a ubiquitous DNA virus of the family Parvoviridae, 60% of adults have a history of previous exposure (Douvoyiannis et al. 2009). Most infections are asymptomatic but the virus is also well known as the cause of erythema infectiosum or ‘slapped cheek syndrome’ in children. In addition, parvovirus may account for up to 4–5% of undiagnosed meningoencephalitis in childhood (Barah et al. 2001). Around one-third of cases occur in the immunocompromised (Douvoyiannis et al. 2009; Barah et al. 2014). Susceptibility in immunocompetent children may be influenced by HLA genotype (Kerr et al. 2002) and host immune response may contribute to encephalopathy in some cases.

The most common CNS presentation is encephalitis (Barah et al. 2014). Classic erythema infectiosum rash is seen in only a third of cases, and even less in the immunocompromised. Neurological features are of a nonspecific encephalitis syndrome with or without cerebellar involvement. Onset of neurological symptoms may be before, during or after onset of rash. Parvovirus has a tropism for erythroid progenitor cells (Heegaard and Brown 2002) and 44% of children with encephalitis demonstrate anaemia (Barah et al. 2014); stroke secondary to aplastic crisis should be considered as a differential for neurological impairment in children with sickle cell disease (Douvoyiannis et al. 2009). CSF pleocytosis is observed in around half of encephalitis cases (Barah et al. 2014). Viral DNA is usually detected in the CSF and CSF anti-B19 IgM is detectable in one-third of cases (Douvoyiannis et al. 2009). Serum anti-B19 IgM may also support the diagnosis. MRI may be normal or demonstrate nonspecific white matter T2-hyperintensity and mild ventriculomegaly (Kerr et al. 2002; Douvoyiannis et al. 2009; Barah et al. 2014).

IVIg is often used in parvovirus infection to neutralise the virus, although the mechanism of action is not fully understood (Barah et al. 2014). Encephalitis cases are often treated with steroid and IVIg although evidence of efficacy is mixed (Douvoyiannis et al. 2009; Barah et al. 2014). Outcome is variable with up to 14% mortality and neurological sequelae including language impairment and developmental delay in up to 26% (Barah et al. 2014). Other reported CNS manifestations of parvovirus include aseptic meningitis (with good prognosis), transverse myelitis and Reye syndrome (Barah et al. 2014). Some cases of anti-NMDA receptor encephalitis may be triggered by parvovirus (Grillo and da Silva 2013).

**Rubella Virus**

Rubella virus is a single-stranded RNA virus of the family Togaviridae. Congenital rubella infection is a cause of severe neurological disease. Postnatally acquired infection, which is now rare in vaccinated settings, may be asymptomatic or cause an exanthematous febrile illness (German measles). Severe encephalitis is described in 1 per 5000 cases. The mechanism is unclear and may be due to direct invasion and/or be immune-mediated. It may occur simultaneously with the rash or up to a week later; rash may be absent in 15–19% of cases (Bahloul et al. 2013; Chaari et al. 2014). Clinical features include agitation, confusion and seizures. Severity is variable; comatose presentation requiring intensive care admission is described (Bahloul et al. 2013). Serum anti-rubella IgM is usually detected during the acute illness, and is also detected in the CSF in around half of cases (Bahloul et al. 2013). Detection of rubella in urine by culture or PCR may support the diagnosis (Kneen et al. 2012). Management is supportive only. Mortality in the modern era is 8–9.5% (Bahloul et al. 2013; Chaari et al. 2014) with full recovery reported in the majority of survivors.

**Rotavirus**

Rotavirus comprises five species of double-stranded RNA virus in the family Reoviridae. It is the most common cause of childhood gastroenteritis worldwide (Parashar et al. 2003). Rotavirus infection was previously thought to be restricted to the epithelial cells of the gut, but following findings of circulating rotavirus antigen and RNA in the majority of infected children (Blutt et al. 2003), it is now understood as the cause of a range of extra-intestinal complications (Blutt and Conner 2007). Neurological manifestations include meningoencephalitis, encephalopathy, cerebellitis and seizures. The mechanisms of CNS involvement are not fully understood. Some cases are likely due to direct viral invasion, as suggested by the presence of rotavirus RNA in the CSF, but others may be para-infectious phenomena induced by the rotavirus enterotoxin NSP4 (Dong et al. 1997; Estes and Morris 1999), leading to neuronal cell membrane destabilisation (Tian et al. 1996), elevated CSF nitric oxide levels (Kawashima et al. 2004) and/or neuroinflammation. Variability in NSP4 between strains may be the explanation for observed variations in pathogenicity (Goldwater et al. 2001). Management of rotavirus infection is supportive only. The incidence of gastroenteritis has reduced since routine vaccination for rotavirus was introduced to the United Kingdom in 2013 (Bawa et al. 2015); it is hoped that the burden of neurological disease will decrease accordingly in future.

**Seizures**

Prevalence of seizures in children hospitalised with rotavirus infection is 4–7% (Johansen et al. 2008; Le Saux et al. 2010; Lloyd et al. 2010). Seizures may be febrile or afebrile and typically start on the third day of illness (Bass et al. 2007). Most are brief and generalised (Lloyd et al. 2010). CSF analysis and neuroimaging are normal in the majority of cases (Lloyd et al. 2010) although PCR reveals the presence of rotavirus in the CSF in some (Liu et al. 2009). Electrolyte abnormalities and cerebral sinovenous thrombosis should also be considered as secondary causes of seizures in children.
with severe diarrhoeal illness. Outcome is excellent with only 7% of children requiring chronic anticonvulsant therapy in one series (Lloyd et al. 2010). Rotavirus vaccination is associated with an 18–21% reduction in seizure incidence over the following year (Payne et al. 2014).

Neonatal rotavirus infection has recently been described as a cause of seizure onset on days 4–6 of life with white matter injury on MRI (Lee et al. 2014; Yeom et al. 2015). Changes are best visualised on diffusion-weighted imaging, appearing as diffuse symmetrical lesions in the cerebral white matter and corpus callosum with restricted diffusion (Lee et al. 2014). In most cases rotavirus is detected in the stool but not the CSF (Yeom et al. 2015), suggesting a para-infectious mechanism of CSF involvement, possibly toxin mediated (de Vries and Bearden 2015). Cystic evolution of white matter changes is described in some cases with neurodevelopmental sequelae (Verboon-Maciolek et al. 2012).

**EncEphalitis and EncEphalopathy**

Encephalitis is a rare complication of rotavirus infection (Hongou et al. 1998; Kehle et al. 2003; Goto et al. 2007). One series of 984 children hospitalised with rotavirus gastroenteritis found a 1.7% prevalence of encephalitis with abnormal EEG (Johansen et al. 2008). Most cases occur in children aged 6–24 months. The typical history is of encephalopathy and seizures presenting on day 2–3 of gastroenteritis. CSF pleocytosis is observed in 48% and EEG is abnormal in 91% of cases. Three-quarters of children enjoy full recovery without sequelae (Dickey et al. 2009).

Encephalopathy without encephalitis is also described in association with CNS penetration (Nakagomi and Nakagomi 2005). Associated syndromes include haemorrhagic shock and encephalopathy syndrome (HSES) (Kuki et al. 2015), clinically mild encephalitis/encephalopathy with reversible splenial lesion (MERS) (Takanashi 2009), acute necrotising encephalopathy and acute encephalopathy with biphasic seizures and late reduced diffusion (AESD) (Hoshino et al. 2012) (see the Acute Encephalopathy Syndromes Occurring in Association with Viral Illnesses section).

**Cerebellitis**

There are several case reports of cerebellitis associated with rotavirus infection in children (Nigrovic et al. 2002; Shihara et al. 2007; Dickey et al. 2009; Kobayashi et al. 2010; Kubota et al. 2011; Thompson et al. 2012). Symptoms include ataxia, agitation, behavioural arrest, dysphasia and mutism. Presence of rotavirus RNA in the CSF is variable. MRI typically reveals focal or diffuse cerebellar T2-hyperintensity with or without restricted diffusion. Acute neurological impairment may persist for weeks to months and chronic sequelae including dysarthria and cognitive difficulties are reported (Thompson et al. 2012).

**Lymphocytic Choriomeningitic Virus**

Lymphocchoriomenigitis virus (LCMV) is a zoonotic arenavirus which can rarely cause aseptic meningitis in humans. The reservoir host is the house mouse and the virus is found worldwide. Human infection is acquired following contact with excreta of infected mice, guinea pigs or hamsters, and can also be acquired vertically and via organ transplantation (Fischer et al. 2006). Postnatally acquired infection is usually either asymptomatic or associated with an influenza-like illness, but a CNS syndrome is also described (Barton and Hyndman 2000). Neurological features in the immunocompromised include meningoencephalitis (characterised by markedly elevated CSF protein in the presence of mild lymphocytic pleocytosis) (Fig. 11.20) and subdural effusions (Fischer et al. 2006).
The virus is difficult to detect by culture or PCR. Ribavirin has proven efficacy in the treatment of other arenaviruses and may be used empirically in suspected lymphohoriomeningitis virus infection in the immunocompromised (Wilson 2013).

**CHRONIC VIRAL INFECTIONS**

Viral infections of the CNS in children may present as subacute or chronic meningitis, encephalitis or myelitis syndromes. Immunocompromised children are especially susceptible to viral agents presenting in this manner, including measles (inclusion body encephalitis), enteroviruses, HIV, and several of the herpesviruses. Subacute onset of CNS viral infection is unusual in immunocompetent children in the era of measles vaccination, which has greatly reduced the incidence of subacute sclerosing panencephalitis (SSPE) (Campbell et al. 2007). Most of the chronic encephalitides are primary, with presence of the responsible organism in the CNS; they form a heterogeneous group that includes well-defined types (e.g. SSPE, rubella panencephalitis, HIV encephalopathy, human T lymphocytic virus myelitis) and poorly understood cases that are possibly not directly due to virus infection. The mechanisms of chronic viral encephalitis are complex and vary according to the interaction between the infecting agent and the host immune response. The well-defined types are reviewed below.

**MEASLES VIRUS**

Measles virus causes two distinct chronic encephalitides.

**Measles Inclusion Body Encephalitis**

Measles inclusion body encephalitis, also known as subacute measles encephalitis, is a rare, chronic encephalopathy occurring as a delayed complication of measles several months after primary infection. It is observed mainly in immunocompromised patients (Murphy and Yunis 1976), particularly those with acute lymphoblastic leukaemia (Hughes et al. 1993), although it occasionally occurs in apparently immunocompetent children. Contrary to the usual post-infectious encephalitis (i.e. ADEM), the measles virus is present in large quantities within the brain; paramyxovirus nucleocapsid inclusion bodies are visualised within cells by electron microscopy and measles RNA is detected by reverse transcriptase-PCR. Focal necrosis is the main histological finding (Mustafa et al. 1993). The inflammatory reaction is variable but often inconspicuous (Lacroix et al. 1995).

The disease presents 2–12 months after measles infection, case contact or vaccination, although a history of these is absent in up to 18% of cases (Mustafa et al. 1993). Average age is 6 years. Nearly all cases present with altered consciousness and seizures (Buchanan and Bonthius 2012). Epilepsia partialis continua is the first manifestation in many cases (Aicardi et al. 1977; Luna et al. 1990; Barthez Carpentier et al. 1992). Focal seizures are often recurrent, treatment-refractory and associated with Todd paralysis (Buchanan and Bonthius 2012). Progressive deterioration leads to coma. Other neurological signs may include focal motor deficits, language impairment, visual impairment and dysphagia (Mustafa et al. 1993). In some patients, a retinopathy is present (Haltia et al. 1977).

Diagnosis can be challenging as CSF may initially be normal or show only slight changes. In the majority of cases there is intrathecal synthesis of measles virus antibody with rising titres detectable in the CSF and high antibody titre in the serum also. In the most severely immunosuppressed children, however, antibody production may be impaired. MRI is usually normal at presentation, later demonstrating nonspecific abnormalities including oedema, atrophy and ventriculomegaly (Bitnun et al. 1999). The EEG may show background slowing with repetitive slow-wave complexes at a rate of about 1Hz (Aicardi et al. 1977; Colamaria et al. 1989).

The course is fatal in three-quarters of cases, with death usually occurring within weeks of onset (Buchanan and Bonthius 2012). Management is largely supportive. A few cases have been treated with intravenous ribavirin but survivors are left with severe sequelae (Mustafa et al. 1993).

**Subacute Sclerosing Panencephalitis**

Subacute sclerosing panencephalitis (SSPE) is a devastating long-term degenerative complication of continued aberrant measles virus replication in the CNS subsequent to primary infection (Connolly et al. 1967). Diagnosis of SSPE is made after two per 100,000 measles infections but the actual rate is estimated to be four to 11 per 100,000 (Bellini et al. 2005, Campbell et al. 2007). A rate of one per 1 million is reported in vaccinated children, but these cases are caused by wild type not vaccine strains of measles (Jin et al. 2002; Miller et al. 2004); that is, vaccination does not cause SSPE (Bellini et al. 2005; Campbell et al. 2007). The interval between primary infection and symptom onset is up to 7 years. SSPE is more common in children who had primary measles under 2 years of age. Perinatally-acquired infection may result in a shorter latency and more fulminant course (Campbell et al. 2007).

**Clinical features of SSPE**

Early clinical diagnosis is challenging as the first stage of illness is characterised by subtle progressive symptoms (Honarmand et al. 2004). In two-thirds of cases there are personality changes and insidious intellectual deterioration with an aphasic–apraxic–agnostic predominance. Often, such children are regarded as suffering from psychological problems and referred to psychiatric clinics. In a quarter of patients neurological signs or seizures are the first manifestations. Involuntary movements usually appear within 2–3 months and are characteristic of the second stage. The movements may be myoclonic jerks; the differential diagnosis of dementia with myoclonic jerks includes Creutzfeldt–Jakob disease. Usually they are more complex, involving several successive limb segments in a repetitive
pattern. Onset of each movement is abrupt, but the duration is longer than that of a common myoclonic jerk, often lasting several seconds. Abnormal movements recur periodically, although the intervals between two jerks are not equal and may vary from day to day in the same patient. The movements are usually bilateral, but strictly unilateral jerks may occur. They are absent during sleep and may disappear and reappear without apparent reason. In some patients, they may be replaced or preceded by periodic manifestations more typical of epilepsy, in particular by atonic seizures with head nods or complete falls, or rarely by typical myoclonias. Generalised epileptic seizures, absence-like fits or partial seizures are uncommon (Andermann 1967; Kornberg et al. 1991). In the third stage, extrapyramidal or pyramidal dysfunction, or both, become prominent. Extrapyramidal dyskinesias may appear, and parkinsonian rigidity is common. Dementia is severe and the child is bedridden. The terminal stage is characterised by progressive unresponsiveness, worsening hypotonia or decerebrate rigidity, swallowing and respiratory difficulties, and autonomic dysfunction. The median duration of the disease is about 12 months and the course is usually regularly progressive. Subacute forms, lethal in as little as 6 weeks, are occasionally seen (Nihei et al. 1977). Contrariwise, long periods of arrested progression may occur. Periods of spontaneous remission may last up to several years (Risk and Haddad 1979).

Ocular manifestations occur in over half of cases (Babu and Biswas 2007) and consist mainly of bilateral chorioretinitis, which preferentially involves the macular area and may be associated with pallor of the disc. This may appear months or even years before the classic manifestations of SSPE (Robb and Watters 1970). Optic neuritis with atrophy is also described, and less commonly cortical blindness. Papilloedema can be observed with transient increases of ICP. The electroretinogram is normal but visual evoked potentials are impaired. Cases with lateralising or other focal features may pose a diagnostic challenge. Spastic hemiplegia and unilateral spasms may occur. Some cases present with cortical blindness or hemianopia and may be confusing. Occasionally, signs of intracranial hypertension in association with focal features may wrongly suggest a tumour (Glowacki and Goscinski 1973).

**Diagnosis of SSPE**

The spectrum of EEG abnormalities in SSPE is wide. The hallmark finding of periodic complexes is observed in 80% of cases. Characteristic abnormalities may be observed before any clinical manifestation (Wulf 1982) but they are most often detected during the stage of motor dysfunction (Praveen-Kumar et al. 2007). The complexes typically are formed of high-voltage polysphasic slow-wave complexes recurring periodically in association with clinical jerks although they may also occur in the absence of clinical manifestations. Their duration ranges from 0.5 to 2 seconds and they recur at 4–15-second intervals. They are usually identical in shape in any given lead. In some cases bursts of spike–wave activity may replace the typical complexes. Background tracings may be initially normal but become progressively slower while the amplitude diminishes.

Diagnosis of SSPE is confirmed by evidence of high titre measles antibody (IgG) in CSF and serum, with a very high CSF:serum antibody titre ratio. The CSF contains no cells, and the total protein is normal or slightly elevated. The virus cannot usually be amplified from the CSF, although viral genome may be amplified from brain tissue. In the early stages MRI may be normal, or demonstrate reduced grey matter volume in the fronto-temporal cortex, amygdala and cingulate gyrus (Aydin et al. 2009). Later neuroimaging reveals T2-hyperintensity in the cortex, basal ganglia and brainstem and symmetrical changes in the periventricular white matter. The final stage is one of diffuse cortical atrophy (Buchanan and Bonthius 2012); however, the correlation between MRI appearance and clinical progression is poor (Ozturk et al. 2002).

**Management of SSPE**

Management of SSPE remains largely symptomatic; evidence of efficacy for antiviral agents in various combinations is mixed. Isoprinosine seems to induce remission in some cases (DuRant et al. 1982). A combination of intraventricular interferon and isoprinosine was reported to increase the rate of remissions from 5–10% to 45% (Yalaz et al. 1992; Gascon et al. 1993), but late recurrences may occur after several years of remission (Anlar et al. 1997). In a small randomised controlled trial, oral isoprinosine alone was compared with oral isoprinosine and intraventricular interferon-alpha2b. No group difference was detected but overall rates of satisfactory outcome (stabilisation or improvement) of around 35% were higher than historical spontaneous remission rates of 5–10%, suggesting that treatment is superior to no treatment (Gascon 2003). Other combination treatments used have included ribavirin (both intraventricular and intravenous) with isoprinosine (Aydin et al. 2003; Hosoya et al. 2004). Death occurs within 2–4 years of disease onset in most cases (Cobb et al. 1984).

**HUMAN IMMUNODEFICIENCY VIRUS**

HIV-1 is a retrovirus that infects cells that carry the CD4 receptor and a chemokine co-receptor (e.g. CCR5, CXCR4), including helper T lymphocytes (CD4 cells) and monocytes. Infants may be infected with HIV in utero, at birth, or during breastfeeding, but the majority are infected around the time of delivery. Maternal plasma HIV viral load is the most important predictor of infant infection with HIV, but preterm delivery, prolonged rupture of membranes, presence of other sexually transmitted infections, chorioamnionitis and interventional vaginal delivery all increase the risk of transmission (Abrams et al. 1995; Peckham and Gibb 1995). In non-breastfeeding populations, 15–20% of infants are infected compared to 30–40% in breastfeeding populations (ECS 1991, 1994; Newell et al. 2004). Interventions including antiretroviral therapy (ART) in pregnancy, during delivery and post-partum, prelabour caesarean section and avoidance of breastfeeding can reduce mother to child transmission of HIV to around 0.5% (Townsend et al. 2014). In younger
children, due to persistence of transplacental maternal antibodies, direct methods of identification must be used to diagnose HIV infection including HIV RNA PCR, HIV DNA PCR, or proviral HIV DNA amplification. In older children suspected of having perinatally-acquired HIV, HIV serology can be used to screen for infection but PCR must be used to confirm the diagnosis and assess need for ART. Advance-ment of HIV disease and requirement for antiretroviral treat-ment is defined by clinical assessment and measurement of the CD4 count and plasma HIV viral load (Bamford et al. 2015).

Neurological complications of perinatally-acquired HIV infection may be caused by direct effects of HIV itself or sec-ondary to opportunistic infections, other co-infections, cere-brovascular disease, autoimmunity, malignancy or toxicity of antiretroviral medication.

HIV is a neurotropic virus, although productive infection in the CNS is probably limited to macrophages and microglia. Brain involvement occurs very soon after infection, and infected microglia have been identified as early as 7 days after transfusion of infected blood. In vitro, HIV-induced expres-sion of ICAM-1 on human brain microvascular endothelial cells increases the margination of inflammatory cells in the brain vasculature, leading to increased targets for HIV infec-tion within the CNS (Stins et al. 2003). A small paediatric study demonstrated a relationship between T cell inflamma-to-ry mediators in CSF and CSF HIV viral load (McCoig et al. 2004). HIV in the CNS promotes an inflammatory process, which leads over time to cell death and neuronal loss, probably by the process of apoptosis (Epstein and Gendelman 1993). Pathological findings (Sharer et al. 1986) include diminished brain weight for age. Inflammatory cell infiltrates consisting of microglia, lymphocytes, plasma cells and, especially, multi-nucleated giant cells are distributed throughout the brain but are more prominent in the deep structures, including the basal ganglia and brainstem. Prominent inflammatory changes and calcification of small or medium-sized vessels are present, especially in the deep brain structures. These may explain the occurrence of ischaemic infarcts and strokes in children with HIV (Frank et al. 1989; Park et al. 1990). The spinal cord only rarely shows the vacuolar myelopathy which is frequent in adults (Dickson et al. 1989). Studies in HIV-infected adults have shown a reduction in CNS immune activation with combination ART, but low level immune activation persists on fully suppressive ART with likely deleterious neurological effects (reviewed in Winston and Vera 2014).

The original Centers for Disease Control and Prevention (CDC) classification of HIV disease in children included a number of different presentations of ‘HIV encephalopathy’: failure to attain or loss of developmental milestones and intellectual ability; impaired brain growth or an acquired microcephaly; and acquired symmetrical motor deficit (CDC 1994). These different clinical presentations have differing aetiologies relating not just to activity of HIV in the CNS but also to progression of immune deficiency and opportunistic infections manifesting in the CNS (Mitchell 2001).

Around 20% of HIV-infected children become severely symptomatic or die in the first year of life. These ‘rapid pro-gressor’ infants are more likely to be born to mothers with more advanced HIV disease, and they are at highest risk of early presentation with HIV encephalopathy (Blanche et al. 1994; Lobato et al. 1995; Tardieu et al. 2000). Overall, up to 10% of HIV-infected children have signs of encephalopathy, usually presenting with motor impairment and development-mental delay. More subtle cognitive abnormalities occur in at least 30% of children with HIV, and many have speech and language difficulties and problems with school perform-ance (Tardieu et al. 1995; Pearson et al. 2000). Infants clas-sically present with developmental delay, microcephaly and a diplegic motor impairment. This is often in association with other opportunistic infections including cytomegalovirus and Pneumocystis jirovecii pneumonia. In one detailed study from the United States, infants infected with both HIV and CMV had a significantly increased risk of CNS disease and a worse long-term neurological prognosis (Kovacs et al. 1999). These infants present like other children with cerebral palsy with a fixed neurological insult and consequent development-problems; they do not demonstrate a pattern of progressive demen-tia as seen in adults or older children infected with HIV when the brain is more mature (Tardieu et al. 2000).

CT in symptomatic children has demonstrated brain atrophy in over three-quarters of cases, with increased white matter attenuation and calcification of the basal ganglia in approximately a quarter (Belman et al. 1986; DeCarli et al. 1993; Pearson et al. 2000) (Fig. 11.21). MRI shows high signal from the white matter and cortical atrophy in most cases (Chamberlain et al. 1991; Pavlakis et al. 1995). A more recent MRI study from Africa has shown white matter signal abnormalities to be present from very early on in perinatal HIV infection, even in the context of early ART initiation (Ackermann et al. 2014). The relevance of these white matter changes to neurodevelopmental outcome remains to be explored. In a small study of 39 children (aged from <1 year to 13 years), the level of HIV viral load in the CSF was related to severity of cortical atrophy, but not to intracerebral calcification (Brouwers et al. 2000). In addition, basal ganglia calcification was not related to the severity of the neurological symptoms. In HIV encephalopathy the CSF is most often normal but may contain a mild excess of lymphocytes associated with a modest, often transient, elevation of protein.

In the era before successful treatment of HIV, only around 50% of affected children survived to 10 years of age, and those with neurological signs or symptoms had a very high risk for rapid disease progression at all ages (Pearson et al. 2000). Thirty to fifty per cent of children in the pre-combination ART era developed HIV encephalopathy (Epstein et al. 1988). With the advent of combination ART, the majority of HIV-infected children are likely to survive long-term (Gibb et al. 2003). In addition, there has been a dramatic decrease in the incidence of HIV encephalopathy (Patel et al. 2009). Adolescents in current cohorts with a history of severe immuno-suppression/AIDS have been shown to have a higher risk
of neurocognitive and psychiatric impairment (Wood et al. 2009). Early identification of HIV-infected infants who may be at risk of encephalopathy is crucial, so that treatment may be started early enough to prevent permanent neuronal damage, if that is possible (Sanchez-Ramon et al. 2003). Within a French observational cohort, 40 infants who received ART before 6 months of age did not have early-onset severe HIV disease including encephalopathy during the first 24 months of life, whereas in the deferred therapy group (n=43), three developed encephalopathy (Faye et al. 2004). Although these numbers are small, treatment in infancy seems reasonable to attempt to prevent permanent neurological complications. However, where motor neuronal damage has already occurred in infancy, it is not surprising that it cannot be reversed by combination ART (Foster et al. 2006). However, it has been suggested that ART may prevent or improve more subtle neuropsychological/neurocognitive problems (Sanchez-Ramon et al. 2003). Early ART initiation was found to be associated with better neurodevelopmental outcomes in HIV-infected infants in a large prospective study in Africa (Laughton et al. 2012). Early HIV viral suppression has now also been shown to be associated with improved neurocognitive outcomes in a large US cohort study (Crowell et al. 2015). A smaller observational cohort study in the Netherlands found subtle neurocognitive impairment in a group of mainly ART-treated children, higher CD4 percentage at time of ART initiation and longer duration of ART being associated with better working memory and attention control respectively (Koekkoek et al. 2008).

A scoring system has been developed for potential CSF penetration of different ART drugs (Letendre et al. 2008). How this relates to concentrations in neuronal tissue and differing neurological outcomes in HIV-infected children is yet to be fully determined (Crowell et al. 2015).

Whether or not ART-treated survivors of vertical HIV infection will have an increased risk of early onset of HIV dementia or other neurological syndromes in adult life can only be speculated at this stage. The importance of monitoring for potential acute and long-term neurotoxicity of antiretroviral drugs continues to be an essential aspect of clinical care of HIV-infected children and adolescents as they transition to adult services. A recent cohort study of 59 children with perinatally-acquired HIV found 22% to have language impairment, 14% abnormal muscle tone and 12% delay in reaching developmental milestones. Ventricular enlargement and sulcal widening (29%) and white matter lesions (38%) were common (van Arnhem et al. 2013). Although this cohort included a significant number of children from the pre-combination ART era, it is likely to be representative of the current clinical cohort in Europe and the United States and increasingly in the African setting and we should focus efforts on optimising care for these children and adolescents as they progress to adult life while optimising treatment strategies to minimise the risk of neurological disease in children born with HIV today.

**HUMAN T LYMPHOCYTE VIRUS**

Human T lymphocyte virus type 1 (HTLV-1) was the first human retrovirus to be identified. It is associated with adult T cell malignancies and is the causal agent of HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP) in children and adults. Approximately 15–20 million people are infected worldwide, mostly in West Africa, South America, the Caribbean and Japan (Verdonck et al. 2007). It is uncommon in Europe but has been reported in at-risk groups including immigrants from endemic areas, sex workers.
and injecting drug users (Zehender et al. 2004). Transmission occurs via contact with infected bodily fluids including blood and breast milk. Mothers who breastfeed for longer, have higher breast milk viral load and have greatest HLA concordance with their children are more likely to transmit the infection (Wiktor et al. 1997; Li et al. 2004; Biggar et al. 2006). Infection is mainly of CD4+ T cells (Sato and Matsuoka 2010); 0.25–4% of carriers develop HAM/TSP, by incompletely understood mechanisms (Verdonck et al. 2007). There is a female predominance. There is a latency period of many years; onset is usually in the fourth or fifth decade of life. Cases in children are documented as young as 6–7 years (Roman 1988; Gessain and Gout 1992). Pathologically, HAM/TSP is characterised by infiltration of the white and grey matter of the spinal cord with CD4+ T cells and macrophages. HTLV-1 RNA is detectable within lesions (Lehky et al. 1995). HTLV-1 is also associated with a severe infective dermatitis in vertically infected children, which may occur along with early onset of HAM/TSP (Primo et al. 2005). Both conditions are probably related to the host anti-HTLV-1 immune response as well as HTLV-1 viral load (de Oliveira Mde et al. 2004; Sabouri et al. 2005). A rare smouldering retinal vasculitis with ultimate retinal degeneration has been reported in Japanese adolescents with HTLV-1 (Nakao and Ohba 2003). Short stature and anaemia may also be associated with HTLV-1 infection in children (Primo et al. 2005).

The clinical presentation of HAM/TSP has been better characterised in adults than children. It is a progressive chronic myelopathy with preferential damage to the lower thoracic cord (Aye et al. 2000), leading to symmetrical weakness, spasticity and hyperreflexia in the lower limbs with bladder and bowel dysfunction (Lairmore et al. 2012). Sensory involvement is mild (Primo et al. 2005). Intention tremor, optic atrophy and cerebellar signs are found in some patients and may occasionally be prominent (Kira et al. 1993). CSF may show mild lymphocytic pleocytosis with elevated protein. CSF/serum HTLV-1 antibody ratio is elevated (Verdonck et al. 2007). HTLV-1-specific T cells have been isolated in some cases (Kubota et al. 2002) and HTLV-1 proviral load may be elevated (Lezin et al. 2005). MRI in adults reveals multiple disseminated white matter lesions in the brain and spinal cord with perivascular demyelination (Lairmore et al. 2012); however, most paediatric cases have normal neuroimaging (Primo et al. 2005). Other causes of myelopathy must be excluded including spinal cord compression and parasites; HAM/TSP may present as a multiple sclerosis mimic with positive oligoclonal bands.

Oral or intravenous steroids are the mainstay of treatment, especially in early disease (Verdonck et al. 2007; Araujo et al. 2008; Pillat et al. 2011). Interferon-alpha may also be of some benefit (Izumo et al. 1996; Oh et al. 2005; Pillat et al. 2011). A small trial of zidovudine plus lamivudine did not find any benefit (Taylor et al. 2006). Sodium valproate, methotrexate, pentoxifylline, azathioprine and danazol have also been tried (Araujo et al. 2008). The typical course in children is of rapid progression over 2 years with considerable motor impairment and autonomic dysfunction. The family of affected children should be screened for HTLV-1 as familial clustering of HAM/TSP has been reported (Primo et al. 2005).

JOHN CUNNINGHAM VIRUS

John Cunningham virus (JCV) derives its name from the initials of the patient with progressive multifocal leukoencephalopathy (PML) in whom it was first identified (Padgett et al. 1971). It is a ubiquitous, neurotropic human polyoma-virus of the family Papovaviridae. It is the cause of progressive multifocal PML, a fatal demyelinating disease, in immunocompromised patients. It is now known to be a ubiquitous childhood infection, with over one-third of healthy individuals having seroconverted by adulthood (Kean et al. 2009). After asymptomatic primary infection (acquired by faeco-oral, respiratory, seminal or blood-borne transmission), JCV lies latent in the kidney, bone marrow, brain and lymphoid tissues (Stahl et al. 2011); it is detectable in the tonsillar tissue of 39% of healthy children (Monaco et al. 1998). PML develops due to reactivation of JCV in children with HIV (Berger et al. 2001) or other causes of immunocompromise including congenital immunodeficiency and treatment for haematological malignancy (Redfearn et al. 1993; Angelini et al. 2001; Demir et al. 2005). PML is also reported at initiation of antiretroviral treatment for HIV due to immune reconstitution inflammatory syndrome (PML-IRIS) (Nuttall et al. 2004). Over 400 cases of PML have been reported to date in patients receiving treatment with the therapeutic monoclonal antibody natalizumab for relapsing-remitting multiple sclerosis, but very few of these were in children, the youngest being 15 years old (Dong-Si et al. 2015).

Risk of PML with natalizumab therapy can be stratified by duration of treatment, exposure to previous immunomodulatory drugs and JCV antibody status (Gorelik et al. 2010). Histopathological features of PML are of focal demyelination with abundant lipid-laden macrophages, bizarre astrocytes, and enlarged oligodendrocytes with intranuclear inclusions (Schwenk et al. 2014).

Clinical presentation of PML is variable and may be insidious with cognitive deterioration, or more rapidly progressive with seizures, hemiparesis, ataxia and dysarthria (Schwenk et al. 2014). Appearance on MRI is of asymmetrical, T2-hyperintense lesions mostly affecting the frontal and parieto-occipital subcortical white matter, without oedema or mass effect (Nickerson et al. 2012; Schwenk et al. 2014). The periventricular white matter is relatively spared (Fig. 11.22).

Contrast enhancement is absent in 84% of cases (Schwenk et al. 2014). The spinal cord may also be involved (Bernal-Cano et al. 2007). CSF cell count, protein and glucose are usually normal. Definitive diagnosis can be achieved by detection of JCV DNA in the CSF, although sensitivity is only 59% (Schwenk et al. 2014).

Management focuses on restoration of immune function by reduction of immunosuppression (Pinto and Dobson 2011). Transmission occurs via contact with infected bodily fluids including blood and breast milk. Mothers who breastfeed for longer, have higher breast milk viral load and have greatest HLA concordance with their children are more likely to transmit the infection (Wiktor et al. 1997; Li et al. 2004; Biggar et al. 2006). Infection is mainly of CD4+ T cells (Sato and Matsuoka 2010); 0.25–4% of carriers develop HAM/TSP, by incompletely understood mechanisms (Verdonck et al. 2007). There is a female predominance. There is a latency period of many years; onset is usually in the fourth or fifth decade of life. Cases in children are documented as young as 6–7 years (Roman 1988; Gessain and Gout 1992). Pathologically, HAM/TSP is characterised by infiltration of the white and grey matter of the spinal cord with CD4+ T cells and macrophages. HTLV-1 RNA is detectable within lesions (Lehky et al. 1995). HTLV-1 is also associated with a severe infective dermatitis in vertically infected children, which may occur along with early onset of HAM/TSP (Primo et al. 2005). Both conditions are probably related to the host anti-HTLV-1 immune response as well as HTLV-1 viral load (de Oliveira Mde et al. 2004; Sabouri et al. 2005). A rare smouldering retinal vasculitis with ultimate retinal degeneration has been reported in Japanese adolescents with HTLV-1 (Nakao and Ohba 2003). Short stature and anaemia may also be associated with HTLV-1 infection in children (Primo et al. 2005).

The clinical presentation of HAM/TSP has been better characterised in adults than children. It is a progressive chronic myelopathy with preferential damage to the lower thoracic cord (Aye et al. 2000), leading to symmetrical weakness, spasticity and hyperreflexia in the lower limbs with bladder and bowel dysfunction (Lairmore et al. 2012). Sensory involvement is mild (Primo et al. 2005). Intention tremor, optic atrophy and cerebellar signs are found in some patients and may occasionally be prominent (Kira et al. 1993). CSF may show mild lymphocytic pleocytosis with elevated protein. CSF/serum HTLV-1 antibody ratio is elevated (Verdonck et al. 2007). HTLV-1-specific T cells have been isolated in some cases (Kubota et al. 2002) and HTLV-1 proviral load may be elevated (Lezin et al. 2005). MRI in adults reveals multiple disseminated white matter lesions in the brain and spinal cord with perivascular demyelination (Lairmore et al. 2012); however, most paediatric cases have normal neuroimaging (Primo et al. 2005). Other causes of myelopathy must be excluded including spinal cord compression and parasites; HAM/TSP may present as a multiple sclerosis mimic with positive oligoclonal bands.

Oral or intravenous steroids are the mainstay of treatment, especially in early disease (Verdonck et al. 2007; Araujo et al. 2008; Pillat et al. 2011). Interferon-alpha may also be of some benefit (Izumo et al. 1996; Oh et al. 2005; Pillat et al. 2011). A small trial of zidovudine plus lamivudine did not find any benefit (Taylor et al. 2006). Sodium valproate, methotrexate, pentoxifylline, azathioprine and danazol have also been tried (Araujo et al. 2008). The typical course in children is of rapid progression over 2 years with considerable motor impairment and autonomic dysfunction. The family of affected children should be screened for HTLV-1 as familial clustering of HAM/TSP has been reported (Primo et al. 2005).
Chapter 11 Infectious Diseases

2014; Schwenk et al. 2014). There are case reports of cidofovir being tried as antiviral therapy in both HIV-infected (Hugonenq et al. 2002; Robinson et al. 2004) and HIV-uninfected children (Angelini et al. 2001; Weber et al. 2011), with mixed results. Cytarabine (Aksamit 2001) and mirtazapine (Verma et al. 2007) have been tried in adults but also lack clear evidence of efficacy. PML-IRIS may be treated with steroids (Tan et al. 2009; Schwenk et al. 2014). Mortality is 69% in HIV-infected and 80% in HIV-uninfected children (Schwenk et al. 2014).

**BK virus** is a related polyomavirus which has been associated with meningoencephalitis in patients with HIV (Vallbracht et al. 1993; Bratt et al. 1999). There is increasing interest in the role of the polyomaviruses in neuro-oncogenesis (Crawford 2010), with JCV DNA detected in a significant proportion of paediatric medulloblastomas (Krynska et al. 1999) and ependymomas (Okamoto et al. 2005). However, a causal relationship has not yet been established.

**ENTEROVIRUSES**

Chronic enteroviral meningoencephalitis is described in children with inherited or acquired antibody deficiencies such as Bruton disease (X-linked hypogammaglobulinaemia), HIV and common variable immunodeficiency (Cooper et al. 1983; Tormey et al. 2003). The clinical picture is of chronic lymphocytic meningitis with variable features of brain involvement such as insidious intellectual deterioration, disturbances of consciousness and focal seizures or neurological deficits. Other presentations include progressive myelopathy, myelopathy progressing to encephalopathy, pure encephalopathy, retinopathy, sensorineural hearing loss, and dermatomyositis (Rudge et al. 1996). The course is chronic and often fatal. Diagnosis is by PCR or culture of the CSF or biopsy tissue (Sawyer 2001). Quantitative PCR (see Box 11.1) may be used to monitor treatment efficacy (Quartier et al. 2000). Treatment by intrathecal and intraventricular injection of gammaglobulins may help to improve symptoms, but does not always clear infection (Erlendsson et al. 1985; Johnson et al. 1985; McKinney et al. 1987; Quartier et al. 2000). Pleconaril inhibits viral replication in some enteroviruses and has been efficacious in some cases (Tormey et al. 2003; Wildenbeest et al. 2012). However, the outcome of chronic enteroviral meningoencephalitis is usually fatal (Tormey et al. 2003). Enteroviruses may also be capable of persisting within the CNS in immunocompetent individuals but the long-term consequences are largely unknown (Rhoades et al. 2011).

**PROGRESSIVE RUBELLA PANENCEPHALITIS**

A few children with congenital rubella (Townsend et al. 1975) and an occasional patient with acquired rubella (Lebon and Lyon 1974) have developed this very rare fatal panencephalitis (Stahl et al. 2011) with prominent cerebellar involvement some 10 years after primary infection. Insidiously progressive dementia is the first manifestation, followed by ataxia and myoclonic seizures. CSF examination shows mononuclear pleocytosis and increased protein with massive elevation of specific IgG (Vandvik et al. 1978b). Rubella virus has been isolated from the brain and leukocytes. Pathologically, inflammatory infiltrates and astrocytosis are prominent (Townsend et al. 1982; Frey 1997). The course is fatal in several years. No treatment is known.

**ENCEPHALOPATHIES OF OBSCURE ORIGIN THAT MAY BE RELATED TO VIRAL INFECTIONS**

**BEHÇET SYNDROME**

Behçet syndrome is rare in children but has been reported in infants as young as 2 months (Ammann et al. 1985). A transient form has been observed in infants born to affected mothers (Lewis and Priestley 1986). The disease features recurrent ulcerations of the mouth and genitalia, skin lesions often resembling erythema nodosum, anterior uveitis, keratitis, hypopyon and, less commonly, retinal involvement that in some cases may be isolated. CNS involvement is present in up to 25% of patients and may rarely precede the oculocutaneous
manifestations. Neurological manifestations include involvement of the cerebral hemispheres, spinal cord, cerebellum or brainstem (Nakamura et al. 1994). Pseudotumour cerebri with or without sinus thrombosis may be observed (Shakir et al. 1990). MRI may show disseminated areas of intense signal in T2 sequences (Wechsler et al. 1992; Saltik et al. 2004). The brainstem is consistently involved. Periventricular infiltrates with or without thrombosis are frequent (Wechsler et al. 1992). The disease may present as a cerebrovascular disease (Iragui and Maravi 1986) or as a chronic brainstem encephalitis (Ito et al. 1991). The diagnosis may be helped by the cutaneous sensitivity to mechanical trauma (pathergy). Behçet syndrome has a complex genetic aetiology; it is most common in those of Mediterranean and Eastern origin, although it also affects Caucasians. An enhanced inflammatory response and overexpression of pro-inflammatory cytokines are the prominent features of Behçet syndrome. This likely antigen-driven immune response in Behçet syndrome is possibly triggered by an infectious agent in a genetically susceptible host. Supporting this is the consistent association of disease susceptibility with polymorphisms in the human leukocyte antigen complex, particularly HLA-B*51. The diagnosis is a clinical one and so far there is no single laboratory test specific for the diagnosis of Behçet syndrome (Uziel et al. 1998; Marshall 2004). The immune modulating agents cyclosporin and azathioprine have performed well in clinical trials, and evidence is accumulating for the efficacy of anti-tumour necrosis factor therapy for certain types of Behçet syndrome.

**RASMUSSEN ENCEPHALITIS**

Rasmussen encephalitis is a chronic epileptic disorder (see also Chapter 16) characterised clinically by progressive neurological deterioration, focal seizures often progressing to intractable epilepsy, cognitive decline and hemispheric atrophy (Deb et al. 2005) (Fig. 11.15). The aetiology of this encephalitis remains unknown, and an autoimmune response triggered by a viral infection is a possibility. The multifocal distribution of pathological changes, as well as the heterogeneity in the stages of cortical damage in each patient, are consistent with an ongoing and progressive immune-mediated process of neuronal damage that involves neuroglial and lymphocytic responses, resembling other autoimmune CNS disorders such as multiple sclerosis (Pardo et al. 2004). A formal set of diagnostic criteria and a therapeutic pathway for the management have been proposed (Bien et al. 2005).

### PRION DISEASES OF THE NERVOUS SYSTEM

Prions are infectious pathogens comprising abnormal forms of a protein encoded in the host genome (Collinge 2005). Prion disease is associated with accumulation of disease-related isoforms of the normal cellular prion protein (PrP	extsuperscript{C}). Different strains of prion occur despite the absence of any agent-specific genetic material. Folding of the proteins themselves may encode strain diversity with different subsequent effects on the host. Prion diseases include Creutzfeldt–Jakob disease (CJD), Kuru, Gerstmann–Sträussler–Scheinker disease (Brown et al. 1994) and fatal familial insomnia (Medori et al. 1992) in humans, and scrapie and bovine spongiform encephalopathy (BSE) in sheep and cattle. They are neurodegenerative conditions which can be classified as sporadic (85–90%), hereditary (10–15%) or acquired (1–3%) (Takada and Geschwind 2013). The pathogenesis of sporadic prion disease is not fully understood; hereditary cases are associated with mutations of the PRNP (Prion Protein) gene; and acquired forms are caused by transmission of infection from human to human or, as a zoonosis, from cattle to human (Prusiner and Hsiao 1994; Will 2003). The sporadic and hereditary types usually present in later life although sporadic CJD (sCJD) has been rarely reported in young people (Kulczycki et al. 1991). The pathological findings in CJD are of PrP	extsuperscript{Sc} deposition in the brain with fibrillar plaques and spongiform vacuoles, particularly in the cerebellum (Budka 2003). This section focuses on prion diseases as infectious diseases, that is, acquired prion diseases.

### ACQUIRED CREUTZFELDT–JAKOB DISEASE

Most cases of iatrogenic Creutzfeldt–Jakob disease (iCJD) were acquired from human growth hormone treatment and dura mater grafts derived from cadaveric brain tissue with undiagnosed CJD infection (Billette de Villemeur et al. 1996; Billette de Villemeur 2003). Other sources included corneal grafts, gonadotrophic hormone, and improperly sterilised EEG depth electrodes and other neurosurgical equipment. Improved recognition of potentially infected individuals combined with modern sterilisation practices are thought to have largely ended the era of iCJD (Brown et al. 2012).

A novel human prion disease termed variant Creutzfeldt–Jakob disease (vCJD) emerged in the United Kingdom in the 1990s after changes in animal feeding and abattoir procedures led to human infection with the prion strain causing BSE in cattle (Will et al. 1996; Epstein and Brown 1997). Over 200 cases have been reported to date (Takada and Geschwind 2013), almost all in susceptible individuals with PRNP codon 129 polymorphism (Kaski et al. 2009). The number of cases still incubating in the UK remains unknown; analysis of 32 441 archived appendix samples found one in 2000 contained abnormal PrP (Gill et al. 2013). Four probable cases of vCJD occurred following transfusion of red blood cells from asymptomatic donors who subsequently developed the disease (Ironside 2012). However, incidence of vCJD has been declining since 1999–2000 (Ironside 2012) and national...
surveillance of progressive intellectual and neurological deterioration in children since 1997 had, by 2009, identified only six children with vCJD (Verity et al. 2010).

Cases of CJD are reported in patients as young as 12 years (Heath et al. 2010). The presentation is with slowly progressive neurological disturbance manifesting mainly as dementia, myoclonus and cerebellar signs. Neuropsychiatric symptoms such as depression or mood swings may predominate for 6 months or more prior to onset of neurological symptoms (Takada and Geschwind 2013). Dysaesthesia is also reported (Corato et al. 2006). The hallmark MRI finding is the pulvinar sign, in which the posterior thalamus is brighter than the anterior putamen on T2- or diffusion-weighted imaging (Takada and Geschwind 2013). Dysaesthesia is also reported (Corato et al. 2006). The hallmark MRI finding is the pulvinar sign, in which the posterior thalamus is brighter than the anterior putamen on T2- or diffusion-weighted imaging (Takada and Geschwind 2013). Dysaesthesia is also reported (Corato et al. 2006). The hallmark MRI finding is the pulvinar sign, in which the posterior thalamus is brighter than the anterior putamen on T2- or diffusion-weighted imaging (Takada and Geschwind 2013).

MYCOTIC INFECTIONS OF THE NERVOUS SYSTEM

Mycotic infections of the nervous system produce granulomatous meningitis or abscesses. In the majority of cases, mycotic infections occur as opportunistic infections in patients with immunodeficiency, indwelling devices or structural defects. As these infections are rare, advice regarding the most appropriate and up-to-date treatment should always be sought from microbiological specialists in the field. Outcomes from CNS fungal infection are often poor, but they are better than those reported in adult case series (Schwartz et al. 2011).

ASPERGILLUS INFECTION

Invasive aspergillosis is an uncommon but often lethal complication in severely immunocompromised patients. Conditions associated with CNS infection in infants and children include preterm birth haematological malignancy, solid organ and bone marrow transplant (especially in the context of prolonged neutropenia), advanced HIV disease and chronic granulomatous disease. Infection may cause brain abscesses, vasculitis, meningoencephalitis or encephalitis. Haemorrhage may occur most commonly into sites of infarction. *A. fumigatus* is the most common pathogen in the genus Aspergillus causing CNS infection. CNS Aspergillus infection may be associated with sinus or lung infection (Dotis et al. 2007). The eye and orbital structures may also become involved, leading to proptosis or ophthalmoplegia. Infection reaches the brain directly from the nasal sinuses or is blood-borne from the lungs and gastrointestinal tract. Single or multiple abscess formation with blood vessel invasion leading to thrombosis is a characteristic feature on neuropathological examination (Kleinschmidt-DeMasters 2002). Aspergillus should always be considered in immunocompromised patients with an acute onset of focal neurological deficits. Diagnosis of an intracranial mass lesion should be confirmed with neuroimaging (Fig. 11.23). Dual infections with other fungi may also occur, especially where the sinuses are the source. Direct examination and culture of tissue specimens is required to confirm the diagnosis, but treatment should be started on suspicion. Diagnosis may be supported by detection of fungal antigens using blood tests such as β-D-glucan or galactomannan (Leeflang et al. 2008; Wright et al. 2011). Though there are concerns regarding sensitivity and specificity of these assays, they may be used to monitor for early signs of fungal infection in at-risk individuals, to guide pre-emptive treatment and to monitor response to therapy (Wright et al. 2011). Fungal PCR are more recently being employed to aid diagnosis (Reinwald et al. 2013).

A combined approach with antifungal treatment and neurosurgical intervention with stereotactic removal of Aspergillus abscesses, granulomas and focally infected brain has demonstrated improved survival (Middelhof et al. 2005; Giacchino et al. 2006). Where possible, immunosuppressive treatment should be reversed and immune modulation to improve phagocytic function should be considered. The antifungal, voriconazole, which has excellent CNS penetration, has the most promising treatment results and is a recommended first-line therapy, liposomal amphotericin B being an alternative (Schwartz et al. 2005; Theuretzbacher et al. 2006; Schwartz et al. 2011; Blyth et al. 2014). Evidence for the use of combination or sequential antifungals in CNS aspergillosis is very limited but this strategy has been successfully employed in some case reports (Ehrmann et al. 2005; Schwartz et al. 2011; Hatipoglu and Hatipoglu 2013; Reminiac et al. 2014).

CANDIDA INFECTIONS

Candida species may invade the meninges from the bloodstream in cases of disseminated candidiasis. Such cases occur most commonly in relatively immune-incompetent preterm infants with prolonged hospital stay and frequent antibiotic exposure (Tripathi et al. 2012). Infants with congenital anomalies, with central venous access, receiving total parenteral nutrition, or with shunted hydrocephalus are most at risk of candidal...
invasion of the CNS (Devlin 2006). Most neonatal fungal infections are due to *C. albicans*. The sources of candidiasis in neonatal intensive care units are often endogenous following superficial colonisation. Disseminated candidiasis presents like bacterial sepsis and can involve multiple organs such as the kidneys, brain, eye, liver, spleen, bone, joints, meninges and heart. Candidal invasion of the CNS may also occur in children receiving myelosuppressive chemotherapy, most often for haematological malignancies. A more protracted period of neutropenia and receiving total parenteral nutrition increases the risk for CNS candida in these patients (McCullers et al. 2000). Confirming the diagnosis is difficult and requires culture of the organism from blood or other sterile bodily fluids (sensitivity of blood cultures is low): a high index of suspicion is required. Other candidal species, such as *C. tropicalis*, may also invade the CNS, and culture is important to ascertain sensitivity to antifungal treatment. In infants and children with risk factors, even a single colony of yeast in the CSF should not be considered a contaminant and treatment should be commenced before positive identification. Isolation of candida from a neonatal blood culture should prompt lumbar puncture (Faix 1984; Tripathi et al. 2012). As with Aspergillus infection (see Aspergillus Infection section), diagnosis of invasive candidal infection may be supported by detection of fungal antigen in blood through ELISA (Wright et al. 2011) or in CSF using PCR. First-line antifungal treatment options include liposomal amphotericin, fluconazole and echinocandins (e.g. micafungin). Some less common candida species are resistant to first-line agents. Isolation and identification of the organism can therefore guide empiric choice of first-line therapy prior to formal sensitivity results being available (Juster-Reicher et al. 2003; Tripathi et al. 2012). As is the case with CNS Aspergillus infection, combination antifungal therapy has been used for severe invasive candida infection, however, there is no good evidence for additional benefit (Hatipoglu and Hatipoglu 2013).

**CRYPTOCOCCUS NEOFORMANS INFECTION**

Cryptococcosis due to *Cryptococcus neoformans* is a systemic fungal infection now most commonly seen in adults with advanced HIV disease. It is rarely seen in HIV-infected children, and following glucocorticoid therapy or solid organ transplant (Severo et al. 2009). CNS involvement is the most serious complication and spread is usually haematogenous from the lungs. The organism produces a granulomatous arachnoiditis that may cause hydrocephalus, cranial nerve palsies and vasculitis of large vessels. The disease may very rarely occur in previously well children (Tjia et al. 1985). Presenting symptoms include headache and fever. The diagnosis of cryptococcosis is difficult, especially in immunosuppressed patients. Blood cultures as well as CSF cultures should be undertaken. The CSF usually shows moderate lymphocytic pleocytosis, increased protein and low glucose. India ink staining demonstrates yeasts in only 60% of patients with positive culture. Cultures may take many days to yield growth and may be initially negative in a proportion of cases. Demonstration of the presence of antigen in the blood and CSF is highly sensitive and specific as well as rapid (Antinori et al. 2005). The test may be positive in up to 90% of cases of cryptococcal meningitis (Siberry et al. 2013). The CSF may be normal in some cases; hence the need to repeat lumbar puncture and to culture large amounts of fluid. Neuroimaging may show cerebral oedema, hydrocephalus and occasionally mass lesions (Fujita et al. 1981). Repeated lumbar puncture may be required to reduce ICP during the acute phase. However, some patients will require shunting. Untreated CNS cryptococcosis is usually fatal. Sequelae in late-treated cases may include blindness,
deafness and chronic hydrocephalus. Treatment practices are guided by evidence from studies in adults. Antifungal combination treatment initially with amphotericin B and flucytosine has been demonstrated to be most effective and is currently recommended (Brouwer et al. 2004; Perfect et al. 2010; Hatipoglu and Hatipoglu 2013); subsequent prophylaxis to prevent remission is advised with flucytosine where there is ongoing immunosuppression (Bicanic and Harrison 2004; Perfect et al. 2010).Cryptococcal meningitis in the context of severe immunosuppression secondary to HIV infection may contribute to clinical deterioration following initiation of antiretroviral therapy. This is caused by an immune reconstitution inflammatory syndrome (IRIS). Evidence supports the practice of initiating antifungal treatments prior to commencing antiretroviral therapy to minimise the risk of this occurring (Siberry et al. 2013).

_C. gattii_ is a rare cause of cryptococcal meningitis and is found most commonly in tropical and subtropical regions. In contrast to _C. neoformans_ it is more frequently isolated in immune competent children (Chen et al. 2014).

**OTHER MYCOTIC INFECTIONS**

Mucormycosis (or Zygomycosis) is a rare fungal infection by environmental moulds from the order Mucorales that usually infects the sinuses and in the immunocompromised may penetrate locally into surrounding tissues including the eye and brain. Combined infections with Aspergillus may also occur. Local surgical treatment as well as antifungal therapy may be required. Voriconazole resistance is common. Liposomal amphotericin B is recommended as first-line therapy. Recent evidence suggests that posaconazole may also be an additional effective therapy but evidence is limited (Rogers and Frost 2009; Blyth et al. 2014).

CNS infections caused by _Coccidioides immitis, Histoplasma capsulatum_ or _ Blastomyces dermatitidis_ are rare in western Europe. These fungal infections are common in some regions of the Americas, Africa and Asia. CNS infection usually occurs as part of a disseminated infection in the immunocompromised and usually with pulmonary manifestations. Clinical features include headaches, low-grade fever, weight loss and minimal meningeal signs. Hydrocephalus may occur. The diagnosis is suggested by the presence of pulmonary lesions, which may remain quiescent for many years. Liposomal amphotericin is probably the most effective treatment (Wheat et al. 2005; Panicker et al. 2006; Siberry et al. 2013).

_Scedosporium apiospermum_ is a fungus found in the soil and contaminated water. CNS scedosporium infection is usually associated with severe immunosuppression (Blyth et al. 2014) but has also been reported in paediatric cases of near drowning (Katragkou et al. 2007). _Scedosporium_ spp. are often resistant to first-line antifungal agents. Treatment should therefore be guided by expert advice and in vitro sensitivity data (Blyth et al. 2014).

Many other rare forms of fungal infection may occur, and should be considered in the immunocompromised with poor phagocytic function. Expert advice should be sought for treatment and management. Often a combined surgical and drug treatment may be required, especially if there is abscess formation.

---

**PROTOZOAN AND PARASITIC INFESTATION OF THE CNS**

With the exception of toxoplasmosis and, to a certain extent, neurocysticercoisis, protozoan or parasitic involvement of the CNS is rare in developed countries. Malaria is, however, of increasing importance because mass travel to endemic countries has developed enormously and because preventive treatment is not always taken or effective. Table 11.16 lists the main clinical features and available treatments for some protozoan and parasitic diseases.

**MALARIA**

Malaria is a tropical parasitic disease of red blood cells, transmitted by the Anopheles mosquito, of which five species infect humans (_P. vivax, P. falciparum, P. malariae, P. ovale_ and _P. knowlesi_). In non-endemic countries such as the UK, case fatality is around 1% but increases in the elderly (Smith et al. 2008; Maliti et al. 2012). In endemic areas, such as parts of Africa, mortality is highest in young children, and at least 1 million children are estimated to die from malaria annually in Africa alone (Snow et al. 2005). Cerebral involvement, a severe complication of malaria most often caused by _P. falciparum_ is a major cause of death, with the peak incidence of cerebral malaria in children aged between 2 and 6 years. Cerebral malaria in children is defined by three criteria: disturbances of consciousness with inability to localise pain (Blantyre coma score <3/5) more than 1 hour after a seizure; presence of parasitaemia; and absence of other causes of encephalopathy. The histopathological hallmark is engorgement of the cerebral capillaries and venules with parasitised and non-parasitised red blood cells (MacPherson et al. 1985). The earliest symptom is usually fever, followed by signs of respiratory distress (secondary to metabolic acidosis and/or anaemia), convulsions and a decreased level of consciousness. Movement disorders and abnormal postures are common. Seizures, which may occur in any form of malaria, are common, and can be generalised or focal. Some may be subclinical. They are associated with a poorer outcome, particularly if prolonged. Status epilepticus is present in 10–20% of cases. Hypoglycaemia is present in 30% of patients and is of severe prognostic significance (Molyneux et al. 1989). Raised ICP is present in most children (Newton et al. 1989).

Adapted from Abramowicz (2004) and with reference to AAP (2012), Simarro et al. (2012) and Lurje et al. (2010).

et al. 1991) with cerebral malaria, and is thought to be due to increased cerebral blood volume. Those children with a markedly elevated ICP have a higher mortality, and greater incidence of long-term sequelae.

Diagnosis is generally made on history, clinical examination, and examination of thick and thin blood smears. Rapid tests for falciparum malaria have a specificity and sensitivity above 97% (Abba et al. 2011) but are not as good as an experienced microbiologist’s confirmation. The CSF findings are usually unremarkable, and if pleocytosis is seen on CSF, experienced microbiologist’s confirmation. The CSF findings are usually unremarkable, and if pleocytosis is seen on CSF, a recent trial in African children showed convincingly that aggressive fluid management was associated with increased mortality (Maitland et al. 2011). Gram-negative sepsis has been associated with severe malaria in children: thus broad spectrum antibiotics should be considered (Scott et al. 2011). The average mortality rate of cerebral malaria is between 15% and 20% (Marsh et al. 1995; Idro et al. 2005), with residual disability present in up to 30% of survivors (Birbeck et al. 2010). Some sequelae are transient; for example, ataxia, others may improve partially over months (motor disorders such as hemiparesis and cortical blindness), while others remain a problem (e.g. seizures and cognitive deficits).

**ACQUIRED TOXOPLASMOSIS**

Infection with *Toxoplasma gondii* is usually mild or asymptomatic, but the CNS can be infected, causing meningoencephalitis in an immunocompetent host, encephalitis and chorioretinitis in neonates following transplacental infection, chorioretinitis as a primary infection, or intracerebral mass lesions in the immunocompromised host.

**NEUROCYSTICERCOSIS**

Neurocysticercosis (NCC) is the most common helminthic disease of the CNS and in many developing countries a leading cause of acquired epilepsy. The disease results from poor sanitation, when humans become the intermediate host in the life cycle of *Taenia solium* by ingesting the eggs of the tapeworm. Infection by the encysted form of *T. solium* may then occur within brain parenchyma, the basilar cisterns or rarely
Chapter 11 Infectious Diseases

Figure 11.25  Sagittal (a) T1-and (b) axial T2-weighted images of multiple cystic lesions secondary to E. granulosis hydatid disease.

the spinal cord, causing inflammation, oedema and residual calcification. Neurocysticercosis usually presents in children when cysts start dying, and provoke inflammation. They present usually with prolonged focal or generalised seizures, but occasionally with focal deficits, signs of raised ICP secondary to cysticercotic encephalitis or hydrocephalus (from blockage of the ventricular system by cysts), or even cognitive decline. NCC is thought to be the most common cause of acquired epilepsy in endemic regions. Diagnosis is made by demonstrating either a single ring-enhancing lesion with surrounding oedema on CT scan or by seeing multiple lesions, some of which may be calcified. MRI may reveal a scolex (Fig. 11.24a) or multiple lesions (Fig. 11.24b) MRI may reveal a scolex which is pathognomonic. Differentiation of a single lesion from other single granulomata, such as a tuberculoma, is difficult, but clinical data taken together with neuroimaging and immunological tests can help confirm the diagnosis. Del Brutto et al. (2001) have proposed a set of diagnostic criteria for neurocysticercosis to aid in diagnosis. Treatment with albendazole (15mg/kg/day for 8 days) has proved effective and superior to praziquantel (Sotelo et al. 1990), with steroids added in cases of heavy infestation or when side effects develop with treatment. A meta-analysis has also shown that the use of albendazole appears to decrease the long-term risk of seizures (Del Brutto et al. 2006).
ECHINOCOCCOCCOSIS

Human infestation by the dog tapeworm, *Echinococcus granulosus*, is known as hydatid disease and is common in sheep-raising countries. Humans are infected by ingesting the ova shed by dogs (the definitive hosts). *E. granulosus* causes cystic hydatid disease, and is mainly responsible for liver and lung hydatids, although in 5% cysts develop in the CNS. As the cysts are slow-growing, they frequently remain asymptomatic until they reach considerable dimensions. Clinical features are mainly symptoms and signs of intracranial hypertension, while focal neurological deficits are rare. On CT or MRI, the cysts appear as round or oval masses with a smooth border and a content of CSF density (Fig. 11.25). Midline shift and ventricular distortion may occur (Tuzun et al. 2002). ELISA or indirect haemagglutination for echinococcal antigens may be helpful.

TETANUS

Tetanus is a serious vaccine-preventable infection that, although rare in industrialised countries, is common in the developing world and is still common in the developing world with neonatal tetanus accounting for over half the cases. Vaccine strategies have resulted in a significant reduction of cases, but still the WHO estimates that in 2015, 34,000 neonates died from neonatal tetanus (WHO 2017). Umbilical cord infections and penetrating wounds contaminated with dirt, faeces and saliva are at high risk for introduction of spores of *Clostridium tetani*. These spores germinate and multiply, and tetanus results from the action of the soluble exotoxin produced, tetanospasmin, which binds to specific receptors on the neuronal cell membrane. It is taken up by nerve terminals and is transported via retrograde axonal transport to the corresponding cell bodies and surrounding presynaptic terminals. The toxin prevents the release of inhibitory neurotransmitters from the presynaptic terminals thus producing uncontrolled firing, with consequent muscle spasms. The clinical manifestations are due to both the central and peripheral actions of the toxin on the release of acetylcholine at the motor plate. Symptoms appear between 3 and 21 days after injury. Shorter incubations are associated with the most severe forms and neonatal tetanus (3–14 days). There are four types of tetanus: generalised, localised, cephalic and neonatal. The first manifestation of tetanus is usually trismus, often associated with neck and back stiffness, salivary stasis and dysphagia. Retraction of the angles of the mouth results in the classic ‘risus sardonicus’ appearance. Subsequently, rigidity becomes generalised and tetanic spasms develop, often precipitated by sensory stimuli. Consciousness is preserved. Sudden respiratory failure due to prolonged spasms, airway blockage or bronchopneumonia accounts for most fatalities. In some cases, tetanus remains localised around the infected wound, in the form of a spa to limit to neighbouring muscles. Cephalic tetanus is consecutive to *C. tetani* oitis or a facial wound. Some degree of trismus is present. Often facial palsy and occasionally paralysis of other cranial nerves are seen. All forms of localised tetanus may secondarily become generalised. Neonatal tetanus follows infection of the umbilical stump in infants of unimmunised mothers. Infants present with weakness and inability to suck, usually in the second week of life. Mortality is high, and developmental delay common in survivors. Diagnosis is clinical, with isolation of *C. tetani* successful in only 30% of cases, and no responsible wound apparent in 7–30% (Crone and Reder 1992). Treatment of tetanus demands intensive care for the maintenance of a free airway and adequate ventilation. The use of sedatives, especially benzodiazepines, is helpful. If adequate ventilation cannot be maintained because of the spasms, neuromuscular blockade is indicated. At the same time, antibiotic treatment (usually with high-dose penicillin G) is given to eradicate the organisms, and neutralisation of any as yet unbound toxin is achieved with antitoxin. Despite such measures, the mortality of tetanus is high, but in those who survive, recovery although slow is often complete. The best prophylaxis of tetanus is immunisation with tetanus toxoid. However, severe tetanus may occur in immunised patients.

DIPHTHERIA

Diphtheria is a rare disease in developed countries. It is caused by a Gram-positive, aerobic bacillus *Corynebacterium diphtheriae*, which, following a throat infection, produces a toxin that blocks the incorporation of amino acids into polypeptide chains and inhibits protein synthesis, resulting in tissue destruction and membrane formation. Neurological manifestations present as one of two forms: local paralyses and polyneuropathy. Local paralyses appear three weeks after throat infection and consist primarily of paralysis of the soft palate and paralysis of accommodation.
Oculomotor and pharyngeal paralyses are possible. One to two weeks later, a symmetrical generalised sensorimotor polyneuropathy occurs with abolition of the deep tendon reflexes. Deep sensory involvement is more involved than motor functions because the toxin induces a segmental demyelination that predominates on the posterior roots (Solders et al. 1989). Cardiac involvement may occur and the neurological picture may closely resemble the GBS. The course is usually toward complete spontaneous cure. Diagnosis is clinical, although culture of the bacillus from a throat swab is possible. Treatment is with diphtheria antitoxin, although this will only neutralise unbound toxin, and antibiotics (penicillin or erythromycin). There is no specific treatment of diphtheritic paralyses apart from supportive measures. Mortality is around 5–10%, although higher in the young and elderly. Recovery is normally complete.

**BOTULISM**

Botulism is caused by the powerful neurotoxin produced by the spore-forming bacterium *Clostridium botulinum*. The botulinum neurotoxin causes paralysis of peripheral nerve terminals by inactivating neurotransmitter release. There are six phylogenetically distinct clostridia which produce seven different botulinum neurotoxin serotypes (A–G), four of which (A, B, E and F) cause naturally occurring human botulism (Rossetto et al. 2014). There may be an eighth serotype (H), but this still requires experimental validation (Dover et al. 2014). Five forms of botulism occur and they are classified according to the route of entry of toxin. The most common type (food botulism) is due to ingestion of the preformed toxin in improperly sterilised preserves or canned foods. In infantile botulism, however, type *C. botulinum* spores are ingested and produce neurotoxin in the digestive tract. This is then absorbed through the intestinal wall producing systemic effects. Less common is wound botulism, where the toxin is produced as a result of a wound infection by *C. botulinum*. This has recently become more frequent as a result of HIV infection and intravenous drug abuse. The fourth type is adult enteric botulism, and the fifth is inhalational, from botulinum toxin being used as a biological weapon.

Patients present with cranial nerve paralyses, causing symptoms such as diplopia, dilated pupils unreactive to light and blurring of vision as a result of paralysis of the ciliary muscles, dysphonia and dysphagia. As the disease progresses in a descending manner, diffuse paralysis with areflexia and respiratory difficulties develops. Autonomic involvement produces dryness of the mucous membranes and bladder distension. Such signs in the presence of fully preserved consciousness are highly characteristic. In food-borne botulism, symptoms can appear within hours of ingestion of contaminated food; gastrointestinal symptoms are common, with abdominal pain, diarrhoea and vomiting. Wound botulism presents as above without the gastrointestinal manifestations. Infantile botulism can occur at any time during the first year of life, but in the majority of cases occurs before the age of 6 months. It frequently follows the introduction of solid food in breastfed infants, and ingestion of honey may be a risk factor. It is characterised by a prodromal phase of constipation with progressive development over 4–5 days of the complete picture of hypotonia, areflexia, poor sucking, prossis and paralysis of other cranial nerves and of the limbs (Thompson et al. 1980; Schreiner et al. 1991). Respiratory difficulty is frequent, and ventilatory support is necessary for most patients. Administration of aminoglycoside antibiotics may precipitate respiratory difficulties (L’Hommedieu et al. 1979; Long et al. 1985). A mild form may be marked only by hypotonia and poor feeding (Thompson et al. 1980). Moreover, asymptomatic carriers are known to exist. It is thus difficult to attribute other syndromes, such as sudden infant death syndrome, to botulism on the sole basis of isolation of *C. botulinum* from the stools (Sonnenbend et al. 1985).

The diagnosis of botulism is made clinically, with neurological symptoms resulting from the blockade at neuromuscular transmission at the neuromuscular junction. Routine laboratory tests including CSF are usually normal, and the diagnosis is made by demonstration of the toxin in the blood or of the organism in the stool. EMG can be helpful to exclude other pathologies. It shows brief, low-amplitude potentials and an incremental response to fast (25–30Hz) repetitive nerve stimulation characteristic of a presynaptic block (Gutierrez et al. 1994). The response to slow (2–5Hz) stimulation is more variable, with increased, normal or decreased responses (Cornblath et al. 1983). Differential diagnoses include neonatal myasthenia, sepsis, viral CNS infections and various other causes of disordered neuromuscular transmission (Swift 1981).

Treatment involves early (within 7 days) administration of botulinum immunoglobulin (BIG), to prevent progression of the illness, plus both respiratory and nutritional supportive care (Haffner 2006). Recovery takes place over a period of several weeks but some weakness may persist for months to years. Relapses may occur (Glauser et al. 1990). It is of note that large quantities of toxin are secreted for months but tolerance develops for unknown reasons.

**OTHER TOXIN MEDIATED DISORDERS**

Some other bacterial infections may act on the CNS through neurotoxins. Shigella infection is associated with a higher incidence of convulsions than explained by associated fever (Ashkenazi et al. 1987). Infection by *E. coli* O157:H7 seems to be a frequent cause of the haemolytic uraemic syndrome (Boyce et al. 1995).

Immune mediated and inflammatory disorders taken together are relatively common in paediatric neurology practice as children are more likely than adults to encounter infectious diseases and immunisations (Chitnis et al. 2016). A variety of disorders are considered in this category including demyelinating conditions such as acute disseminated encephalomyelitis (ADEM), multiple sclerosis, optic neuritis and transverse myelitis as well as other inflammatory disorders of white matter including vasculitis, infections, and granulomatous disorders (Table 12.1). Acute auto-antibody mediated disorders such as anti-N-methyl-D-aspartate (NMDA) receptor mediated encephalopathy, tumours such as Langerhans cell histiocytosis and genetic disorders including Aicardi-Goutières syndrome as well as some mitochondrial diseases are also included under this category, making it one of the most challenging areas of neurology. Many of these disorders are self-limited and reflect a brief encounter with a new infection but at other times the first episode of a more chronic disorder such as multiple sclerosis. In this section we discuss these disorders as well as some information that can be used to provide prognosis of future events and therapy.

### ACUTE DEMYELINATING SYNDROMES

Several disorders referred to as acute demyelinating syndromes (ADS) are responsible for episodes of nervous system dysfunction due to immune mediated disruption of myelin in the central nervous system (CNS) in children (Rotas et al. 2006). A recent Canadian study (Banwell et al. 2009) of 200 children, 1–18 years of age presenting with ADS found the most common presentations of ADS were optic neuritis (23%), ADEM (22%) and transverse myelitis (22%). Children with ADEM were more likely to be younger than 10 years while children with mono-lesional ADS such as optic neuritis and transverse myelitis were more likely to be older than 10 years. ADEM differs from other version of ADS because it includes encephalopathy (Table 12.2): there were 73 incidents per year in the study leading to an annual incidence of 0.9 per 100 000 children while a family history of multiple sclerosis was reported in 8%.

with multiple sclerosis. Disease compared to 15% with monophasic disease. During (3%) and neuromyelitis optica (3%). Familial autoimmune neuritis (22%), monofocal ADS (16%), transverse myelilitis followed by polyfocal ADS with encephalopathy (24%), optic presented with polyfocal ADS without encephalopathy (30%). After the first 3 months from symptom onset no new clinical symptoms or MRI abnormalities are found.

**Pediatric multiphasic acute disseminated encephalomyelitis**
1. Two clinical events meeting criteria for acute disseminated encephalomyelitis, separated in time by greater than 3 months
2. No evidence for clinically-silent new lesion formation on MRI between acute disseminated encephalomyelitis episodes

Pediatric monophasic acute disseminated encephalomyelitis
1. A first polyfocal clinical event affecting the central nervous system
2. Encephalopathy defined as alteration in consciousness not due to fever, systemic illness or a postictal phase
3. Abnormal brain MRI within the first 3 months of clinical symptoms typically demonstrating:
   a. diffuse, poorly demarcated (>1–2 cm) lesions predominantly affecting the white matter
   b. lesions in the thalamus, basal ganglia, deep grey matter or spinal cord (typically longitudinally extensive)

After the first 3 months from symptom onset no new clinical symptoms or MRI abnormalities are found.

ACUTE DEMYELINATING ENCEPHALOMYELITIS

Acute demyelinating encephalomyelitis (ADEM) is an immune-mediated inflammatory demyelinating disorder of the nervous system that produces a prominent encephalopathy, is more common in children than in adults and thought to be triggered by infectious diseases or vaccinations (Tenembaum et al. 2007; Pohl et al. 2016). Two forms of ADEM have been defined, the classic monophasic form, recurrent ADEM and multiphasic ADEM which is a relapse with new features (Table 12.1). According to the International Paediatric Multiple Sclerosis Study Group criteria (IPMSSG; Table 12.2) modified in 2013 (Waldman et al. 2014), monophasic ADEM is characterised by a first polyfocal event affecting the CNS associated with an alteration in consciousness not due to another systemic illness and associated with poorly demarcated white matter lesions as well as lesions in the thalamus, basal ganglia, deep grey matter or spinal cord. It is a relatively rare disorder with an incidence in the United States and Canada of about 0.3/100,000 population. The incidence is higher in the winter and spring months in both the United States and United Kingdom consistent with link to infections. Historically ADEM occurred with an incidence of 1:1000 after infection with measles and 1:10,000 after varicella zoster or rubella virus, but the incidence associated with these illnesses has fallen dramatically where vaccination for these diseases is widespread (Tenembaum et al. 2007). The incidence was also relatively high after vaccination with Pasteur’s rabies vaccine and smallpox vaccination but it has fallen as these vaccines have improved. The presentation of ADEM can resemble other inflammatory disorders of the nervous system as shown in Table 12.1 and it has been reported as a rare presentation of human immunodeficiency virus (HIV) infection in children (Patra et al. 2014). A typical patient with ADEM is under 10 years of age and develops an infectious illness followed in a few days by fever, malaise and headache, nausea as well as vomiting and then by drowsiness, confusion and seizures (Tenembaum et al. 2002). Examination usually shows specific focal neurological signs including bilateral up-going toes, increased reflexes, cranial nerve palsies and optic neuritis which is often bilateral, meningeal signs and slurred speech or aphasia, hemiparesis and ataxia. Signs of spinal cord impairment or polyradiculoneuropathy can also occur as well as prolonged seizures or status epilepticus. Examination of cerebrospinal fluid (CSF) is important to rule out treatable bacterial or other CSF infections but is generally performed after the MRI to rule out mass lesions and increased intracranial pressure (Table 12.1). The CSF in ADEM often shows pleocytosis and oligoclonal bands and the EEG slowing consistent with encephalopathy.

Neuroimaging with magnetic resonance imaging (MRI) plays an important role in the diagnosis of ADEM usually associated with prominent asymmetrical bilateral T2 and fluid inversion recovery (FLAIR) enhancing lesions that reflect pathology in myelin as well as areas of restricted diffusion that may reflect vasogenic oedema (Fig. 12.1). Scattered enhancing lesions also appear in subcortical and cortical grey matter and in the spinal cord in ADEM which may also show prominent enhancement with gadolinium. Pathologically these lesions correspond to infiltrates of T-cells and macrophages associated with demyelination. MRI is important for distinguishing ADEM from the first attack of multiple sclerosis and other disorders. Although 45% of all children with an initial demyelinating episode will have a second episode, only 20% of children initially diagnosed with ADEM will later be diagnosed with multiple sclerosis (Yeh and Tardieu 2010). Ketelslegers et al. (2010) compared diagnostic criteria for distinguishing multiple sclerosis from ADEM (Mikaeloff et al. 2004a, b, 2007) and confirmed the newer criteria recommended by Callen et al. (2009) who reported that periventricular lesions are more frequent in children with multiple sclerosis compared to ADEM. The presence of >2 periventricular lesions, black holes and/or a lesion distribution that was not diffusely bilateral on T2-weighted images made multiple sclerosis more likely to be present than ADEM.

Experimental autoimmune encephalomyelitis (EAE) has been reported to be a model for ADEM and cross-reactive
T cell responses have been demonstrated between viral sequences and myelin basic protein (Javed and Khan 2014). Several characteristic imaging patterns of cerebral involvement have been described including scattered small lesions, large confluent lesions, symmetrical bi-thalamic involvement and hemorrhagic lesions. The latter finding may indicate acute hemorrhagic leukoencephalitis (AHL) which is a more fulminant and aggressive form of ADEM with a higher mortality (Kuperan et al. 2003). Patients with AHL may have perilesional oedema and severe increased intracranial pressure with magnetic resonance spectroscopy showing low levels of N-acetylaspartate (NAA), a marker for mitochondria in neurons, as well as elevated lactate in regions of prolonged T2 signal (Aydin et al. 2010). AHL has been reported following a variety of viruses including the H1N1 strain of influenza as well as enterovirus infections and it has also been observed in patients following diphtheria, tetanus toxoid and pertussis vaccinations. The disorder has also occurred in patients with mutations in the complement factor I pathway as well as in three sibling infants in a family in Tunisia with genetic mutations in the RANBP2 gene (Broderic et al. 2013; Jeganathan et al. 2013; Tabarki et al. 2013; Di Meglio et al. 2014).

The clinical presentation of patients with ADEM is often alarming and patients are usually admitted to intensive care units. However, despite the nature of their presentation children with ADEM are very likely to recover with few neurological deficits and MRI lesions in the brain often disappear as well (Tenembaum 2013), with full recovery seen in 50–70% of patients and 20–30% recovering with some minor residual disability: average time to recover is 1–6 months. However the mortality rate may be as high as 5% and there may be milder neurocognitive deficits even in children who appear to have a full neuromotor recovery (Suppiej et al. 2014).

The IPMSSG consensus definitions for ADEM require that it must be multifocal, polysymptomatic and include encephalopathy (as an essential requirement). An alternative diagnosis for a first acute inflammatory event is ‘clinically isolated syndrome’ (CIS), with a CIS event being either monofocal (such as isolated optic neuritis) or multifocal but cannot include encephalopathy. As with adults, children with two or more discrete demyelinating events separated in time and space meet criteria for multiple sclerosis; in children with multiple sclerosis the demyelination events must not meet ADEM criteria. To test the usefulness of these new criteria a new cohort of 40 patients (18 males, 22 females; mean age 8 years [SD 4 years 4 months]) with CNS demyelination were studied. Using IPMSSG definitions the presenting diagnosis was ADEM in 12 patients and CIS in 28 patients and at
presentation patients with CIS were more likely to have intrathecal synthesis of oligoclonal bands and fulfil KIDMUS multiple sclerosis MRI criteria, compared with patients with ADEM \( (P < 0.025) \).

Patients were followed-up for a mean of 2 years and 2 months with only one of 12 patients with ADEM going on to develop multiple sclerosis during the study period while 13 of 28 patients with CIS relapsed and fulfilled a diagnosis of multiple sclerosis \( (P < 0.025) \).

The proportion of children with ADEM subsequently diagnosed with multiple sclerosis within 5 years varies between 10% and 18% (Waldman et al. 2014). The methodology of the study has an impact on this proportion: when the criterion of encephalopathy in ADEM definition is strictly applied the percentage of children with ADEM who subsequently are diagnosed with multiple sclerosis becomes lower (an absence of encephalopathy at first demyelinating event is a well-defined risk factor for relapse); however, the region of study might also be a factor. In any case this proportion is lower than that of children with any type of first demyelinating event subsequently diagnosed with multiple sclerosis, the percentage being between 18% and 46% depending on studies and methodology (Mikaeloff et al. 2004b, 2007).

Dale and Pillai (2007) followed groups of children with ADEM, multiphasic disseminated encephalitis (MDEM) and multiple sclerosis for approximately 5 years and reported that subcortical white matter lesions were common in both groups although periventricular lesions were more common in multiple sclerosis. In contrast, in ADEM there was relative periventricular sparing and MRI follow-up revealed complete or partial lesion resolution in 90% as well as no new lesions while all multiple sclerosis patients had new lesions at follow-up. Female sex and age greater than 11 years are associated with a greater risk of multiple sclerosis after ADEM while a normal brain MRI is associated with a lower risk. Absence of non-enhancing T1 hypointense lesions and less than 2 periventricular lesions at onset favour ADEM while periventricular T2 lesions and more than one hypointense T1 lesions favour multiple sclerosis. A United States study of ADEM and multiple sclerosis diagnosed in children after long term follow-up found that none of the patients who presented with encephalopathy developed multiple sclerosis (Alper et al. 2009). Family history of multiple sclerosis is also more common in children with multiple sclerosis over ADEM while the multiphasic form of ADEM comprises 5% or less of children, most of whom develop multiple sclerosis.

Therapy for ADEM is generally started with high dose steroids such as intravenous methylprednisolone (10–30mg/kg/day to a maximum of 1 gram per day) followed by a steroid taper of prednisone over 4–6 weeks. Some data suggests that the outcome of ADEM is improved by steroids but there are no large controlled trials, while IgG and plasma exchange have also been used. Dale et al. (2000) reported that 20% of 35 children in their series who presented with ADEM relapsed and were classified as having multiphasic disseminated encephalomyelitis (MDEM). These patients generally relapse with signs similar to the original event and may respond to repetition of the same therapy.

**OPTIC NEURITIS**

Optic neuritis presents with sudden onset of diminished vision in one or both eyes due to inflammation of the optic nerve. It can present with swelling of the optic nerve head and a relative afferent pupil defect as well as visual field restriction and painful eye movements. Retrobulbar optic neuritis is diagnosed when there are typical signs and symptoms of optic neuritis without optic nerve head swelling. A new technique called retinal optical coherence tomography can assess damage to the retinal fiber layer caused by optic neuritis (Balk and Petzold 2014). Optic neuritis can be caused by multiple sclerosis as well as a variety of other disorders including viral and bacterial infections, viral encephalitis, Lyme disease, sarcoid, cat scratch fever, sinusitis, vaccinations, inherited white matter disorders, B12 deficiency, vasculitis and diabetes, as well as some medications (Toosy et al. 2014). Autoimmune disorders such as systemic lupus erythematosus (SLE) and Sjogren syndrome can also cause optic neuritis while neuromyelitis optica generally causes bilateral optic neuritis in association with transverse myelitis and is associated with antibodies to aquaporin-4 (Wingerchuk and Weinshenker 2014). Optic neuritis is generally associated with better recovery in children than in adults (Brady et al. 1999) with a recent study of paediatric patients with a median age of 11 years with their first episode of optic neuritis showing that 77% regained normal visual function within 1 year although 34% developed signs of multiple sclerosis or neuromyelitis optica (Absoud et al. 2011). The presence of white matter lesions and oligoclonal bands in CSF on an MRI at the time of diagnosis of optic neuritis as well as older age substantially increased the risk of having multiple sclerosis diagnosed (Bonhomme et al. 2009; Heussinger et al. 2013). Another study of optic neuritis in children by Wilejto et al. (2006) reported that optic neuritis was associated with a risk of diagnosis of multiple sclerosis within 2 years in 36% of patients and bilateral optic neuritis carried a greater risk of later multiple sclerosis than unilateral. Clinical findings extrinsic to the visual system on baseline examination and MRI evidence of white matter lesions outside the optic nerves were strongly associated with later diagnosis of multiple sclerosis (Waldman et al. 2011). The randomised, controlled trial of corticosteroids in the treatment of acute optic neuritis in adults found that intravenous methylprednisolone followed by oral prednisone sped up the recovery of vision and resulted in slightly better vision at 6 months but there has been no comparable study in children with optic neuritis (Beck et al. 1992).

**ACUTE TRANSVERSE MYELITIS**

Acute transverse myelitis (ATM) affects one to three per million children per year and is suspected when there is acute
onset of sensory, motor or autonomic dysfunction attributable to spinal cord dysfunction with a defined sensory level and MRI rules out extra-axial compression but shows gadolinium enhancement (Transverse Myelitis Working Group 2002; Absoud et al. 2011; Ketelslegers et al. 2012). According to the Transverse Myelitis Consortium Working Group diagnosis guidelines, the diagnosis of transverse myelitis is also supported by pleocytosis, oligoclonal bands or elevated IgG index in the spinal fluid. However, it is also important to rule out other causes of spinal cord paralysis including arterial stroke, AVM, collagen vascular disorders such as SLE as well as infectious diseases including HIV and herpes (Verhey and Banwell 2013; Sarioglu et al. 2014). Guillain-Barré syndrome (GBS) can also present with ascending numbness, tingling and leg weakness but GBS generally lacks CSF pleocytosis and a definable sensory level or spinal cord lesion on MRI. ATM is usually a monophasic illness and a history of previous episodes of myelopathy, optic neuritis or brain lesions on MRI may suggest multiple sclerosis. Neuromyelitis optica (NMO) should also be suspected with recurrent transverse myelitis, especially if there is concurrent bilateral optic neuritis, involvement of a spinal lesion greater than three vertebral segments on magnetic resonance and/or serum antibodies to aquaporin-4 protein (Absoud et al. 2014). A small number of children with transverse myelitis plus ADEM have also been reported and they present with signs of encephalopathy and central demyelination plus flaccid paralysis as well as electromyographic evidence of axonal loss in nerve roots and worse than average prognosis (DeSena et al. 2014).

ATM in children less than 18 years of age is a relatively rare disorder estimated to account for about 20% of the 1400 individuals diagnosed each year in the United States. One of the largest centre-based follow-up studies of children with ATM by Pidcock et al. (2007) showed 47 affected individuals of whom 42 were monophasic and idiopathic, with four later diagnosed with NMO, ADEM, SLE or multiple sclerosis. In this cohort there were two distinct groups by age at onset, less than 3 years of age and the other 5–17 years of age with males and females equally affected. Evidence of an infectious disease such as fever or elevated white blood cell count was present on average of 11 days prior to spinal cord symptoms of ATM, while 28% had been given an immunisation or allergy injection within the previous 30 days and antecedent trauma to the child such as a fall was documented in 13%. Almost 90% of children described sensory loss and numbness, weakness, urinary dysfunction and pain at the onset of illness with the same number becoming bed/wheelchair bound and some needing assisted ventilation within 2 days of onset. Gadolinium infusion showed magnetic resonance enhancing lesions in 74% and the CSF white blood cell count was elevated in 50% and protein in 48% but these values were normal in 31% while oligoclonal bands were present in less than 5%. At follow-up, 67% were able to walk or use a manual wheelchair to travel 150 feet and 50% required intermittent bladder catheterisation and experienced persistent numbness and dysesthetias. Older age at onset, shorter time to diagnosis, lack of CSF pleocytosis and fewer spinal cord segments involved were associated with better outcome while hypodensity of the cord on T1-weighted images was associated with worse outcome.

The largest study to date of risk factors for poor outcome following idiopathic transverse myelitis in children is a recent European study of 95 children less than 16 years of age from clinical centres in France and the United Kingdom (Deiva et al. 2015). This study reported that 17% relapsed with a diagnosis of multiple sclerosis in 14% and NMO in 3%. Female sex and the presence of associated brain lesions on MRI were identified as risk factors for relapse using logistic regression analysis. Twenty-eight (30%) of the transverse myelitis group had a poor outcome defined by a Kurtzke Expanded Disability Status Scale (EDSS) score of ≥4 or an American Spinal Injury Association impairment (ASIA) scale score of <D. The risk factors linked to poor outcome through logistic regression were female sex (odds ratio: 5.8), severe ASIA scale at onset (odds ratio: 33.5), gadolinium enhancement on spinal MRI (odds ratio: 24.1), absence of pleocytosis (odds ratio: 4.6) and absence of cervical or cervico-thoracic lesions on spinal MRI (odds ratio: 3.9).

Another study of prognostic indicators for paediatric acute transverse myelitis reported short time to maximal deficit, long time of peak neurological impairment and initial time of treatment, increased protein levels of CSF and secondary infections were associated with a poor prognosis (Chen et al. 2013) These studies of prognostic factors for relapse and disability are important for planning international collaborative trials to define better therapies and improve outcomes.

Treatment for children with transverse myelitis includes intravenous corticosteroids (70%), intravenous immunoglobulin (33%), oral steroids (28%), plasmapheresis (15%), acyclovir (11%) but there was no discernable difference in outcome in this retrospective study. Sebire et al. (1997) compared a group of patients with transverse myelitis treated with high dose methylprednisolone treatment (1g/1.73m2) for 3–5 days with a historical group of ten patients without steroids and reported the median time to walk independently was significantly reduced from 97 days to 23 days as well as that the proportion of patients with full recovery was 80% versus 10%. Many centres administer intravenous solumedrol 1gr/day intravenous for 3–5 days after ATM is diagnosed which is generally supported by evidence based guidelines (Scott et al. 2011) as is consideration of plasmapheresis or rituximab for immunomodulatory therapy used in adults with the disorder (Bigi and Banwell 2014; Carrithers 2014).

BRAINSTEM ENCEPHALITIS

BRAINSTEM ENCEPHALITIS

BRAINSTEM ENCEPHALITIS in children presents as an acute inflammatory process with encephalopathy and prominent signs of brainstem dysfunction including external ophthalmoplegia, ataxia, multiple cranial nerve involvement, tremor, myoclonic jerks as well as swallowing and speech problems (Pavone et al. 2014). As many as half of individuals with ADEM have lesions in the brainstem and present with brainstem signs.
Multiple sclerosis was first described by Charcot in 1868/1869 and his pupil Pierre Marie reported 13 individuals affected by multiple sclerosis with onset in childhood by 1883. Since the 1950s paediatric multiple sclerosis has re-emerged as a disease entity (Waldman et al. 2014, 2016; Lee and Chitnis 2016; Tardieu et al. 2016). Paediatric multiple sclerosis in children is typically a chronic remitting-remitting demyelinating disorder in which lesions are disseminated over space and time in the nervous system (Table 12.3). Primary progressive multiple sclerosis is rare in children and should prompt the search for an alternative diagnosis.

Estimates in the United States suggest 8000–10 000 children have multiple sclerosis and patients with paediatric multiple sclerosis are thought to comprise 5% of all multiple sclerosis patients throughout the lifespan. A recently estimated incidence of paediatric multiple sclerosis in Germany was 0.64 per 100 000 population with most older than 10 years of age having an incidence of 2.64 per 100 000. Children often experience more frequent relapses than adults especially during the first few years after diagnosis, although over-all disease progression may be slower and children experience lethargy and seizures as well as psychiatric and intellectual decline (Waldman et al. 2014).

Epidemiological data indicates females predominate approximately two to one in children over 10 years of age and that a childhood spent in temperate climates where inadequate exposure to sunlight limits vitamin D increases the risk of paediatric multiple sclerosis (Munger et al. 2014).

The fact that multiple sclerosis clusters in some families with large numbers of affected siblings per generation and varies in incidence widely around the world, with some ethnic groups

**MULTIPLE SCLEROSIS**

According to the National Multiple Sclerosis Society, multiple sclerosis (MS) is a chronic disease that affects the brain and spinal cord, causing problems with movement, sensation, vision, balance, and other functions. The cause of MS is still unknown, but it is believed to be an autoimmune disorder, meaning the immune system mistakenly attacks healthy tissue. The symptoms of MS can range from mild to severe and can affect anyone at any age, but it is most common in young adults.

**Clinical Definitions of Pediatric Multiple Sclerosis and Related Disorders**

<table>

(DeSena et al. 2014) while another smaller group presents with ophthalmoplegia, ataxia and drowsiness which has been called mesencephalitis or rhombencephalitis and hypothesised to be localised to the midbrain. Miller Fisher described cases of ophthalmoplegia, ataxia and areflexia, postulating that it was a variant of GBS because of the diminished reflexes and albinocytological dissociation (Wakerley et al. 2014; Yuki et al. 2014). These disorders appear to be a continuum of abnormalities in the brainstem with some being caused by GBS: those with overlapping GBS develop limb weakness. Abnormal MRI findings in the brainstem were detected in 23% but the EEG was abnormal 70% of the time (Wakerley et al. 2014) with these patients sometimes positive for IgG antibodies to the GQ1b ganglioside antigen characteristic of Miller-Fisher syndrome, while the inflammatory nature of the disorder has been confirmed in several autopsy reports (Paparounas et al. 1999). Similar cases of brainstem encephalitis have been reported after a variety of infections in children and adults including mycoplasma pneumoniae infection, Ebstein-Barr virus, H1N1 influenza, streptococcus and cat scratch fever (Meyer Sauter et al. 2014). Enterovirus 71 emerged in the late 1990s in eastern Asia as a neuroviral virus that causes large outbreaks of hand-foot-mouth disease, herpangina as well as fever and, in some children, meningitis, acute flaccid paralysis and brainstem encephalitis complicated by pulmonary oedema and cardiopulmonary collapse. Enterovirus infections in neonates can cause severe disease characterised by meningoencephalitis, myocarditis, pneumonitis and/or hepatitis as well as coagulopathy (Lee et al. 2014). A large number of affected individuals have also been reported after Japanese encephalitis and enterovirus type 71 infection in children associated with complications such as meningitis, poliomyelitis like syndrome and encephalopathy. Some patients with Japanese encephalitis had opsoclonus, gaze palsies, pupillary changes and seizures while an aggressive form of brainstem encephalitis leading to death has been described in a child with an auto-antibody to y-aminobutyric acid type B receptor (Krueger et al. 2014). Glycine receptor antibodies have also been described in patients with brainstem encephalitis (Carvajal-Gonzalez et al. 2014).

Neuroimaging revealed involvement of the brainstem, basal ganglia and hippocampus. Zeng et al. (2012) described MRI changes in children with enterovirus71-induced brainstem encephalitis including lesions in the dorsal pons, medulla, cerebellar dentate gyrus, midbrain and thalamus. Treatment of brainstem encephalitis has been successful with intravenous immunoglobulin (Ig) administration and other immunomodulatory therapy including alemtuzumab (Pavone et al. 2014).

such as African-American children having a higher incidence, supports a genetic influence. Genome wide association, linkage studies and single-nucleotide polymorphism analysis point to an association of multiple sclerosis in both children and adults with human leukocyte antigens (HLAs) contained within the major histocompatibility complex especially the HLA-DRB1*1501 allele with an odds ratio of 3 (Disanto et al. 2011; Waubant et al. 2016).

The diagnosis of multiple sclerosis is based on the history and neurological examination as well as MRI and the exclusion of alternative diagnoses (Table 12.4, Fig. 12.2). Multiple sclerosis typically produces neurological signs and symptoms that are waxing, waning and linked to changing locations in the brain and spinal cord over time, lesions, which can be well visualised using MRI. The use of the McDonald diagnostic criteria of the International Panel on Diagnosis of multiple sclerosis in adult was recently revised in 2010 and previous versions have resulted in earlier diagnosis of multiple sclerosis with a high degree of specificity and sensitivity; these criteria have led to fewer false positives and allow earlier initiation of therapy (Sadaka et al. 2012). These criteria have been modified for paediatric use by the IPMSSG to provide definitions for paediatric multiple sclerosis, CIS, ADEM and NMO in 2012 (Table 12.3; Krupp et al. 2013; Chitnis and Pohl 2016). A diagnosis for multiple sclerosis can be satisfied by any of the following criteria:

1. Two or more non-encephalopathic (non-ADEM) clinical inflammatory CNS events separated by more than 30 days and involving more than one area of the CNS;
2. One nonencephalopathic event typical of multiple sclerosis with magnetic resonance findings consistent with the 2010 Revised McDonald Criteria for dissemination in space and in which the MRI shows at least one new enhancing or nonenhancing lesion consistent with dissemination in time;
3. One ADEM episode followed by a nonencephalopathic clinical event, 3 or more months after symptom onset, that is associated with new MRI lesions that fulfill 2010 McDonald criteria for dissemination in space;
4. A first, single, acute event that does not meet ADEM criteria and whose MRI findings are consistent with the 2010 McDonald criteria for dissemination in space and time, applying only to children >12 years.

These guidelines also provide several radiological criteria that have been tested with respect to their ability to establish a diagnosis of multiple sclerosis in children based on dissemination in time and space. Characteristics of MRI lesions that lead one to a diagnosis of multiple sclerosis are lesions in a periventricular location, hypointense lesions on T1 imaging and the absence of bilateral diffuse lesions. A long-term follow-up study using the IPMSSG criteria in children with CNS demyelination demonstrated the usefulness of these guidelines (Peche et al. 2013; Banwell et al. 2016).

Cerebrospinal Fluid in Multiple Sclerosis
Younger children with multiple sclerosis tend to have higher CSF neutrophil counts than older children or adults while oligoclonal bands as evidence of intrathecal immunoglobulin are less likely to appear in younger patients. The absence of CSF IgM has been associated with an increased relapse rate. Proteomic analysis of CSF has demonstrated increased levels of several axoglial proteins localised to the area where the oligodendroglia meet the axonal membrane. Several studies indicate that oligoclonal bands are present in a high percentage of children and adolescents with relapses of multiple sclerosis (Waldman et al. 2014).

Multiple Sclerosis and Cognitive Development in Children
Cognitive development and mood are often affected in children with multiple sclerosis and impairment has been reported in executive function, processing speed, visuomotor integration and attention in several studies, particularly when multiple sclerosis begins in younger children (Amato et al. 2014, 2016; Hosseinì et al. 2014). Several longitudinal studies reported cognitive decline in paediatric patients with multiple sclerosis over several years which may be related to diffusion tensor imaging (DTI) studies which show reduced fractional anisotropy...
Part V  Postnatal Extrinsic Insults

in the corpus callosum and related areas of white matter (Till et al. 2011, 2012, 2013; Julian et al. 2013). A correlation between reduced fractional anisotropy in white matter and impaired performance in mathematics and processing speed has been reported in children without other white matter imaging changes (Till 2012). White matter changes have also been reported in magnetisation transfer sequences from children with multiple sclerosis. Supporting children and adolescents with multiple sclerosis often requires a multidisciplinary approach that takes into consideration the perspectives of patients and their parents. Support from social workers, psychologists and psychiatrists is often helpful as families deal with the impact of the diagnosis of multiple sclerosis and the side effects of medications needed to treat it. Appropriate sensitive and focused care should include the perspectives of the patient and parents and should be aimed at enhancing individual and family coping (Krupp et al. 2016).

CLINICALLY ISOLATED SYNDROMES

Continued observation of the patient over time usually confirms or rules out the diagnosis of multiple sclerosis but the future is less clear with the appearance of initial demyelinating CIS events such as optic neuritis, internuclear ophthalmoplegia or transverse myelitis episodes seen mostly in adolescents and that carry a high risk of conversion to multiple sclerosis. Neuteboom et al. (2008) retrospectively reviewed 117 children below age 16 who initially presented with a monofocal CIS (referable to a single location such as optic nerve, brainstem, hemisphere, cerebellum or spinal cord) or an initial polyfocal CIS. Over a period of 54 months, 31% of children with an initial monofocal event were diagnosed with multiple sclerosis later based on additional demyelinating episodes dispersed in time and space while those who presented with a polyfocal event were diagnosed with multiple sclerosis 13% of the time.

Figure 12.2 A 14-year-old girl with a diagnosis of multiple sclerosis. (A and D) Axial T2-weighted and (B) FLAIR images showing multiple ovoid shaped hyperintense lesions in both cerebral hemispheres involving the periventricular deep and subcortical white matter. (E) Axial T1-weighted MR image after the intravenous injection of contrast agent shows enhancement of a left frontal lesion indicating active inflammation (arrows on D and E). (C and F) Parasagittal FLAIR images show the typical radial arrangement of the demyelinating plaques following the course of the intramedullary veins also known as Dawson’s fingers (arrow in C). An elevated IgG index and presence of oligoclonal CSF bands were more often observed in children who developed multiple sclerosis. MRIs were diagnosed with a predetermined scoring system using criteria based on the revised McDonald criteria or the KIDMUS MRI criteria (Banwell 2008) which were highly specific with the McDonald criteria positive in 60% of children with multiple sclerosis versus 7% in the monophasic patients and the KIDMUS criteria positive in 49% of children with multiple sclerosis versus 4% of those with monophasic events. An ADEM-like presentation or lesions in the basal ganglia identified patients at low risk for multiple sclerosis. Mikaeloff et al. (2004a) reported on 296 children with a first episode of acute CNS demyelination followed for 3 years and found at the end of follow-up that 57% had a diagnosis of multiple sclerosis, 29% had a monophasic event of ADEM and 14% had a single isolated event: in this group the rate of second attack was higher in older children and lower in children with ADEM presentations. These two studies support the notion that isolated demyelinating events are more likely to predict multiple sclerosis than polyfocal events and ADEM.

**ADEM VERSUS MULTIPLE SCLEROSIS**

There is often concern about the likelihood that children with ADEM will acquire multiple sclerosis since both are demyelinating disorders. At times the differential diagnosis between ADEM and multiple sclerosis can be confusing, for reasons including that ADEM may recur with signs continuing to meet criteria for ADEM rather than multiple sclerosis, so called multiphasic ADEM. Dale et al. (2000) reported several important differences between patients with ADEM and multiple sclerosis including a much higher incidence of a predemyelinating illness and encephalopathy as well as a much lower incidence of white matter lesions in ADEM than multiple sclerosis. Bilateral optic neuritis was more common in ADEM than multiple sclerosis but unilateral optic neuritis was seen in multiple sclerosis but not in patients with ADEM. From an MRI standpoint Callen et al. (2008) analysed scans from children with first episodes of ADEM as well as multiple sclerosis and found patients with the latter had more periventricular white matter lesions than those with the former although the total number of white matter lesions in both groups was similar. Patients with multiple sclerosis also had fewer bilateral magnetic resonance lesions and more black holes seen on T1-weighted images. The data from Mikaeloff et al. above also support the the statement that ADEM is usually not a harbinger of multiple sclerosis (Dale and Pillai 2007).

**Therapy for Paediatric Multiple Sclerosis**

Multiple sclerosis is characterised by CNS inflammation, formation of plaques, demyelination, axonal injury and axonal loss. The pathogenesis of multiple sclerosis is thought to involve the movement of autoreactive T-cells, monocytes and B-cells from the peripheral circulation through the blood–brain barrier into the brain where they attack oligodendroglia and axons to cause demyelination and gliosis (Ciccarelli et al. 2014; Bar-Or et al. 2016). White cells are initially activated in peripheral lymph nodes by self-antigens presented by antigen-presenting macrophages, B-cells and dendritic cells in association with major histocompatibility class II molecules. T-cells activated outside the CNS are re-activated within the brain by local antigen-presenting cells (microglia, astrocytes and B-lymphocytes). Secreted proinflammatory cytokines such as IL-2 and interferon (IFN)-γ attack myelin, stimulate microglial cells and astrocytes, recruit inflammatory cells and induce antibody production by plasma cells. Helper CD4 T-cells and cytotoxic CD8 T-cells are the major types of cells in multiple sclerosis plaques in the brain, while auto-reactive CD4 helper T-cells secrete pro-inflammatory cytokines. Some evidence suggests that T-cells react more strongly to myelin in children than adults with multiple sclerosis and also express more interleukin 17 compared to adults (Kamm et al. 2014).

Medications used to treat multiple sclerosis are shown in Table 12.5 (Brenton and Banwell 2016). Intravenous methylprednisolone is commonly used to shorten severe episodes, especially those that affect vision. The first-line disease-modifying
drugs for children are the interferons β-1a and β-1b that modify the multiple sclerosis disease process when given chronically (Waubant et al. 2001; Ghezzi et al. 2005, 2016; Banwell et al. 2006). The exact mechanism of action for the interferons is not fully understood, but they may act by decreasing the synthesis of inflammatory cytokines–interferon gamma and tumour necrosis factor alpha. Interferon β-1b may also stabilise the blood–brain barrier damaged in multiple sclerosis by blocking apoptosis of the endothelial cells that make up the blood–brain barrier (Haghooy et al. 2012). In adults large randomised double-blind trials (Jacobs et al. 2000) have shown that treatment with interferon β at the time of the first demyelinating event is beneficial for patients with brain lesions on MRI that indicate a high risk of clinically definite multiple sclerosis. The IPMSSG (Chitnis et al. 2012) reviewed the literature on disease-modifying drugs for multiple sclerosis in children 2012 and found eight studies in children 11–14 years of age given interferon β-1a once a week intramuscularly in doses escalating from 10mcg to 44mcg weekly. These studies all found that the interferons β-1-a and β-1-b were well tolerated and side effects consisted mostly of flu-like symptoms, mild elevation in liver enzymes and reaction at the injection site, with major side effects rare.

Glatiramer consists of artificial polypeptides that compete with endogenous myelin proteins for uptake into helper T-cells for antigen presentation (Yeh 20110). Ghezzi et al. (2005) examined the disease modifying effect of interferon β-1a, β-1a (Rebif) and glatiramer acetate in a group of 76 adolescents with a mean age at onset of 12.4 years, finding that the mean annualised relapse rate fell from 2.4 to 0.4 in the interferon β-1a group, 3.2 to 0.8 in the Rebif-Betaferon group and 2.8 to 0.25 in the glatiramer acetate group. Based on this information the IPMSSG recommended that all paediatric patients with multiple sclerosis should be considered for treatment with either a β interferon or glatiramer acetate as first-line therapy. Current data suggests the IFNs and glatiramer acetate are safe and effective therapies in paediatric patients with multiple sclerosis and the group also recommended these first-line medications for children presenting with clinically isolated syndromes as described above. The report recommended dosing should be titrated upward to the adult dose of interferons over several weeks as recommended by the medication label and that appropriate blood testing such as liver function tests should be followed.

Options for children with multiple sclerosis who do not respond to first line medications are less clearly documented (Ghezzi 2014; Chitnis et al. 2016). Cyclophosphamide has been used for children with multiple sclerosis who continue to worsen despite first-line therapy and there is considerable experience with this drug in paediatric oncology. Makhani et al. (2009) reported 17 patients who continued to worsen despite first-line therapy and the majority of children responded with a reduction in relapses and stabilisation 1 year later, however, this drug can cause nausea, vomiting and neutropenia. Natalizumab works by binding to integrin molecules on the blood–brain barrier to block entry of peripheral white cells which initiate the multiple sclerosis process in the brain however this drug is a powerful immunosuppressant and may increase susceptibility to progressive multifocal leukoencephalopathy (PML) in some individuals (Tur and Montalban 2014). Natalizumab is only available in the United States and Europe through restricted distribution programmes.

The newer drugs teriflunomide, fingolimod and dimethyl fumarate have not been used as much in children but have complementary mechanisms to the older drugs and might be expected to provide benefit when first-line drugs have failed. These new drugs also have the benefit of being active when taken orally while older drugs have to be given subcutaneously or intramuscularly. Fingolimod, a sphingosine 1-phosphate receptor modulator, is a new disease-modifying therapy approved by the US FDA in 2010 for the first-line treatment of relapsing forms of multiple sclerosis in adults (Kappos et al. 2010). Further studies evaluating the pharmacokinetics, appropriate dosing and comparisons of efficacy among these agents are needed to determine the most appropriate and evidence-based treatment decisions in this population. The B-cell suppressing drug rituximab has also been used in adult demyelinating diseases and a retrospective series of 11 cases of paediatric multiple sclerosis and neuromyelitis optica has been reported by Beres et al. (2014). Eight patients with neuromyelitis optica, two with relapsing-remitting multiple sclerosis and one with secondary-progressing multiple sclerosis, were treated for a median number of three cycles and 82% reportedly experienced a reduction in relapses. There were no serious infections but three patients had infusion reactions managed with a reduction in infusion rate. Clinical trials of new oral compounds such as fingolimod, teriflunomide and others are currently ongoing.

### Antibody-Mediated Encephalopathy

This large group of diseases is heterogeneous both in terms of clinical symptoms and the demonstration of the causative link between the detected antibody and the disease.

### Neuromyelitis Optica

NMO or Devic disease usually presents with bilateral optic atrophy and a spinal cord lesion that resembles transverse myelitis and is based on the presence of:

1. A spinal cord lesion extending over three or more vertebral segments on MRI;
2. A brain MRI that does not meet the criteria for multiple sclerosis; and

Brain lesions in NMO are commonly seen in the optic chiasm and area postrema of the brainstem: although once
considered a subtype of multiple sclerosis, it is now thought to be a separate diagnostic entity with a distinct pathophysiology and therapeutic approach. The AQP4-IgG antibody directed against aquaporin-4 water channels is highly specific for NMO while titre in plasma correlates with NMO disease activity. AQP4-antibody-positive plasmablasts which make IgG are selectively increased in the blood of patients with NMO when a relapse is occurring. AQP4-positive patients are more often female (10:1), show a relapsing pattern of disease and exhibit other types of auto-immunity including SLE, Sjögren syndrome, autoimmune thyroid disease and myasthenia gravis (Jurynczyk et al. 2014). Successful treatment is associated with a fall in AQP4-IgG and therapies directed at B cells such as rituximab and plasma exchange are more effective than interferon treatments used in multiple sclerosis. AQP4-positive sera from humans has been shown to reproduce the NMO pathology in mouse spinal cord slices when combined with human complement. Glutamate-mediated neurotoxicity has also been implicated in the NMO-IgG mediated neuropathology. NMO spectrum disorders can also be diagnosed in patients affected by AQP4-IgG seronegative but are seropositive for antibodies against myelin oligodendrocyte glycoprotein (MOG-Ig), with these patients generally younger at onset of symptoms (Hardy et al. 2016).

From a clinical standpoint the oligoclonal bands found in approximately 90% of CSF samples from patients with multiple sclerosis are found in only 18% of patients with NMO. Brain lesions in NMO tend to be located in regions where there is high expression of the AQP4 receptors on water channels such as the dienecphalon, hypothalamus and aqueduct. MRI in NMO often shows lesions in optic nerves and spinal cord that are hyperintense on T2 weighted images and hypointense on T1-weighted images and which enhance with gadolinium (Hardy et al. 2016). Inflamed lesions enlarge due to oedema in the acute phase and may persist for months during which time they become atrophic (Kister et al. 2013). However, despite their differences from patients with multiple sclerosis affected by NMO, they may also have lesions that do fulfill criteria for multiple sclerosis. The reason for the long segment lesions seen in NMO spinal cord lesions is not understood although studies with optical coherence tomography (OCT) have shown neuroaxonal damage that reflects damage to the retinal ganglion cells in NMO is greater than in multiple sclerosis, which is consistent with the clinical observation of more severe visual dysfunction in NMO than in multiple sclerosis (Bouyon et al. 2013). Infections preceed episodes of relapse in NMO about 30% of the time and these patients may be more susceptible to tuberculosis as well as human immunodeficiency virus infections.

For treatment of acute episodes of NMO corticosteroids and plasma exchange are generally the first line of therapy and methylprednisolone at 1000mg/day for 5 days for adults is generally given as in multiple sclerosis. Plasma exchange given every other day for 2 weeks is also reported to be effective by reducing the level of the AQP4 antibody and cyclophosphamide as given for refractory multiple sclerosis in children can also be useful (Wingerchuk et al. 2004; Mealy et al. 2014); azathioprine has also been given to patients with NMO to suppress T cell function. Mycophenolate (mofetil) has also been reported to reduce the relapse rate in NMO and the monoclonal antibody rituximab directed at B cells has been reported to help patients with NMO in small trials while IVIG has also been reported to show activity in NMO by reducing levels of IgG. On the other hand some therapies used for multiple sclerosis such as interferon-β may make NMO worse by increasing levels of the NMO antibody: this is consistent with evidence that multiple sclerosis and NMO disease activity may involve different groups of T-cells.

**ANTI-MYELIN OLIGODENDROCYTE GLYCOPROTEIN ENCEPHALITIS**

Antibodies to myelin oligodendrocyte glycoprotein (MOG) have been implicated in the pathogenesis of multiple sclerosis and can induce demyelination in animal models of multiple sclerosis (Bansal et al. 2013). MOG also appears to be a major target of the humoral immune response in children with inflammatory demyelinating disorders of the CNS (Thulasirajah et al. 2016). Brilot et al. (2009) investigated the occurrence of antibodies to native MOG in 47 children during their first episode of CNS demyelination related to either ADEM (n=19) or CIS (n=28) and compared them to a comparison group of healthy children using a cell based bioassay. Forty per cent of children with ADEM or CIS had high serum immunoglobulin G (IgG) titers to nMOG while none of the control children had anti-MOG antibodies. In contrast only three children in the demyelinating group had IgM antibodies, all of whom were in the ADEM group. Anti-nMOG IgG titers did not differ between the ADEM and CIS group and did not predict conversion from CIS to multiple sclerosis during a mean 2-year follow-up. IgG antibodies to nMOG not only bound to the extracellular domain of nMOG but also induced natural cell-mediated killing of nMOG-expressing cells in vitro. These auto-antibodies may also have significant as markers for the persistence of demyelination (Brilot et al. 2009).

Lalive et al. (2011) measured serum anti-MOG antibodies using ELISA and flow cytometry in 11 children with ADEM, 22 with multiple sclerosis, seven with viral encephalitis with healthy controls and their Epstein-Barr virus (EBV) serostatus also determined in 13. Anti-MOG antibodies were detected in children with demyelination and these antibodies were highly reactive in the group with ADEM. Anti-myelin basic protein reactivity was detectable equally in all groups but the presence of this or anti-MOG did not associate with EBV serostatus, age, sex, or disease course. Probstel et al. (Probstel et al. 2011) reported a prospective 5-year study of 77 children at the onset of demyelinating diseases, 25 of whom had immunoglobulin antibodies directed at MOG. Anti-MOG antibodies declined rapidly in all 16 patients with monospecific ADEM and one patient with a CIS however in six of eight (75%) children...
eventually diagnosed with multiple sclerosis anti-MOG antibodies persisted with a secondary increase in titre over time. These anti-MOG antibodies were predominantly IgG1 and their binding was blocked by anti-MOG antibodies derived from an animal model of autoimmune encephalitis. Highly reactive anti-MOG antibodies declined rapidly in children with viral encephalitis but remained elevated in children with demyelination. This data suggests that the persistence of anti-MOG antibodies may have prognostic value for diagnosing childhood multiple sclerosis versus monophasic ADEM. Patients with NMO who have anti-MOG antibodies as well as antibodies to AQP4 have been reported to have a milder phenotype than patients without anti-MOG antibodies (Sato et al. 2014). Baumann et al. (Baumann et al. 2015) compared the clinical and radiological features of paediatric patients with ADEM and with and without anti-MOG antibodies, finding that the group with anti-MOG antibodies had an MRI characterised by large, bilateral and widespread lesions in the brain, with longitudinally extensive transverse myelitis and a favourable clinical outcome compared to children without MOG antibodies.

**ANTI-GLUTAMATE RECEPTOR ENCEPHALOPATHIES AND RELATED DISEASES**

The discovery of childhood encephalopathy associated with the presence of anti-NMDA receptor antibodies appears to be the ‘tip of the iceberg’ as many new auto-antibodies to synaptic proteins associated with neurological disorders are continuing to appear in the literature (Vincent et al. 2011; Irani et al. 2014; Leypoldt et al. 2014; Rossi 2014): this large group in which the best described entity is the anti-NMDA encephalopathy is also discussed in Chapter 19. Anti-NMDA receptor encephalopathy presents as a dramatic delirium with agitation and movement disorder that can rapidly deteriorate to coma with respiratory failure and the need for ventilation and management of autonomic instability in an intensive care unit. In the classic form it presents in young women with ovarian cysts or teratomas and removal of the cyst rapidly leads to clearing of the sensorium (Gresa-Arribas et al. 2014). In such individuals the anti-NMDA antibody within the CNS is related to cross reaction with NMDA neuronal receptors within the ovarian teratoma. CSF anti-NMDA antibody titres within the CSF are more closely related to outcome than those in the serum with this disorder relatively specific for neurons. However, Titulaer et al. (2014) recently reported overlapping demyelinating syndromes in patients with anti-NMDA receptor encephalitis. A small number of patients with anti-NMDA receptor encephalitis also have clinical or radiological phenotypes suggestive of multiple sclerosis, ADEM or NMO and are seropositive for MGO-Ig or AQP-IgG (Hardy et al. 2016). Another large emerging group of auto-antibody disorders in children presents as encephalitis with refractory seizures, status epilepticus and antibodies to the inhibitory GABA-A receptor (Petit-Pedrol et al. 2014). Similarly, human disorders have been associated with autoantibodies to the GABA-B receptor (above) as well as to the metabotropic glutamate receptor 5, the AMPA glutamate receptor and glutamic acid decarboxylase (GAD), the synthetic enzyme for GABA (Petit-Pedrol et al. 2014).

**STREPTOCOCCAL INFECTION-RELATED DISORDERS**

**Sydenham chorea**, which has mostly disappeared from developed countries, is one of the major manifestations of rheumatic fever but can be observed in isolation. Bilateral or unilateral chorea is associated with head movement and grimacing as well as behavioural alterations, with treatment associating anti-streptococcus treatment with steroids. Paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections (PANDAS) are probably a different entity although the syndrome remains controversial (Marcello and Martino 2013). It is defined by the presence of an obsessive–compulsive disorder and tics with abnormal movements precipitated by streptococcal infections and frequently relapsing (Dale et al. 2002; Mell et al. 2005; Singer et al. 2005; Singer et al. 2015).

**HASHIMOTO ENCEPHALOPATHY AND ANTI-THYROPEROXIDASE ANTIBODIES**

Hashimoto encephalopathy is characterised by the presence of anti-thyroperoxidase antibodies (anti-TPO) in a child affected by acute encephalitis with predominant seizures, neuropsychiatric symptoms and an alteration of consciousness or dystonia (Castillo et al. 2006); it is also a chronic disease that relapses in many individuals. The role of anti-TPO antibodies in the causation of the neurological symptoms is not confirmed and they might be only a marker of the disease. In a recent review we studied eight individuals with Hashimoto encephalopathy with compatible clinical symptoms and a median anti-TPO titer of 2838.5IU/ml, (range 812–8550IU/ml) (Mamoudjy et al. 2013). For these individuals and those mentioned in previous publications median age at onset was 12 years (range: 9–15) but an affected child aged 2 years and 10 months has also been reported (Erol et al. 2011). Most of the patients were girls with normal thyroid function who had an acute onset while the CSF was frequently abnormal with pleocytosis (13%), high protein titers (63%) and oligoclonal bands (43%). The EEG at onset was abnormal in some individuals but no specific pattern has been described. Similarly, brain MRI was abnormal in 50% of the children in our series with abnormalities involving the white and grey matter usually distinctive enough for clear differential diagnosis from multiple sclerosis (Fig. 12.3). As a result we routinely test for anti-TPO antibody in children with acute encephalitis without clear-cut features of ADEM or those presenting in relapse, unless the clinical and radiological symptoms are
typical of multiple sclerosis. Hashimoto encephalopathy usually responds to steroid treatment but relapses are frequent: immunosuppressive treatments (cyclophosphamide, mycophenolate-mofetil or azathioprine) have been used but there is currently no consensus concerning their efficacy in the absence of formal results of clinical trials.

**INFLAMMATORY DISEASES OF THE WHITE MATTER THAT MIMIC MULTIPLE SCLEROSIS AND RELATED DISORDERS**

The differential diagnosis of an acute inflammatory disease of the white matter in a given child requires great care because the choice of treatment differs considerably between the various diseases (Hintzen et al. 2016). Many entities cause monophasic or relapsing white matter inflammatory syndromes and some other non-inflammatory entities also induce relapsing white matter disease. All of them should be considered as a possible diagnosis not only at the time of the first acute demyelinating event but even more carefully in individuals with presumed ‘resistant’ multiple sclerosis (Tardieu 2013). These conditions include vasculitis and congenital immuno-genetic diseases as well as tumour, genetic or metabolic diseases and migraine (Table 12.1). Table 12.1 does not aim to provide an exhaustive list of possible conditions but is based on our experience as the national reference centre for neuroinflammatory diseases of the CNS in France. It is the experience of most reference centres that 8–10% of all entities referred receive a different diagnosis requiring a different treatment.

**Clues to the Differential Diagnosis of White Matter Inflammatory Diseases**

The main clinical characteristics will be described for each entity but the following features should challenge the diagnosis of ADEM (or less frequently multiple sclerosis): onset before the age of 1 year; a consanguineous family or the existence of another child in the family that has previously displayed
severe acute neurological symptoms, a gradual progression of clinical symptoms, any non-neurological symptoms or signs such as liver or spleen enlargement, lymphadenopathy, cutaneous vasculitis symptoms (including livedoid vasculitis) and uveitis. Several atypical inflammatory demyelinating syndromes may present with atypical clinical or MRI findings or poor response to treatments for multiple sclerosis (Hardy et al. 2016). The diagnosis should also be re-evaluated if relapses persist despite treatment in a child previously diagnosed with multiple sclerosis. Similarly, the following neuroradiological symptoms on MRI are infrequent in ADEM and multiple sclerosis: a single lesion, high symmetrical white matter lesions, an absence of lesions of the basal ganglia or brainstem, signs of arachnoiditis or lesions restricted to the brainstem and basal ganglia. A normal MRI despite frank symptoms of encephalitis is frequently observed in very young infants with familial hemophagocytic lymphohistiocytosis while CT can be used to search for calcifications suggesting a more restricted group of diseases including Aicardi-Goutières syndrome and related diseases. Normal CSF results despite an ‘inflammatory appearance’ on MRI or an associated fever are frequent in individuals with hemophagocytic lymphohistiocytosis, whereas high concentrations of protein in the CSF (>1g/l) are more frequently observed in arachnoiditis or tumours than in ADEM. However, none of these clinical or radiological findings is absolute and biological markers are required. In individuals with acute demyelinating inflammatory disease for which a diagnosis of ADEM has not been established determinations should be carried out including complete blood formula, erythrocyte sedimentation rate, C-reactive protein, complement activity, ALT/AST, ferritin, triglycerides, anti-nuclear antibodies as well as sometimes anti-thyroid and anti-neuronal antibodies. Lactate/pyruvate ratios in blood and CSF are useful for the detection of respiratory chain dysfunction, particularly in patients with MRI lesions restricted to the brainstem and basal ganglia.

VASCULITIS

Cerebral vasculitis is one of the most challenging differential diagnoses of multiple sclerosis and ADEM (Table 12.6), defined by neuropathological characteristics while clinical, MRI and biological symptoms are heterogeneous, none being specific. By definition the cerebral vessel walls in cerebral vasculitis are infiltrated by inflammatory cells, usually T lymphocytes which should be distinguished from the more usual perivascular infiltration observed in many inflammatory diseases of the brain where vessels are surrounded by monocytes, B and T lymphocytes. The infiltration of brain vessel walls by lymphocytes during vasculitis induces reactive changes in endothelial cells resulting in ischaemic lesions probably related to local thrombosis (Calabrese 1988). This can occur in vessels of different size (large, medium or small). The types of lymphocytes or monocytes infiltrating the vessel walls are poorly described and little is known of their antigenic specificities in relation to the targeted vessel. It is interesting to speculate on the pathway followed by wall-infiltrating T lymphocytes with the best hypothesis their crossing of the blood–brain barrier at the venule level and re-entering the vessel wall at a different point, maybe after transport through the Virchow-Robin spaces (Bechmann 2007).

Cerebral vasculitides are commonly split into (1) primary CNS vasculitis where cerebral vasculitis occurs in isolation and (2) secondary cerebral vasculitides that occur as part of a systemic multi-organ disease or are associated with a specific biological marker.

**COMMON FEATURES OF PRIMARY AND SECONDARY CEREBRAL VASCULITIS**

Cerebral vasculitides, irrespective of their aetiology, have many clinical features in common with a wide range of symptoms, some acute, subacute and chronic with the most common symptoms being headache, confusional states or behavioural alterations. Headaches are usually of migrainous type but may result also from increased intracranial pressure due to intracranial sinus thrombosis. Behavioural alterations can be highly variable and misleading, resulting in depression, cognitive alteration, more frank psychiatric symptoms or progressive cognitive regression. The main initial challenge is then to recognise early symptoms as part of an inflammatory disease, ruling out more common diagnoses such as migraine or depression. Acute hemiparesis is another more dramatic initial symptom which may result from an ischaemic stroke with large vessel involvement, intracerebral hemorrhage or venous thrombosis, a diagnosis requiring a cerebral MRI with magnetic resonance angiography. Finally, seizures, abnormal movement disorders or myelopathy are possible initial symptoms. No clinical symptom or group

ANCA, anti-neutrophil cytoplasmic antibodies.
of symptoms is specific of a given entity although seizures and chorea are more frequent in SLE and stroke (especially in brainstem or due to sinus thrombosis) in Behcet disease and antiphospholipid syndromes. Diagnostic clues in clinical diagnosis investigations are often found outside of the CNS with special attention to the skin and to the kidney.

Similarly, cerebral vasculitis can induce highly variable modifications of cerebral MRI appearances. Multifocal areas of increased signal in grey and white matter on T2-weighted images, frequently with gadolinium enhancement, are the most typical aspect. These initial lesions result, on repeated MRI, in areas of cortical atrophy. Highly suggestive of vasculitis is the association, on the same cerebral MRI, of acute, gadolinium-enhancing lesions with atrophic areas suggestive of previous acute events. Leptomeningeal gadolinium enhancements are frequent as are more diffuse non-specific hyperintense lesions of the white matter with the same MRI aspects observable in brain lymphoma or in any inflammatory disease of the white matter. Larger cerebral infarcts are also observed which result from large or medium sized arterial obstructions (as observed in SLE, Behcet disease or antiphospholipid syndrome) or cerebral venous thrombosis (more frequent in Behcet disease). Inflamed vessel walls can occasionally be highlighted by enhancement after gadolinium injection. Cather cerebral angiography may also demonstrate medium vessel obstruction although this is a relatively infrequent finding and the procedure is usually to be avoided. Finally, it should be remembered that MRI can be normal despite neuropathological demonstration of vasculitis.

CSF characteristics are very similar in the different brain vasculitides with an elevation of the CSF protein content and pleocytosis. The results of other biological tests to be performed are described in the individual syndromes.

Characteristics of the Different Brain Vasculitides

While the strict definition requires tissue examination infrequently obtained such overlapping symptoms led to various classifications based on the initial symptoms, presumed size of the involved vessels as well as presence or absence of extraneurological symptoms and abnormal biological results. The diagnosis of a primary CNS vasculitis is one of exclusion, keeping in mind that a multi-organ disease can have onset in isolation in the brain to be expressed in other organs after a delay.

Main Syndromes with Secondary Cerebral Vasculitis

Table 12.6 gives a list of diseases in which a cerebral vasculitis can be observed. Only the two most frequent ones will be described here.

Systemic Lupus Erythematosus

Several large series of children with childhood-onset SLE contributed to a better description of the natural history (Bader-Meunier 2005; Bensele 2007; Hiraki 2008; Ramirez-Gomez 2008; Descloux 2009; Levy 2009; Singh 2009). The disease occurs usually in adolescents but 15% of children had symptoms before the age of 8 in one series (Bader-Meunier 2005; Descloux 2009). The most frequent general symptoms at onset are malaise, arthritis and fever, associated with neurological symptoms in 18–27% of patients in the different series. Neurological symptoms consist of headache (60–66% of patients in the different series), mood disorders (Yu 2007; Muscal 2010) and cognitive dysfunction (29–36%), seizures (20%) and stroke (11–24%) while chorea and abnormal movements are less frequent (4%). Neurological manifestations increase in frequency during the course of the disease (35–60% of patients), usually during acute exacerbations of the disease to subside with improvement of systemic manifestations. Their diagnosis is always a challenge to distinguish between the consequence of an acute cerebral vasculitis, of an adverse effect of treatment or of lesions in other organs leading, for example, to a concomitant high blood pressure.

Cerebral MRI at onset has the same non-specific characteristics as other cerebral vasculitides. Similarly, CSF studies, although usually showing cellularity and high protein content, do not give specific clues. The diagnosis is established considering the multi-site involvement and characteristic biological markers: hemolytic anemia, thrombocytopenia, leuko- and lymphopenia, high antiphospholipid and cardiolipin antibody titres, low CH50 and C4 determinations, high titres of specific auto-antibodies comprising antinuclear antibodies, anti-double-stranded DNA, anti-SSA, anti-SSB, antiSm and anti-RNP antibodies.

Treatment is based on immunosuppressive therapy with high-dose pulses of methylprednisolone, frequently associated with other immunosuppressive agents, the most frequently used being cyclophosphamide and azathioprine.

Behcet Disease

Behcet disease is a systemic disorder that can involve any organ, with neurological symptoms being reported in 20% of individuals (Amman et al. 1985; International Study Group for Behcet’s Disease 1990; Bahabri 1996; Kone-Paut 1997; Kone-Paut 1998; Vaiopoulos 1999; Kari 2001; Al-Araji 2009; Metreau-Vastel 2010; Kone-Paut 2011; Uluduz 2011). The disease is usually observed in adolescents but also 8–16% of patients who are less than 8 years old. Patients originate more frequently from Mediterranean countries and two-thirds display HLA-B51 (Ohno 1982). Finally, familial cases are observed in 23% of the series from Turkey but 8% of patients from France (Metreau-Vastel 2010; Uluduz 2011). The most frequent neurological manifestations are linked to a high intracranial pressure due to cerebral venous sinus thrombosis (Alper 2001). It can come in isolation while more characteristic Behcet symptoms will be observed during the subsequent course of the disease. The diagnosis should be considered in any child with cerebral venous sinus thrombosis with no obvious cause while a smaller percentage of children have
other neurological symptoms at onset such as focal neurological deficits (Atkinson 2008; Metreau-Vastel 2010) and meningoencephalitis while GBS and isolated transverse myelitis have been observed. The course of the disease is relapsing, sometimes despite treatment. Cerebral MRI can demonstrate venous sinus thrombosis best observed after gadolinium enhancement (Saltik 2004; Metreau-Vastel 2010; Ulduz 2011). In the Turkish series isolated superior sagittal sinus thrombosis was observed in 42% of patients and concomitantly with transverse sinus thrombosis in another 30%, the remaining patients having isolated unilateral transverse sinus or internal jugular vein thrombosis (Ulduz 2011). Other patients have signs of stroke on cerebral MRI. CSF studies are normal in half the patients with erythrocyte sediment rate and C-reactive protein level frequently elevated during active phases of the disease (Metreau-Vastel, 2010). Treatment is with steroids and immunosuppressants, as well as azathioprine and colchicine on a frequent basis. The use of anticoagulation in individuals with cerebral venous sinus thrombosis is not consensual but was undertaken in most of our patients.

**Primary Central Nervous System Vasculitis**

The diagnosis of childhood primary angiitis of the CNS is based on three criteria: (1) an acquired neurological deficit, (2) angiographic or histological evidence of cerebral vasculitis, and (3) absence of evidence of systemic vasculitides or any other condition to which the findings could be secondary (Calabrese 1992; Salvarini 2007; Elbers 2010). There is a loose and partly negative definition that leads to a further distinction between small vessel primary CNS vasculitis and medium-large primary CNS vasculitis.

*Small vessel primary cerebral vasculitis* is a rare condition and a very difficult diagnosis. It can affect children at any age with the most common clinical presentations being, in the largest series, seizures (85%), headache (62%) and cognitive decline (54%) (Lanthier 2001; Benseler 2005; Elbers 2010). Interestingly, two patients presented with optic neuritis and two had spinal cord involvement, increasing the risk of misdiagnosis with multiple sclerosis. CSF was abnormal in all patients with increased opening pressure, pleocytosis and elevated protein content. Inflammatory markers in blood are usually elevated, a difference with multiple sclerosis. MRI showed the same various aspects as other CNS vasculitides although lesional and leptomeningeal gadolinium enhancements were more frequent, with the magnetic resonance angiography normal in all individuals. A definitive diagnosis requires brain biopsy but a difficult task is to determine the site of specimen sampling; to observe a mere perivascular infiltration is not unusual and fails to confirm the expected diagnosis. Lack of specific histological features correlates with inadequate specimen sampling, prolonged time to biopsy and prior steroid treatment (Hutchinson 2010). Treatment consists in high-dose pulses of methylprednisolone associated usually with pulses of intravenous cyclophosphamide followed by maintenance therapy with azathioprine or mycophenolate mofetil.

**Medium and large vessel vasculitides** are more frequent than small vessel vasculitis but there is a large overlap between this entity and ‘transient cerebral arteriopathy’, the most frequent cause of strokes in children, described in Chapter 15 (Chabrier 2000; Sebire 2006; Braun 2009). The usual clinical expression is a stroke or, and less frequently, transient ischaemic episodes. The pathological aspects of vessels are best demonstrated by magnetic resonance angiography, at the level of the A1 segment of the left anterior cerebral artery and M1 segment of the left middle cerebral artery. Several studies have now established that varicella zoster virus (VZV) infection is more frequent in the months preceding the stroke in affected children than in the general population (Sebire 1999; Gershon 2014; Thomas 2014); however, a second and less frequent form of post VZV arteriopathy involves smaller vessels and consists in multiple small infarcts observed within days after acute varicella (Gilden 2009). Finally, bacterial infection or Lyme disease can also induce vasculopathy and stroke with MRI demonstrating vessel wall thickening and gadolinium wall enhancement (Lebas, 2010).

**IMMUNOGENETIC DISEASES MIMICKING MULTIPLE SCLEROSIS AND RELATED DISORDERS**

Congenital immunogenetic diseases are rare but many of these diseases may involve the CNS. The neurological symptoms are generally not isolated and diagnosis is based principally on extraneurological symptoms, however, this is not always applicable to hemophagocytic lymphohistiocytosis (HLH) (Haddad 1997; Fledmann 2005; Horne 2008) which has several different forms including familial hemophagocytic lymphohistiocytosis (FHLH), Chediak-Higashi disease, Griscelli disease and Purtillo disease (Jenka 2012). FHLH is the most frequent form of HLH and results from genetic defects impairing the cytotoxicity of CD8 T lymphocytes. These genetic defects may remain asymptomatic until a trigger, most often a viral infection, induces the uncontrolled polyclonal activation of CD8+ T lymphocytes and macrophages, resulting in the overproduction of cytokines. We recently evaluated children at the onset of the different types of HLH and compared them with children of a similar age diagnosed with ADEM (Deiva, 2012). In HLH, the median age at onset was 2.5 months but the range was wide (0–190 months). Initial symptoms at presentation were not restricted to the CNS in most patients, with fever (>38.5°C) reported in 83% of patients, hepatomegaly in 72%, splenomegaly in 63% and lymphadenopathy in 57%. Neurological symptoms consisted of seizures, impaired consciousness, meningismus and focal motor deficits while common biological signs included pancytopenia, low fibrinogen levels, high liver enzyme levels, hyperferritinemia, hypertriglyceridemia (all present in more than 90% of patients) and hyponatremia (63% of patients) (Ouaché-Chardin 2006;
Mahlaoui 2007). Signs of hemophagocytosis were detected on both blood and bone-marrow smears for 66% of patients. However, neurological symptoms were isolated in 7% of the patients in the series of Mahlaoui (2007) and Deiva (2012). Important clues that can direct the physician to the correct diagnosis include young age and consanguinity or the early death of a sibling. Moreover, in this probably inflammatory and acute encephalitis CSF results were normal in 50% of patients, whereas a high protein titer (>0.5g/L) was found in 50% of patients, high cellularity (>10/ml) in 37% and features of hemophagocytosis in 24% (Mahlaoui 2007); similarly, brain MRI at onset was normal in 67% of patients (Fig. 12.4). In patients with abnormal MRI results white matter lesions were more frequently symmetrical and periventricular with signal hypointensity on T1 sequences in HLH than in ADEM whereas lesions of the thalamus, basal ganglia and brainstem were more frequent in ADEM than in HLH. Gadolinium enhancement was slightly more frequent in HLH than in ADEM (33% vs 16%) in our series but this difference was not statistically significant (Deiva 2012). Early diagnosis can be established by carrying out specific immunological tests (including analyses of perforin expression in lymphocytes and of the cytotoxic ability of the patient’s CD8 lymphocytes) before identification of the causal mutation, essential as treatment requires immunosuppression followed by a bone-marrow transplantation (Ouaché-Chardin Paediatrics 2006; Mahlaoui Paediatrics 2007). Other treatments invariably lead to relapses resulting in severe necrosis of the brain parenchyma.

TUMOURS MIMICKING MULTIPLE SCLEROSIS

The course of multiple sclerosis, with periods of relapse and remission, observed in more than 95% of children with multiple sclerosis should prevent this condition being confused with tumours, but there are exceptions.

Oligodendrogloma and low-grade astrocytoma might initially yield MRI results reminiscent of white matter inflammatory diseases. It may initially lead to the incorrect diagnosis of multiple sclerosis if there are few clinical symptoms. The principal clues are a gradual progression of clinical symptoms or a persistent deficit, the absence of spatial dissemination on initial MRI and of modifications (or only a slight extension) on subsequent MRI scans. Spectroscopy of the pathological lesion may be useful and diagnosis can usually be established on the basis of a biopsy (Vicente 2013; Orphinadou-Vlachou 2013).

Primary cerebral lymphoma can be a much more challenging diagnosis. In a review of 29 children with primary CNS lymphoma disease was confined to the brain (n = 26) or meninges (n = 3) with no evidence of systemic lymphoma at presentation (Abla 2011). The median age at diagnosis was 14 years, the youngest patient being 2 years old. The most frequent initial symptoms were headache and nausea (suggesting an increase in intracranial pressure), cerebellar symptoms, seizure and hemiparesis. On MRI 38% of lesions were disseminated in space, with 41% of the lesions found in the basal ganglia and brainstem (Fig. 12.4). CSF analysis was not informative in most patients (only eight of the 26 had positive CSF cytological results for lymphoma) while all had primary CNS non-Hodgkin’s lymphoma (69% had diffuse large B-cell lymphoma, 17% had anaplastic large T-cell lymphoma, 7% had lymphoblastic lymphoma and 7% had Burkitt-like lymphoma) (Abla 2011). To further illustrate diagnostic difficulties an initial brain biopsy of a large white matter lesion in one of our patients indicated only ‘nonspecific inflammatory lesions’. The appropriate diagnosis was finally established when skin lesions appeared four months after the initial neurological symptoms, leading after pathological evaluation of the skin lesion biopsy specimen to the diagnosis of anaplastic large-cell ALK1+ CD30+ lymphoma with detection of the NPM-ALK transcript. This transcript was retrospectively detected in the brain biopsy specimen leading to the establishment of a diagnosis of primary CNS lymphoma.

Langerhans cell histiocytosis (LCH) is characterised by the proliferation of dendritic cells associated with chronic inflammation. It is a rare disease observed mainly in teenagers although it may occur at any age. Bone is the most frequently affected tissue (79% of the 603 patients in the Korean registry), followed by the skin (19.2%) but 30% of patients had a multisystem disease (Kim 2014). The frequency of neurological symptoms is not fully established, especially as a primary symptom; however, the most frequent clinical presentation is related to infiltration of the hypothalamic-pituitary region inducing a diabetes insipidus and less frequently growth hormone deficiency or other anterior pituitary hormone loss.

The second presentation is related to mass lesion, either solitary or multifocal, either in meninges or in parenchyma including brainstem (Savardekar 2013). Symptoms are those of increased intra-cranial pressure occasionally with seizures. Among the 1411 patients from the French LCH registry, 57 were identified with one or several mass lesions and on the 20 reported in detail (for therapeutic proposals) 13 were children (1–15 years), ten having diabetes insipidus and hypothalamic-pituitary region involvement as well as three having respectively cerebellar ataxia (as an isolated initial symptom), headache (initial symptom) or a visual field defect (during a late reactivation) (Tin et al. 2011).

The third presentation is the most difficult to diagnose associating behavioural disturbances, learning difficulties, ataxia, dysarthria and motor spasticity (Mimouni 2010; Ehrardt 2013). A progressive decline can be observed leading to the designation of Langerhans cell histiocytosis-associated neurodegeneration. It is the rarest initial presentation but was observed during the course of disease in 153 out of 308 LCH patients with MRI findings in the histiocytic society registry and seven out of 29 similar patients in a series from Sweden (Grois 2010; Laurencikas 2011). MRI findings in these patients include symmetrical hyperintense signal in T1-weighted images in the cerebellar grey and white matter, cerebellar atrophy, T2-weighted hyperintense changes in the pons and T1-weighted hyperintensity of the globus pallidus (Fig. 12.4). No systematic study of the CSF in LCH has been published. Treatment (apart from correcting dysfunctions such as diabetes insipidus) depends on localisation and stage of disease and uses mostly chemotherapy, vincristine being presently the standard treatment (Tin et al. 2011).

OTHER GENETIC DISEASES MIMICKING INFLAMMATORY WHITE MATTER DISEASES

Leukoencephalopathies linked to mutations indirectly modifying intra-cerebral inflammation status. This is a large group of rare diseases progressively being discovered. Their clinical symptoms are usually sufficiently different from ADEM and multiple sclerosis to avoid confusion but borderline cases can be observed. The best example is Aicardi-Goutières syndrome, with this neonatal-onset encephalopathy associated with microcephaly, brain calcifications and high interferon-alpha concentration in the CSF (Rice 2007); however, MRI demonstrates the presence of large white matter lesions and clinical onset may occur later in childhood. This syndrome is linked to various mutations affecting RNA metabolism or to proteins that normally prevent the self-activation of innate immunity by cell-intrinsic components (Crow 2007; Rice 2009). Another example is provided by a mutation of the colony-stimulating factor 1 receptor gene which has recently
been demonstrated to be the cause of a dominant form of leukoencephalopathy probably resulting from microglial dysfunction (Rademakers 2012).

**Mitochondrial respiratory chain deficits** are the metabolic diseases most frequently misdiagnosed as optic neuritis, brain-stem encephalitis or multiple sclerosis. These deficits can present with optic neuropathy, the most common form of which being Leber hereditary optic neuropathy (Harding 1992). The mutations characteristic of this disease should be sought in individuals with relapsing optic neuritis or non-resolving optic neuritis. Similarly, acute brainstem encephalitis may have clinical and radiological symptoms very similar to those of mitochondrial diseases, including Leigh disease in particular. An evaluation of lactate content and of lactate/pyruvate ratio in blood and CSF and spectroscopy focusing on the white matter lesions as well as a direct study of respiratory chain activity in lymphocytes, fibroblasts or muscle biopsy specimens should lead to establishment of the correct diagnosis.

The detection of non-specific incidental white matter changes in children with headache, or more specifically **migraine**, is now well established (Candee 2013). Three recent large series demonstrate in respectively 941, 1008 and 449 children with headache a similar rate of 4.3–6% of white-matter hyperintensities with a non-significant trend for a higher prevalence in migraine with aura than without aura (Bayran 2013; Mar 2013; Yilmaz 2013). Lesions are only supratentorial and non-progressive, more frequently in the deep white matter than periventricular with a mean size of 5.1 (SD 4.5mm) in one of the studies (Fig. 12.5). The distinction from multiple sclerosis is usually easy on clinical grounds as well as differences in signal intensity, localisation and absence of gadolinium enhancement.

Part V  Postnatal Extrinsic Insults

Other Inflammatory Diseases of the Central Nervous System

Granulomatous Disorders of the Central Nervous System and Related Disorders

Multisystemic granulomatous disorders are rare in children and isolated CNS forms are even more so. It is a large group of diseases that include sarcoidosis, polyarteritis nodosa, Wegener disease and anti neutrophil cytoplasm antibody (ANCA)-related diseases (Rottem 1993; Bosch 2006; Demirkaya 2012), Whipple disease (Louis 1996; Scheld 2003) as well as infections (cat scratch disease). Only the first two of these disorders will be reported here considering their rarity.

Sarcoidosis

Sarcoidosis is predominantly a lung disease with neurological symptoms in 5–15% of young adults consisting of aseptic meningitis, hypothalamic and pituitary dysfunction, peripheral and cranial neuropathy as well as less frequently CNS space-occupying lesions. Only small series of children with neurosarcoidosis have been reported but some of the described patients did have an isolated neurosarcoidosis (Kone-Paut 1999; Anand 2013). A large survey in France of 205 paediatric patients with interstitial lung diseases indicated that 21 were related to a sarcoidosis. Among these 21 children, three had a disease restricted to the lung and 18 were multisystemic with six having symptoms of uveitis and only one a neurological involvement (Nathan 2012). In another publication 29 children with neurosarcoidosis were gathered, four of them having an isolated neurosarcoidosis and two others having neurological symptoms plus uveitis only (Bauman 2003). The key symptoms for the whole group were uveitis (9/29), seizure (11/29), cranial nerve involvement (6/29), intra-cranial hypertension associated with hypothalamic dysfunctions (6/29), enlarged lymph nodes, liver and spleen, arthritis and swelling of the parotid gland. A recent review added three other individuals of isolated neurosarcoidosis in children (Anand 2013). In CSF elevated opening pressure, lymphocytosis and elevated protein content are common but none of the published series clarified the percentage of children with normal CSF. Brain MRI can demonstrate granulomata in the parenchyma which frequently are enhanced after gadolinium injection, with diffuse gadolinium enhancement of basal meninges and periventricular white matter lesions (Fig. 12.6). Elevation of serum angiotensin-converting enzyme helps in the diagnostic process if present but elevation is not constant, with the same being true for hypercalcemia. A biopsy of the lesion can be required to establish the diagnosis and show non-caseating granuloma. Treatment uses steroids usually as high dose methylprednisolone pulses associated with immunosuppressive drugs but no formal study has been published.

Polyarteritis Nodosa

Polyarteritis nodosa (periarteritis nodosa, PAN) is a rare vasculitis of the medium and small-sized arteries that can induce
necrosis, especially skin necrosis. Polyarteritis nodosa affects the peripheral more frequently than the CNS, characteristically with multiple mononeuropathy (mononeuritis multiplex). It is frequently associated with severe myalgia and cranial nerve involvement with the medium age at onset between 7.9 and 8.6 years in three recent series of patients (Eleftheriou 2013; Falcini 2014; Mondal 2014). The presenting symptoms were fever, myalgia and skin involvement in almost all patients and, in a smaller proportion, hypertension or renal involvement as well as neurological signs. Diagnosis is usually established by skin biopsy showing necrotising vasculitis of the medium sized vessels. It is highly unusual but sometimes necessary to have to perform a nerve or muscle biopsy to establish a diagnosis of PAN in a patient with isolated severe multiple mononeuropathy. CNS manifestations are less frequent and result from vascular obliteration and aneurysm formation resulting in stroke or hemorrhage. Cyclophosphamide and steroids are the most frequent initial treatment: in the published series only 52% of patients were off therapy after a mean follow-up of 6 years and relapse rates were 35% and 33% (Eleftheriou 2013; Falcini 2014).

AUTO-INFLAMMATORY DISORDERS WITH NEUROLOGICAL INVOLVEMENT

Neonatal onset multisystem inflammatory disease (NOMID) or Chronic inflammatory neurological cutaneous articular syndrome (CINCA)

CINCA (aka NOMID and related diseases). Auto-inflammatory syndromes are monogenic diseases caused by mutations of genes coding for proteins involved in the regulation of the inflammatory response. A subgroup called ‘cryopyrin-associated periodic syndromes’ (CAPS) is caused by mutations in the NLRP3 (or CIAS1) gene encoding for cryopyrin, a protein that activates IL-1beta (Caso 2013). This includes chronic infantile neurological cutaneous and articular syndrome (CINCA), Muckle–Wells syndrome and familial cold urticaria in order of decreasing severity. CINCA syndrome appears during the first year of life, associating fever, urticaria-like skin rash, uveitis, headache, arthralgia and fatigue. Later on, episodes of severe headache due to increases intra-cranial pressure and chronic polymorphonuclear aseptic meningitis are variably associated with uveitis, papilledema, optic nerve atrophy with decreased vision and perceptive deafness. MRI is not specific, showing in individuals with severe ventriculomegaly and signs of arachnoiditis. Treatment uses different types of anti IL-1 agents such as anakinra, a recombinant, non-glycosylated version of human IL-1 receptor antagonist that is effective also on neurological symptoms (Neven 2010).

SUSAC SYNDROME

SUSAC syndrome is a rare disorder. A recent review gathered 304 affected individuals in the literature, children representing less than 10% with the youngest reported patient being 8 years old (Dörr 2013). It is viewed as an autoimmune disease leading to occlusion of microvessels and characterised by recurrent episodes with visual disturbances due to lesions on the retina, hearing deficit and neurological symptoms. The latter are very similar to those observed during vasculitis with headache in 80% of the 304 published cases, frequently associated with cognitive impairment; however, the characteristic triad is usually not fully present at onset. CSF is abnormal with elevated protein content (the presence of oligoclonal bands is unusual but described) and mild lymphocytic pleocytosis with diagnosis established on the demonstration of retinal artery occlusion by fluoroscein angiography, of hearing deficit and usually non-specific but sometimes highly characteristic MRI brain lesions. The most frequent consists of numerous strongly hypointense signals in the corpus callosum and less frequently in the periventricular area on the T1-weighted images; however, hypo-intense lesions can be observed in any location both supra- and infra-tentorial. Significantly they have not been described in the spinal cord. The best treatment is not established but requires steroids and immunosuppressive agents.

CEREBELLITIS

ACUTE CEREBELLAR ATAXIA AND ACUTE CEREBELLITIS

Acute ataxia may be the consequence of an inflammatory reaction within the cerebellum and is sometimes differentiated from acute cerebellitis, the latter being more severe (Gill 2010). Here the two terms are considered as equivalent with benign and severe forms, acute cerebellar ataxia being a clinical description and acute cerebellitis referring to the pathophysiology. Acute cerebellar ataxia is characterised by a sudden onset of ataxia following, or in association with, a viral illness. Frequency and usual benign outcome precluded the constitution of large prospective population-based cohorts with most of the reported series hospital-based and probably skewed toward those affected more severely. Acute cerebellar ataxia can be observed in children of all ages although in a combined series of 112 individuals half were affected before 4 years of age (Connolly 1994). The onset of ataxia is usually acute with a marked gait ataxia and dysmetria, the child adopting a widely based stance or possibly avoiding standing altogether. Even in the sitting position a young child may look unsteady. Hypotonia, tremor of the extremities, head and trunk, are usually obvious and in older children speech is slow without the usual intonations with syllables uttered in an explosive manner.

At the onset of the disease clinical evaluation should carefully explore associated symptoms and signs relating to three areas. The first is related to eye movement: nystagmus is frequently observed (although no precise frequency can be established due to large variations between series) whereas sudden random movements of eyes either spontaneously or during voluntary movement are less frequent [but raise other possible diagnoses,
including opsoclonus-myoclonus syndrome (OMS). The second findings are those which suggest either meningitis or raised intracranial pressure (headache, depressed level of consciousness and vomiting while neck stiffness is unusual): any symptom suggesting raised intracranial pressure should prompt further steps detailed below. Finally, myoclonic movements of the arms and any brainstem-related symptoms may be present and tend to be associated with a more severe phenotype.

The respective frequencies of different viral infections that frequently precede onset of neurological symptoms vary according to country and vaccination recommendations. Clinical experience and a few systematic studies suggest that varicella, mumps and EBV infections are more frequently associated with acute benign cerebellitis than other common viral infections (Connolly 1994; Amlie-Lefond 2009). The CSF is abnormal in about half of the patients with a mild pleocytosis, mostly lymphocytic and moderately elevated protein content. In most individuals affected by benign acute ataxia the brain MRI is normal.

The disease is self-limited in benign acute inflammatory ataxia by definition. The ataxia resolves completely with an average duration of cerebellar signs of 2 months although mildly affected children can recover completely within a week. Individuals affected benignly do not require any treatment but in more affected or very uncomfortable children a good symptomatic response has been seen with the use of a short course of steroids (usually 1mg/kg of prednisone for 7 days although no formal study has been conducted).

Acute cerebellitis can induce very severe symptoms usually related to an intense inflammatory reaction with leukocyte infiltration of brain parenchyma and the opening of the blood-brain barrier to soluble factors and water. This leads to posterior fossa or brainstem swelling and should be regarded as a medical and sometimes neurosurgical emergency (Roulet Perez et al. 1993; Kamate et al. 2009). Neurological symptoms usually suggest raised posterior fossa pressure: these include nausea, repetitive yawns, vomiting as well as sixth nerve palsies (due to compression at the brainstem), reduced consciousness level and frequently papilloedema. Symptoms more directly related to brainstem involvement are altered respiratory pattern, blood pressure changes or other cranial nerve palsy and may reflect a life-threatening situation associated with herniation either upward transtentorially or of brainstem with a compressed fourth ventricle and occasional signs of herniation either upward transtentorially or of the cerebellar tonsils into the foramen magnum (Asenbauer et al. 1998; Tabarki 1998; Kamate et al. 2009). If this occurs the clinical consequences are a combination of predominantly cerebellar motor dysfunction with an accompanying cognitive deficit. Very few neuropathological studies are available however and they are restricted to patients who died after very severe inflammation and posterior fossa oedema (Roulet-Perez 1993).

**PERSISTENT, RELAPSING CEREBELLAR ATAXIA**

Persistent cerebellar ataxia incorporates ataxia of both trunk and limbs, dysarthria and a variety of behavioural problems which persist over time. No strict definition has been proposed but if a cut-off for persistent symptoms is set at two months from onset it would represent a third of affected children. Symptoms can be relieved by steroids (usually prednisone 1mg/kg for 10 days and in individuals affected more severely by intravenous high dose methylprednisolone); however, if cerebellar ataxia persists after two to three months the diagnosis should be carefully re-evaluated. Persistence of marked cerebellar ataxia is associated with intellectual disability and behavioural abnormalities more frequent if cerebellar atrophy or patchy necrosis are observed on MRI performed three months after onset (although no optimal date to evaluate prognosis as been defined).

Relapsing acute cerebellar ataxia is unusual and should be differentiated both from the transient exacerbation of a known pre-existing ataxia during an intercurrent febrile episode and also from acute disseminated relapsing inflammatory diseases of the CNS such as vasculitis or multiple sclerosis. A re-evaluation of the diagnosis is also mandatory, especially if the CSF remains persistently normal.

**Differential Diagnosis of Acute Cerebellitis**

Several conditions can mimic acute inflammatory cerebellar ataxia (Table 12.7), being mostly the following:

*Intoxications.* These are usually an easy diagnosis. The spectrum of responsible agents varies between countries and...
cultures, most frequently appearing in western countries as alcohol, benzodiazepines, neuroleptic and antiepileptic drugs. Ischaemic stroke. Ataxia of very sudden onset (or observed at awakening) can be the only or the main symptom of an ischaemic stroke. It is usually associated with some degree of hemiparesis, somnolence or cranial nerve palsy. The MRI will provide the main clue showing on FLAIR and diffusion-weighted sequences a small lesion either in the brainstem (and sometimes lateralised with a sharp demarcation at the mid-line), cerebellum or basal ganglia. A frequent aetiology is an arterial wall dissection at the level of one of the vertebral arteries or less frequently of the basilar artery, producing a thrombus and small down-stream embolus.

Channelopathies and other inherited familial episodic ataxias. These are very rare conditions. The diagnosis depends on the family history as the disease is commonly transmitted as an autosomal dominant trait. There are several types caused by a mis-sense mutation in the potassium channel gene KCNA1 or by mis-sense or nonsense mutation in the calcium-channel gene CACNA1A. In the absence of a family history the diagnosis is more difficult and will be suggested by repetitive bouts of acute ataxia. Ion measurements during symptomatic episodes may give a lead to the relevant genetic test. Leigh disease and other mitochondrial disorders. Repetitive episodes of ataxia with either brainstem, basal ganglia or cerebellar lesions on MRI should raise the possibility of mitochondrial disorders, especially Leigh disease in a young child. Clues to the diagnosis, apart from the MRI features, are the lactate level in CSF (usually higher than 2mmol/l) and lactate/pyruvate ratio in serum (>20). This syndrome may be the consequence of a variety of causal genetic mutations in both mtDNA and nuclear DNA (see Chapter 9). Other metabolic diseases. Hyperammonemias, Hartnup and maple syrup urine variants can have acute or relapsing ataxia as an isolated initial symptom although this is unusual.

Cerebellar tumours. An acute onset with ataxia is unusual but possible. Neck stiffness, vomiting and associated neurological signs will prompt an MRI. Acute labyrinthitis. This is in fact unusual but nausea, vertigo and nystagmus are clues to diagnosis. Benign paroxysmal vertigo in toddlers is characterised by a sudden, unsteady gait in a child who holds on to a parent for stability. The very short duration and sometimes history of migraine in one or both parents will suggest the diagnosis.

OPSOCLONUS-MYOCLONUIS SYNDROME AND OTHER PARA-NEOPLASIC DISORDERS

The chapter on paraneoplastic disorders in paediatric neurology used to be very short. Many syndromes are now recognised: some such as anti-NMDAR antibody encephalitis, anti-Hu encephalitis (Honnorat 2013) or Lambert-Eaton syndrome are only rarely associated with a tumour in children whereas others like OMS are associated with a neuroblastoma in the majority of children. Finally, it is now the custom to search carefully for remote lymphomas or tumours in a child with an evolving inflammatory-like encephalopathy. We followed, for example, a 15-year-old girl with a progressive spastic tetraparesis and abnormal signal on T2 weighted MRI in cortico-spinal pathways that led to the discovery of an intra-abdominal lymphoma.

Two of the well characterised paraneoplastic syndromes are described here.

OPSOCLONUS-MYOCLONUIS SYNDROME
(Dancing Eye syndrome, Kinsbourne’s syndrome)

OMS is now defined by the association of three of the following four diagnostic criteria: (1) opsoclonus; (2) ataxia/myoclonus; (3) behavioural change and/or sleep disturbance; (4) neuroblastoma. Opsoclonus refers to rapid, conjugate, multidirectional eye movements more frequently intermittent than permanent. Ataxia has no special features and, at onset, a false diagnosis of acute inflammatory cerebellar ataxia is frequent. Myoclonus usually involves the arms and varies from tremulous myoclonia to multifocal jerks, whereas others like OMS are associated with a neuroblastoma in the majority of children. Finally, it is now the custom to search carefully for remote lymphomas or tumours in a child with an evolving inflammatory-like encephalopathy. We followed, for example, a 15-year-old girl with a progressive spastic tetraparesis and abnormal signal on T2 weighted MRI in cortico-spinal pathways that led to the discovery of an intra-abdominal lymphoma.

The detection of such characteristic symptoms leads to a search for remote neuroblastoma. In most of the patients the catecholamine metabolites will not be detected in urine and many tumours will escape ultrasound imagery. A combination of MIBG (metaiodobenzylguanidine) scintigraphy and thoraco-abdominal MRI is usually required to detect a small tumour in the paravertebral region in 40–64% of children in the different published series. This does not give a final evaluation of neuroblastoma frequency as the tumour can be small and frequently regress spontaneously with time.

Neuroblastoma associated with OMS is most frequently a low stage, low risk tumour. In most of the patients surgical resection is the only oncological treatment needed. The tumour itself is usually MYCN negative.

OMS is believed to be related to an immune response mostly directed against Purkinje cells (Hero 2013). This is first supported by a higher percentage of human leukocyte antigen class II locus DR B1*01 among patients with OMS (indicating a genetic predisposition to auto-immunity), the detection of auto-antibodies against Purkinje cells (although none has been fully characterised) and the good effect in some patients of treatment directed against antibody-producing lymphocytes. It is likely that a cellular auto-immune response is also present in all or in subgroups of patients.

In the long term the main outcome risk is the occurrence of significant or severe cognitive and neuropsychological deficits while motor outcome is normal or near normal. Within the UK series 7% of patients had a monophasic and sometimes benign disease whereas 61% had a chronic relapsing disease and 32% had several acute exacerbations but were symptom-free between relapses. One of patients had a normal intellectual outcome and cessation of symptoms at the end of follow-up (Brunklaus 2011). Most retrospective studies demonstrate a similarly poor outcome with 60–80% of patients presenting neurological sequelae. A severe initial presentation predicted a chronic disease and later specific learning disabilities.

The optimal treatment of OMS is not fully established (Pranzatelli 2005; Rostasy 2006; Gorman 2010; Hero 2013), with two trials are presently ongoing. One from the Children Organisation Group tested 58 children with neuroblastoma and OMS, randomising one arm to steroids and cyclophosphamide and the other to steroids, cyclophosphamide and immunoglobulins. The second trial in Europe is an escalation from steroids alone through cyclophosphamide and rituximab, the end point being the percentage of children reaching each level of treatment. It is however suggested by uncontrolled series that early immunosuppression (either using cyclophosphamide or rituximab) is more efficient to prevent future cognitive sequelae than steroids alone.

RAPID-ONSET OBESITY WITH HYPOTHALAMIC DYSFUNCTION, HYPOVENTILATION AND AUTONOMIC DYSREGULATION

Rapid-onset obesity with hypothalamic dysfunction, hyperventilation and autonomic dysregulation (ROHHAD) syndrome, also called idiopathic hypothalamic syndrome, has five
diagnostic criteria: (1) apparent normality before onset of obesity; (2) sudden onset of hypothalamic dysfunction defined by one or more of the following findings: rapid-onset obesity, hyperprolactinemia, central hypothroidism, disordered water balance, failed growth hormone stimulation test, corticotrophin deficiency or delayed or precocious puberty; (3) autonomic dysfunction; (4) alveolar hypoventilation; (5) absence of PHOX2B mutation. The last criterion is important to differentiate this syndrome from genetic syndromes due to mutations in the PHOX2B gene (congenital central hypoventilation gene or Ondine syndrome, late onset-central hypoventilation syndrome) (Nunn 1997; Amiel 2003; De Pontual 2008).

ROHHAD syndrome is a rare disorder and no formal natural history study has been published. The age at onset is between 1.5 and 7 years, usually with the onset of rapid obesity. Seizures are reported in a third of patients when focusing on neurological symptoms with the frequency of associated cognitive impairment varying between series and MRI being usually normal. Finally, in a recent exhaustive review 22 of 55 reported patients had an associated neural crest tumour that can be present from onset or can develop at a later stage (Chuan 2014).

Spinal Cord Injury
Accidental and Non-Accidental Injuries by Physical and Toxic Agents

Karen Barlow, Robert Forsyth and Robert Minns

This chapter addresses acquired traumatic, toxic and hypoxic–ischaemic causes of acute brain and spinal cord disease. The emphasis is on acquired brain injury (ABI).

**THE CONCEPT OF ACQUIRED BRAIN INJURY**

An important justification for ABI as an umbrella term for a wide range of heterogeneous insults relates to service provision and planning. Services for children with additional health and education needs are largely designed for the historically greater numbers of children with developmental disabilities (including cerebral palsy [CP]). ABI characteristically causes ‘patchy’ (i.e. focal or multifocal) injuries, resulting in uneven profiles of preserved strength and new weaknesses: the very severely injured child with major new motor control problems, but relatively preserved cognition, poses a severe challenge to augmentative and assistive communication (AAC) services, or the much more common ‘invisibly injured’ profile of a young person who walks, talks and has full independence in activities of daily living, but remains very incapacitated by new executive skill weaknesses (see below).

**EPIDEMIOLOGY**

ABI is the leading cause of death and neurological disability in children after infancy. ABI includes the effects of central nervous system (CNS) infection (see Chapter 11), stroke (see Chapter 15) and tumours (Chapter 14); however, traumatic brain injury (TBI) is the most common cause of ABI in developed countries in childhood (Luerssen et al. 1988; Langlois et al. 2004).

**ACCIDENTAL TRAUMATIC BRAIN INJURY**

Comparison of incidence and mortality rates across published studies can be difficult for a number of reasons. Samples may be population or hospital admission based, prospective or retrospective, and differ in terms of severity thresholds and age limits. Traumatic brain injury (TBI) severity is typically graded using the Glasgow Coma Score (GCS) with a GCS ≤8 regarded as indicative of severe TBI (about 5% of all head trauma); GCS 9–12 indicates moderate TBI (5–10%) and 8–5 minor TBI (GCS >12) (Miller 1993).

Table 13.1 summarises some of the most recent international epidemiological studies of paediatric TBI.

These studies include rates of attendance at accident and emergency departments (A&E), hospitalisation and admission to paediatric intensive care units (PICUs). On average, 10% of children with TBI will be hospitalised, although thresholds for A&E attendance are falling with increased awareness of rare but important complications of apparently minor injury (Colvin et al. 2013). Mortality rates are low and continue to decrease. The number of children killed or seriously injured in road traffic accidents in the UK fell some 67% between 1979 and 2003, assumed to be the result of legislation and road safety campaigns, including improved car impact resilience, the compulsory use of car seats and seat belts for infants and children, traffic calming measures and speed limit enforcement, etc. Causes of TBI are listed in Table 13.2.

Falls are the most common cause of TBI and are most frequent in the first year of life (Langlois et al. 2005a; Faul et al. 2010). Preventive measures, such as safety rails, locks and modification of play equipment and surfaces in play areas, help reduce incidence and severity.

Road traffic accidents are the next most common cause and occur more commonly in the 10- to 15-year age group. It is more common for a child to be a pedestrian (36%) than an occupant of a vehicle. TBI caused by traffic accidents peaks at around 10 years of age. Accidents typically occur in late afternoon and early evening, and the rates peak in the...

summer months (Parslow et al. 2005). Social deprivation is an important risk factor (Parslow et al. 2005) and Langlois et al. (2005b) reported higher rates in African-American children than white children of the same age. Kumar and Mahapatra (2009) reported that, although incidence and mortality rates have been declining for some time in developed countries, this is not the case in developing countries, where mass urbanisation means that trauma is an increasingly important cause of disability and mortality compared with ‘traditional’ factors such as infectious disease (Gore et al. 2011). Mobile phone use while driving motorbikes has emerged as a major new cause of TBI in India (Kumar and Mahapatra 2009).

Particular causes of injury are important at different developmental stages with accidents at home occurring in the first 3 years, injuries related to sport and outdoor play from 4 to 11 years, and traffic-related accidents in adolescents.

### NON-ACCIDENTAL (INFLECTED) BRAIN INJURY

Non-accidental (i.e. inflicted) head injury (NAHI), also known as abusive head trauma is the most common mechanism of head injury at age <2 years. Billmire and Myers (1985) found that in this age group 64% of all head injuries, excluding uncomplicated skull fractures, and 95% of serious head injuries were of non-accidental origin. Physical abuse constitutes about a third of all child abuse and actual brain injury is rare: it occurs in only 0.5% of all cases of abuse and 1–3% of cases of physical abuse (Minns and Brown 2005).

In the late 1990s the annual incidence of NAHI in Scotland was 24.6 per 100000 (Barlow and Minns 2000). The median age at admission was 2.2 months (range 4 weeks to 8.8 months). A separate study estimated an incidence in south-east Scotland of 33.8 per 100000 per year (Minns et al. 2008). A population-based study in North Carolina, USA reported an incidence in the range 14–30 per 100000 (Keenan et al. 2003). An incidence of 14 per 100000 has been reported in Switzerland (Fanconi and Lips 2010).

### SOCIAL PATHOLOGY AND RISK FACTORS FOR NON-ACCIDENTAL HEAD INJURY

Risk factors may vary according to the region or country under study. Prospective studies have identified risk factors including alcohol and drug misuse, previous Social Services intervention, young maternal age, multiple pregnancies, past parental military service and poorer parental educational achievement. Boys are at increased risk (Goldstein et al. 1991, 1993; Keenan et al. 2003; Hobbs et al. 2005; Mok et al. 2010). An ‘index of multiple deprivation’, reflecting local income, employment, education, crime and housing factors, is a risk factor for NAHI in Scotland (Minns et al. 2008). Perpetrators experience biological, social, environmental and financial stresses, which precipitate impulsive violent behaviour, particularly if the threshold for such behaviour is reduced by alcohol or drug misuse. It has recently been shown that NAHI rates rise at times of economic recession (Huang et al. 2011).

### NON-TRAUMATIC COMA

There are many potential causes of coma of non-traumatic origin (NTC) and the aetiology remains unidentified in approximately 14% cases. Infections are the most common causes of NTC, which includes not only meningitis and encephalitis but the indirect neurological effects of systemic (particularly respiratory) infection (Table 13.3 and see Chapter 11). Pneumococcal meningitis has declined in incidence since the availability of the pneumococcal vaccine, but still has a high fatality rate of 13%, and infection in infancy frequently has neurological sequelae. Poor prognostic signs include coma, prolonged seizures and delayed presentation (de Jonge et al. 2010).

Other causes of NTC include hypoxia–ischaemia, exemplified by cardiac arrest or near-miss sudden infant death. Out-of-hospital cardiac arrest has a very poor outcome, particularly if seizures are present. Water temperature is an important determinant of outcome after near drowning, and remarkably good outcomes can be seen after prolonged immersion in ice water (Forseyth and Kirkham 2012).

### PATHOPHYSIOLOGY OF TBI

A child’s brain is more vulnerable to traumatic injury and has a poorer outcome than the adult brain. The infant and juvenile

Adapted from Hawley et al. (2003).
The brain's composition also differs in the immature brain. Water content is higher and myelination, which progresses rapidly in the first 2 years of life, is incomplete (Leppert et al. 2009). In infancy and early childhood, the sutures have not yet fused and have greater elasticity, allowing the skull to deform more easily; this results in slower deceleration and a propensity for shearing injury. The internal skull vault anatomy differs: less prominent bony buttresses allow greater movement of the brain within the skull vault but result in fewer contusions. Greater relative head mass and weaker neck musculature predispose young children to rotational forces after an impact.

</table>

The pathophysiology of TBI is complex. A TBI results in early ionic and neurotransmitter perturbations that initiate a cascade of events that disrupt normal cellular function, including changes in glucose metabolism, free radical production and mitochondrial dysfunction. These processes are collectively referred to as excitotoxicity. (See Prins et al. 2013 for an excellent review.)

Traumatic cellular membrane perturbation and/or pore formation results in an indiscriminate release of neurotransmitters, leading to a massive efflux of potassium and sodium influx. Sodium/potassium pumps try to restore the ionic equilibrium using ATP, with a resultant high metabolic and glucose requirement. Within 6 hours, increases in intracellular calcium occur. Calcium is sequestered from the endoplasmic reticulum and imported into mitochondria, leading to mitochondrial dysfunction, oxidative stress and free radical formation.

Changes in cerebral glucose metabolism are characteristic of TBI, with initial hypermetabolism and a later prolonged period of hypometabolism. Severe injuries have the longest period of decreased metabolism, and animal studies suggest that adults have a more prolonged response than juveniles. Decreased cerebral glucose metabolism may be due to decreased cerebral blood flow (CBF), decreased glucose transporter function or decreased cellular metabolic demand. In the acute phase, a combination of reduced CBF and increased cerebral cellular metabolic demand (i.e. relative ‘uncoupling’ of the usual closely regulated link between CBF and aerobic metabolism) leads to brain energy failure, neuronal dysfunction and cell death.

In the acute phase, cerebral edema results in increased intracranial pressure. Increased intracranial pressure leads to brain displacement, herniation and damage to adjacent or remote brain structures. The mechanisms leading to brain displacement are complex, involving the balance between the forces driving intracranial pressure and brain volume displacement, the rigidity and compliance of the skull, stretch receptors and brainstem reflexes, and the mechanical properties of the brain itself.
and metabolism) creates the potential for an energy crisis and subsequent cascades of secondary injury.

After a TBI, levels of reactive oxygen species rise and overwhelm free-radical-scavenging systems, resulting in oxidative damage. Dysfunctional mitochondria are an important source of free radical generation. These effects result in lipid peroxidation, protein nitration and DNA oxidation. Lipid peroxidation results in damage to the cell membrane and an increase in its permeability. Protein nitration and DNA oxidation impair cellular repair mechanisms. Mitochondrial impairment is important after a TBI and can result in the activation of both apoptotic and necrotic pathways, contributing to cell death. Mitochondria from immature rats show increased susceptibility to apoptosis, contributing to the vulnerability of the young brain to injury (Soane et al. 2008). Changes in mitochondrial function are potentially reversible if the post-TBI cellular energy crisis can be treated.

**Neuroinflammation**

There is strong pathological evidence for a prolonged immune response in TBI, with microglial activation, astrocyte activation and microvascular changes in the blood–brain barrier identifiable months and years after injury. This may contribute to poorer long-term outcomes especially in children (Korn et al. 2005; Ziebell and Morganti-Kossmann 2010; Ramalakshansingh et al. 2011; Shultz et al. 2012; Johnson et al. 2013). The release of ATP from damaged neurons initiates the activation of the innate immune system (predominantly quiescent microglia), resulting in the release of inflammation-promoting mediators (e.g. cytokines, chemokines, and reactive oxygen and nitrogen species). Proinflammatory processes are intended to clear the CNS of potentially harmful substances. Anti-inflammatory processes follow this, performing reparative and regenerative functions considered to be beneficial to neuronal survival. An unbalanced or prolonged inflammatory response can be harmful (Mayer et al. 2013).

**Biomechanics of the Primary Injury**

The forces experienced by the brain depend on the size and weight of the child, the height of the fall, the speed of impact, and whether the child was stationary or moving at the time of the fall. It is usually impossible to know the exact forces applied to the head, but pathologies tend to increase as forces increase. The most common forces are linear and rotational, although penetrating and compression injuries are sometimes seen.

A fall or impact injury results in unidirectional forces (impact loading) causing tissue deformation and local injury such as a skull fracture, epidural haematoma and/or underlying contusions. ‘Contre-coup’ contusion of brain tissue against the skull diametrically opposite to the site of impact is caused by wave-like force propagation through the parenchyma. The locations of contusions depend on the structure and physical properties of the interior of the skull vault, but are commonly found in the inferior frontal and anterior temporal lobes because they rest on the floors of the anterior and middle cranial fossae, respectively. As the interior skull is relatively smooth, coup and contre-coup contusions are relatively rare in infants.

Rotation of the head on the neck (inertial loading) leads to angular acceleration–deceleration forces within the skull, and is an important cause of pathology in TBI. More intracranial pathology is seen as rotational acceleration–deceleration forces rise. Injuries range from tearing of the subdural bridging veins (with resultant subdural and subarachnoid haemorrhages), to axonal and capillary shearing at the grey–white matter junction, and with the highest forces injury to the midbrain and brainstem (Ommaya et al. 2002). In vivo strain modelling using adult human MRI reveals that brain shift patterns are complex, and have high regional and inter-individual variations (Feng et al. 2010; Monea et al. 2012). The highest levels of stretch and shear are seen at the cortical surface of the brain (including frontal, superior and occipital sites), where the potential for displacement is greatest, but high levels are also seen near basal points of attachment of the brain to the skull (e.g. bony prominences, internal carotid arteries, optic and oculomotor nerves, olfactory tracts and the pituitary stalk) (Bayly et al. 2005; Zou et al. 2007). Other mechanisms of brain injury include penetrating injury (e.g. gunshot wounds), compression in road traffic accidents and abusive injuries, and blast injuries but these are infrequent in children.

**COMMON PATHOLOGIES SEEN IN PAEDIATRIC TRAUMATIC BRAIN INJURY**

The distinct biomechanics of injury in the young brain result in the potential to generate larger angular acceleration–deceleration forces. Pathologies therefore vary by age and mechanism of insult (see Figs 13.2–13.5). TBI in the infant and toddler is associated with subdural haematomas and diffuse cerebral oedema. Contusions are seen less frequently than in adult TBI. Hypoxic–ischaemic injury is frequently seen in inflicted TBI (Suh et al. 2001). Adolescents show similar injury patterns to adults, where contusions and axonal injury are the most common pathologies.

Epidural haematomas (EDHs) are almost always associated with linear forces, with or without a skull fracture. Although uncommon in TBI (1–6% of hospital admissions) an EDH is important because treatment often involves surgical evacuation (usually where the diameter exceeds 18mm and/or there is associated raised intracranial pressure [ICP]) (Case 2008). Approximately 10% of EDHs are associated with a ‘lucid interval’, followed by loss of consciousness. The outcome is usually excellent.

Subdural haematomas and haemorrhages (SDHs) are common in paediatric TBI and almost ubiquitous in infantile inflicted TBI. Nearly all SDHs are due to injury to a dural bridging vein, caused by linear or rotational forces, but can
Diffuse axonal injury (DAI) and traumatic axonal injury are the result of shearing rotational forces. However, axons are also damaged by the secondary biochemical cascades that occur over the following hours to days. Pathological studies of DAI have revealed microscopic features corresponding to Wallerian axonal degeneration. Three grades of increasing severity based on the depth of the lesions have been described, with grade 1 comprising lesions at the grey–white matter interface, grade 2 comprising additional lesions in the corpus callosum and grade 3 demonstrating further lesions to the rostral lateral–dorsal brainstem. This mirrors the findings seen in the in vivo human MRI modelling studies discussed above. It is also associated with diffuse vascular injury, hypoxic–ischaemic injury and cerebral oedema. As MRI techniques have improved, it is recognised that many similar radiological features can also be seen with milder injuries but with a much-reduced burden of injury, and the term ‘traumatic axonal injury’ (TAI) has been used for these more limited injuries.

Frontal and temporal contusions result when the brain hits bony buttresses, such as the sphenoid wing or ethmoidal plate. Parenchymal shearing and deformation injury lead to local cerebral oedema and areas of gross or petechial haemorrhage. Cerebral oedema can be classified into two main categories: vasogenic oedema and cytotoxic oedema. Cytotoxic oedema is characterised by an increase in intracellular water content and vasogenic oedema by increased extracellular water.
oedema results from increased intracellular osmolality. Vasogenic oedema results from disturbance of Starling forces and/or increased permeability of the blood–brain barrier (BBB). Cytotoxic oedema typically occurs later than vasogenic oedema, and typically reflects the failure of the sodium/potassium pumps (see above). Vasogenic oedema occurs early after injury but can persist for several weeks, and is an important contributor to increased ICP and secondary injury (see below). Aquaporins, matrix metalloproteinases and vasoactive inflammatory agents play an active role in regulation of BBB permeability, and are generating much interest as potential therapeutic targets for decreasing secondary injury after TBI (Donkin and Vink 2010).

**CLINICAL ASSESSMENT OF TBI**

**Emergency Assessment of Apparently Trivial Head Injury**

The aim of clinical assessment of children after apparently minor closed head injury is to identify those who are at risk of avoidable disability or even death. A very small proportion of these apparently well children will deteriorate in the first few hours after injury as a result of slowly expanding, space-occupying haematomas (either subdural or epidural). Untreated, the expanding haematoma causes the ICP to rise steadily, eventually risking herniation and coning (see below). Prompt identification and neurosurgical evacuation of space-occupying haematoma will dramatically improve the outcome.

The traditional approach to this triage problem was to admit children for periods of 24–48 hours of in-patient observation. However, because deterioration is a very rare event, complacency and inadequate neurological observation were a constant problem. Over the last decade or so, there has been a major change in philosophy with much greater use of early CT on admission. A child with a normal CT scan can be discharged with confidence. However, there are logistical challenges and radiation-exposure concerns about the very widespread use of CT in A&E.

Various decision rules trying to optimise the threshold for CT have been developed: they err on the side of high sensitivity (wishing to miss as few at-risk children as possible) at the expense of specificity (resulting in many normal CT scan results), and place varying emphases on clinician discretion. Box 13.1 shows the CHALICE (Children’s Head Injury Algorithm for the Prediction of Important Clinical Events) clinical decision rule (Dunning et al. 2006).

Comparisons of these rules, based on discriminatory precision (Lyttle et al. 2012; Easter et al. 2014) and health economic (Holmes et al. 2013) criteria, have been reported (Forsyth and Pearce 2013).

**Box 13.1 Children’s head injury algorithm for the prediction of important clinical events (CHALICE)**

A CT scan is required if any of the following criteria are present

**History**

- Witnessed loss of consciousness of >5 min duration
- History of amnesia (either anterograde or retrograde) of >5 min duration
- Abnormal drowsiness (defined as drowsiness in excess of that expected by the examining doctor)
- More than three vomits after head injury (a vomit is defined as a single discrete episode of vomiting)
- Suspicion of non-accidental injury (NAI, defined as any suspicion of NAI by the examining doctor)
- Seizure after head injury in a patient who has no history of epilepsy

**Examination**

- Glasgow Coma Score (GCS) <14, or GCS < 15 if <1 year old
- Suspicion of penetrating or depressed skull injury or tense fontanelle
- Signs of a basal skull fracture (defined as evidence of blood or cerebrospinal fluid from ear or nose, panda eyes, Battle’s sign, haemotympanum, facial crepitus or serious facial injury)
- Positive focal neurology (defined as any focal neurology, including motor, sensory, coordination or reflex abnormality)
- Presence of bruise, swelling or laceration >5 cm if <1 year old

**Mechanism**

- High-speed road traffic accident as a pedestrian, cyclist or occupant (defined as accident with speed >40 mph)
- Fall of >3 m in height
- High-speed injury from a projectile or an object

If none of the above variables is present, the patient is at low risk of intracranial pathology.
Emergency Assessment of Severe TBI

Initial resuscitation priorities are to secure the airway, and ensure adequate ventilation and circulation. Hypoglycaemia should be urgently corrected if present. Coma level should be rapidly assessed, using a young-child adaptation of the GCS where appropriate. Cervical immobilisation is important in any injury of traumatic mechanism, particularly if of high energy (e.g. road traffic accident), or if the GCS <15, or there is any neck pain or tenderness, focal neurological deficit or other clinical suspicion of neck injury. The collar should be removed only after expert neuroradiological and neurosurgical review. To avoid high radiation doses to the thyroid, some authorities recommend plain anteroposterior and lateral cervical X-rays in young children in preference to neck CT, which is the criterion standard in adolescents and adults.

In most circumstances, any child with a GCS <8 or a rapidly deteriorating GCS should be intubated and ventilated because airway control is likely to be inadequate. Intubation and ventilation should also occur when raised ICP appears probable. Prompt recognition and management of raised ICP is potentially lifesaving.

If the GCS is <12 or deteriorating, signs of raised ICP and/or herniation should be actively sought through clinical examination of pupillary and other brainstem reflexes. A dilated pupil commonly indicates third cranial nerve involvement in a herniation syndrome (Fig. 13.5) but rarely may reflect an afferent pupillary defect caused by optic nerve involvement in an orbital fracture. Papilloedema will not usually be present if the ICP has increased rapidly, but the presence of venous pulsation on fundoscopy is useful confirmation of normal ICP (although it is not seen in 10% of the ‘normal’ population). Retinal haemorrhages are pertinent in the assessment of suspected non-accidental (inflicted) injury.

Brain CT has a central role in the emergency evaluation of TBI, particularly if clinical assessment suggests a raised ICP, and should be performed as soon as initial resuscitation and stabilisation have been achieved. In the context of head trauma, neurosurgically remediable causes of raised ICP (particularly haematomas that are causing raised ICP in the rigid box of the skull because of their space occupation) should be actively sought.

Even if initial CT does not identify surgically remediable pathology, most centres would advocate invasive monitoring of ICP via a surgically implanted catheter or transducer (variably placed in the subarachnoid space, brain parenchyma or lateral ventricles), as an important component of neurosurgical intensive care. Increases in ICP in the days after injury should prompt early consideration of repeat CT in case a surgically remediable problem has developed.

Secondary brain injury refers to the phenomenon of injury additional to the direct effects of trauma. As discussed above, cascades of excitotoxicity, free radical production and energy crises are important but are not currently directly remediable. Routine clinical care currently addresses important additional causes of secondary injury, including hypoxia, hypotension, decreased cerebral perfusion and energy failure. These primarily result from systemic shock (e.g. caused by extracranial injury), primary injury to the brainstem, impaired cerebral autoregulation and increased ICP. Other mechanisms include hyponatraemia, seizures, hyperthermia, post-traumatic vasospasm, secondary haemorrhage, apoptosis and perfusion–reperfusion injury. In the infant especially, hypoglycaemia is an additional cause of secondary injury.

MEASURES TO REDUCE INTRACRANIAL PRESSURE AND MAINTAIN CEREBRAL PERFUSION PRESSURE

Differences in ICP between intracranial compartments, or in which brain structures are displaced around or through anatomical barriers, causing further compression and ischaemia (Fig. 13.6).

Subfalcine herniation under the free edge of the falx causes necrosis of the cingulate gyrus and compression of the pericallosal artery. In a tentorial herniation the medial temporal lobe (uncus) shifts through the tentorial hiatus. This results in uncal infarction and compresses the blood supply to the midbrain and brainstem, causing midbrain infarction and haemorrhages (Duret haemorrhages). It can also compress the posterior cerebral arteries, causing focal ischaemia of the calcarine cortex and resulting in cortical blindness.

If a raised ICP is not relieved, descent of the brainstem and cerebellar tonsils causes impaction, and coning occurs at the foramen magnum. This can cause secondary ischaemia of the medulla and upper cervical cord, as well as cerebellar tonsillar necrosis and compression of the posterior inferior cerebellar arteries. The clinical picture of the various shifts and cones is described later. They are important causes of secondary brain injury.

Cerebral perfusion pressure (CPP) is calculated as the difference between mean arterial pressure (MAP) and ICP, and reflects the pressure difference available to drive blood into the intracranial cavity. Inadequate cerebral perfusion can set up a
vicious cycle of cerebral ischaemia, worsening cerebral injury and oedema, further increases in ICP, decreased cerebral perfusion and further ischaemia. This occurs even in the absence of cerebral shift or herniation.

As the ICP rises, the CPP falls and, although derangements in both are associated with poorer outcome, the specificity and sensitivity of the CPP as a predictor of poor outcome are superior to those of the ICP (Chambers et al. 2006). Age-specific norms are available (Chambers et al. 2005) and the duration and severity of derangements predict the outcome (Jones et al. 2003). Chambers et al. (2005) suggest that the CPP should be maintained above 53mmHg in 2–6-year-olds, 63mmHg in 7–10-year-olds and 66mmHg in 11–16-year-olds. International guidelines (Kochanek et al. 2012) suggest a target CPP of 40–50mmHg. The outcome relates to both the magnitude and the duration of the ICP/CPP derangement and cumulative pressure–time indices have been developed (Jones et al. 2005). The optimal CPP for a given patient will depend on cerebrovascular autoregulatory capacity, and will, therefore, probably vary between patients and with time post-injury. Estimation of the optimal CPP measured from high temporal-resolution physiological data has been demonstrated as a research technique, but is not yet in routine clinical use (Guiza et al. 2013). The ICP/CPP data are most likely to influence neurosurgical management decisions in the first 6 hours after injury.

Measurement of the oxygen saturation of internal jugular venous blood returning from the brain ($S_JVO_2$) by an electrode placed at the jugular bulb provides a direct measurement of whole-brain oxygen extraction and thus adequacy of brain oxygenation. $S_JVO_2$ should be kept between 54% and 75%. Lower values indicate cerebral oligaemia, and higher values, cerebral hyperaemia. Direct jugular venous blood sampling can be combined with arterial blood sampling and/or techniques measuring whole-brain CBF to allow calculation of arteriovenous oxygen differences and cerebral metabolic rates. However, the invasiveness of these techniques discourages their routine clinical use.

A comprehensive review of the best available evidence for the management of increased ICP can be found in the Guidelines for the management of severe TBI in children (Kochanek et al. 2012). Medical management of raised ICP includes nursing with the head in midline and tilted up 30° and avoiding unnecessary handling and suction (coughing raises intrathoracic pressure and thus ICP). Cerebral arterioles dilate under conditions of hypercapnia. Past policies of hyperventilation intended to induce hypocapnia, and thus vasoconstriction, certainly reduce ICP; however, the inadvertent ischaemia is now known to worsen outcomes; ventilation to normocapnia with temporary manual hyperventilation in the presence of spikes of raised ICP is now conventional. A similar balance needs to be struck between maintenance of an adequate circulating volume and avoiding cerebral oedema through fluid overload. Boluses of mannitol may be useful in the short term for managing spikes of raised ICP, but eventually become counterproductive (as mannitol eventually elevates intracellular osmolality), and again careful attention to fluid balance after the bolus (avoiding hypovolaemia) is required because it acts as an osmotic diuretic. Obvious seizures will cause raised ICP again and should be treated. However, routine use of prophylactic anticonvulsants is not recommended except in cases of non-accidental injury and infantile TBI, or where there is

---

**Figure 13.6** Brain herniation patterns: (1) subfalcine (also known as cingulate); (2) central; (3) uncal; (4) tonsillar; (5) upward cerebellar (seen with posterior fossa lesions, leading to impingement of the posterior cerebral arteries); and (6) transcalvarial (may occur with skull fracture or at craniectomy sites).
substantial intraparenchymal haemorrhage (Kochanek et al. 2012; Arndt et al. 2013).

Although, hypothermia offers neuroprotective benefit in neonatal asphyxia no benefit has as yet been demonstrated in paediatric TBI (Hutchison et al. 2008). The benefit of other neuroprotective strategies including corticosteroids (Roberts et al. 2004) is also unclear. Hyperthermia should be avoided, although it is not clear whether fever is a risk factor for poor outcome caused by hyperthermia itself or secondary injury associated with neuroinflammatory processes (Bao et al. 2014).

In severe, resistant, raised ICP, surgical approaches may be important. If ICP monitoring is being performed via a ventricular catheter then cerebrospinal fluid (CSF) drainage may be possible at least until the ventricles have completely effaced. There is renewed interest currently in decompressive craniotomy (removal of skull vault bones to allow unrestricted brain swelling). However, evidence of benefit is lacking in both children (A Taylor et al. 2001; Cooper et al. 2011) and adults (Cooper et al. 2011; Sahuquillo et al. 2013).

**General Supportive Measures**

Electrolyte imbalances can occur as a result of cerebral salt wasting, diabetes insipidus and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and should be monitored frequently. Paroxysms of sympathetic hyperactivity with hypertension, fever and hyperhidrosis (sometimes known as dysautonomia) are frequent after severe TBI, often occurring at emergence from a coma, and can be very troublesome. Strategies to treat these should be aggressive because they are distressing for families to witness, and the resultant hyperpyrexia and rhabdomyolysis are a potent cause of renal and renal kidney failure. Management strategies include sympathetic blockade using beta blockers such as propranolol (Cotton et al. 2007), and/or centrally acting alpha2-agonists (e.g. clonidine) (Nordström 2005).

Tracheotomy may be necessary if prolonged ventilation is required. Care should be taken during the prolonged periods of immobility of neurointensive care to prevent pressure sores and the development of contractures, particularly restriction of foot dorsiflexion. Critical care neuropathy and myopathy can also occur in children with prolonged intensive care unit (ICU) admissions.

**Non-Accidental (Inflicted) TBI**

The forensic evaluation of suspected NAHI is outside the scope of this chapter. Secondary hypoxic injury is common and cerebral oedema can be severe. Acute management of seizures can also be challenging, although these typically abate after a few days. Mortality and late morbidity rates are high.
PREDICTORS OF OUTCOME

Determinants of Outcome of TBI
Outcomes from TBI may be considered globally or in terms of specific domains (Forsyth 2008). Global outcome measures include the Glasgow Outcome Scale (McCauley et al. 2001) and a paediatric equivalent – the King’s Outcome Scale for Child Head Injury (KOSCHI) (Crouchman et al. 2001). Domain-specific instruments assess constructs including functional independence, health-related quality of life, neuropsychological domains (e.g. intellectual, adaptive, executive and social function) and measures of gross motor function (McCauley et al. 2012).

Outcomes after TBI are predicted by pre-injury demographic factors, injury-related factors and post-injury factors (Johnson et al. 2009) and are summarised in Table 13.4. Pre-injury demographic predictors include age, prior intellectual ability, the presence of behavioural or psychiatric conditions, socioeconomic status and family dynamics. Post-traumatic injury predictors include success with rehabilitation programmes and interventions. Some rehabilitation techniques improve cognition and behaviour. Integrated and multidisciplinary assessment and coordination of care as part of the rehabilitation improve the overall quality of life for the individual and his or her family.

The long-term impairments after paediatric TBI include behaviour, neuropsychological function (attention, executive function, memory, speed of processing), skills of activities of daily living (ADL), social skills, psychological status and quality of life. An early, impaired memory ability is indicative of persistent problems 2 years later and the need for special education (Miller and Donders 2003). The pattern of interaction between child behaviour problems and family functioning 6 months post-injury is extremely predictive of the burden on the family, parental stress and child behavioural problems at 1 year (HG Taylor et al. 2001b).

Predictors of Outcome after Non-Traumatic Brain Injury
Outcomes after postnatal hypoxic–ischaemic encephalopathy (HIE) are typically poorer than after TBI (Heindl and Laub 2007). They correlate with injury severity (e.g. duration of unconsciousness) (Kriel et al. 1994). Other predictors of poor outcome (death and vegetative state) after postnatal HIE include hypoglycaemia, absent pupillary light reflexes, epileptic seizures, cardiopulmonary resuscitation for more than 10 minutes, and abnormal EEG and brain imaging. The predominance of injury severity in predicting outcome leaves little room for post-injury factors to influence outcome, because pre-injury factors, younger age and ethnicity have been associated with a better outcome (Lee et al. 2006).

Outcome from near drowning is typically bimodal with either relatively intact recovery or death or a vegetative outcome. Immersion in ice-cold water can be protective and associated with a good outcome; warmer temperatures are associated with a worse outcome. Less severe anoxic events may be associated with localised brain lesions and corresponding deficits, for example, of the hippocampus and subsequent memory impairment (Hopkins and Haaland 2004).

Outcome after stroke is determined by type, extent and location of the lesion. Haemorrhagic stroke is more frequently fatal than ischaemic stroke, and seizures are usually a marker of poor global outcome. The size and location of an arteriovenous malformation predicts outcome (Pasqualin et al. 1991). A young age at the time of the stroke will result in a worse global outcome and poor language development (Ganesan et al. 2000; Chapman et al. 2003).

For infectious encephalitides, coma at presentation, repeated seizures and duration of illness are all associated with a poor outcome. The type of encephalitis is also important: Japanese B and herpes simplex virus, and tick-borne encephalitis with optic nerve involvement, are all associated with significant sequelae. Age is associated with a poor outcome in children with bacterial meningitis (Pentland et al. 2000).

For a more detailed review see Forsyth and Kirkham (Forsyth and Kirkham 2012).

Age at Injury
The effect of age at injury on outcome is debated in the paediatric ABI literature. Impressions that young children make better recoveries from brain injury than adults would be expected to are commonplace, but over-simplify a complex picture. Contradictory messages come from literature looking at different domains of outcome after different types of injury. The most optimistic views come from the literature on language outcomes after very early unihemispherical injury: it is clear that language can relocate to contralateral structures, if they are unaffected, with remarkable efficiency (Vargha-Khadem et al. 1997). Such flexibility in localisation may be less possible for domains such as vision and motor function, the ancient evolutionary origins of which are reflected in specialised local cortical microstructures.

TBI is typically diffuse and multifocal. Children tend to make better motor recoveries after TBI than might be expected in adults; however, any advantages of greater plasticity in the immature nervous system need to be balanced against the fact that development is not yet complete and must be completed with an injured brain. It follows that what must be meant by ‘full recovery’, in the context of paediatric ABI, is not just a return to pre-injury levels of function, but completion of development without prejudice. In very simplistic terms, motor function (‘walking’) is largely established by the start of formal schooling and language function (‘talking’) by the end of primary schooling, but important cognitive milestones (‘thinking’) continue to be established throughout adolescence, and indeed into the third decade of life. This is the basis for the common problem, particularly after TBI of ‘invisible'

injuries in children whose good motor recoveries belie the significance of their cognitive morbidity, which becomes steadily more evident with passing years. Under-recognition and non-attribution of late cognitive effects to prior TBI are a common problem (Forsyth 2010).

### Educational Provision

ABI often results in focal or multi-focal brain injury, reflected in ‘uneven’ cognitive profiles with areas of relatively specific weakness and islands of preserved ability. This may create an immediate challenge to return to school, for example, in the situation of a child with severe new problems with voluntary movement control (which would typically also involve speech production), but relatively preserved understanding and cognition. Many children with motor control impairments of similar severity that are of developmental origin (e.g. caused by severe CP) would typically also have severe learning difficulties; however, such a school environment may be totally unsuitable for an older ABI survivor with similar levels of motor impairment. Specialist AAC support is likely to be crucial in such situations. Expressive communication (making oneself understood) ultimately requires the ability to perform movements when wished (and to be relatively free of unintended occurrences of the same movement). AAC approaches rely on identifying the remaining voluntary movements that are most suitable for accessing switching devices to operate communication systems.

Immediately evident consequences of ABI may also include new sensory impairments of vision or hearing. The highly specific and sometimes bizarre sensory and cognitive impairments sometimes reported in adult case literature after an extremely localised stroke (e.g. affecting facial recognition or perception of movement, auditory perception of pitch or timing in sound or even changes in spoken accent) generally arise from perforator artery stroke as a result of atherosclerosis, and are very rare in children. Most educational and behavioural effects of ABI are in high-level cognitive functions and tend to emerge slowly over the years after injury. Particularly after TBI the inferomedial temporal and inferior frontal lobes structures are vulnerable as a result of their proximity to the bony floors of the middle and anterior cranial fossae. Injury to frontal lobes results in difficulties in executive function and socioemotional communication. The term ‘executive function’ is a shorthand for the large number of skills necessary for ‘taking responsibility for one’s own life’ – the self-direction and self-organisation of adulthood. The recognition of such difficulties is often delayed, because until mid- to late-adolescence the affected areas are developmentally silent. Thus, the effects of early injury to frontal lobe structures supporting executive function may remain latent until later adolescence, when expected maturation and manifestation of such abilities fail to occur.

Injury to hippocampal structures reduces new learning efficiency. As an oversimplification, knowledge and skills learned before injury remain largely intact, but children gradually fall behind in new learning (‘not making a year’s progress every year’). These nuances complicate the delivery of informed educational provision for children after an ABI, which is perhaps the single most effective rehabilitation intervention possible. They also complicate issues of appropriate assessment. Even if teaching staff suspect that a child’s problems relate to earlier ABI and request specialist psychological assessment, an uninformed assessment will miss the issues. Much educational assessment is performed on the basis of attainment of accrued abilities (e.g. in literacy and numeracy) over an entire educational career to date. In the case of recent injury, a large proportion of that educational career was completed with an uninjured brain; it will take many years of poorer-than-expected progress until this is reflected in a failure to have achieved age-related expectations. Assumption of a child’s ability to recognise commonalities between multiple examples and to generalise these to new examples is a basic pedagogical approach. Unfortunately, it is a frontal lobe skill that may be specifically impaired so having to explicitly teach this is an unfamiliar challenge to most teachers. Similarly, failure to appreciate the ways in which problems can emerge with time, late after injury, results in under-recognition. Regrettably, it is still all too common for the fact that an injury that occurred

**MANAGEMENT AND CARE**

**Educational Provision**

ABI often results in focal or multi-focal brain injury, reflected in ‘uneven’ cognitive profiles with areas of relatively specific weakness and islands of preserved ability. This may create an immediate challenge to return to school, for example, in the situation of a child with severe new problems with voluntary movement control (which would typically also involve speech production), but relatively preserved understanding and cognition. Many children with motor control impairments of similar severity that are of developmental origin (e.g. caused by severe CP) would typically also have severe learning difficulties; however, such a school environment may be totally unsuitable for an older ABI survivor with similar levels of motor impairment. Specialist AAC support is likely to be crucial in such situations. Expressive communication (making oneself understood) ultimately requires the ability to perform movements when wished (and to be relatively free of unintended occurrences of the same movement). AAC approaches rely on identifying the remaining voluntary movements that are most suitable for accessing switching devices to operate communication systems.

Immediately evident consequences of ABI may also include new sensory impairments of vision or hearing. The highly specific and sometimes bizarre sensory and cognitive impairments sometimes reported in adult case literature after an extremely localised stroke (e.g. affecting facial recognition or perception of movement, auditory perception of pitch or timing in sound or even changes in spoken accent) generally arise from perforator artery stroke as a result of atherosclerosis, and are very rare in children. Most educational and behavioural effects of ABI are in high-level cognitive functions and tend to emerge slowly over the years after injury. Particularly after TBI the inferomedial temporal and inferior frontal lobes structures are vulnerable as a result of their proximity to the bony floors of the middle and anterior cranial fossae. Injury to frontal lobes results in difficulties in executive function and socioemotional communication. The term ‘executive function’ is a shorthand for the large number of skills necessary for ‘taking responsibility for one’s own life’ – the self-direction and self-organisation of adulthood. The recognition of such difficulties is often delayed, because until mid- to late-adolescence the affected areas are developmentally silent. Thus, the effects of early injury to frontal lobe structures supporting executive function may remain latent until later adolescence, when expected maturation and manifestation of such abilities fail to occur.

Injury to hippocampal structures reduces new learning efficiency. As an oversimplification, knowledge and skills learned before injury remain largely intact, but children gradually fall behind in new learning (‘not making a year’s progress every year’). These nuances complicate the delivery of informed educational provision for children after an ABI, which is perhaps the single most effective rehabilitation intervention possible. They also complicate issues of appropriate assessment. Even if teaching staff suspect that a child’s problems relate to earlier ABI and request specialist psychological assessment, an uninformed assessment will miss the issues. Much educational assessment is performed on the basis of attainment of accrued abilities (e.g. in literacy and numeracy) over an entire educational career to date. In the case of recent injury, a large proportion of that educational career was completed with an uninjured brain; it will take many years of poorer-than-expected progress until this is reflected in a failure to have achieved age-related expectations. Assumption of a child’s ability to recognise commonalities between multiple examples and to generalise these to new examples is a basic pedagogical approach. Unfortunately, it is a frontal lobe skill that may be specifically impaired so having to explicitly teach this is an unfamiliar challenge to most teachers. Similarly, failure to appreciate the ways in which problems can emerge with time, late after injury, results in under-recognition. Regrettably, it is still all too common for the fact that an injury that occurred
while the child was at primary school may not even be conveyed to high school staff, on the basis that the child was thought to have ‘recovered’ and the incident is erroneously presumed to be closed. A great deal of information is available to inform the educational remediation of ABI: the challenge is to recognise what is being seen and to make this information available at the right time.

There are important links between executive functions and attention control. Attention control refers to the ability to optimally sustain attention, avoiding the twin extremes of distractibility and the less recognised, but equally disruptive, problem of perseveration or over-fixation on topics – so-called ‘secondary attention-deficit–hyperactivity activity (ADHD)’, that is, deficits of attention and concentration resulting from traumatic injury to the frontal lobes are common.

### Behavioural and Forensic Issues

Social–emotional communication is an important issue, particularly after TBI. Survivors struggle to recognise nuances of irony or sarcasm, misreading social situations and interpreting comments over-literally. They may also be unacceptably blunt and unreserved in expression of their own thoughts (Dennis 2010). Misinterpretation of a comment meant in jest, combined with impulsivity, may result in a physical over-reaction and escalation of a situation, for example possibly even resulting in involvement in the criminal justice system. A recent systematic review estimated the prevalence of past TBI in the offender population to be an astonishing 60% (Shiroma et al. 2010). The causes of this association are undoubtedly complex: children from socioeconomically deprived backgrounds are at greater risk of TBI, as are children with prior psychiatric morbidity such as ADHD (Max et al. 2004) so the occurrence of a TBI event and involvement with criminal justice systems may be independent effects of the same prior causes. However, the ‘coping style’ of the family to which a child returns after TBI is also an important, addressable mediator of late outcomes (Yeates et al. 1997). New educational difficulties may be another important, potentially preventable part of a collapse of self-esteem which may contribute to late behavioural problems.

There is much debate in the psychological literature about the relative value of attempts to retrain cognitive skills on an individual basis versus environmental optimisation (e.g. creating an informed school environment for the child). The evidence base in relation to cognitive restorative therapies is currently limited (Slomine and Locascio 2009). Trials show definite, if modest, effects but the extent to which these benefits generalise to daily function beyond the specific trait practised still has to be established. What is clear is that effective rehabilitation needs to be ecologically valid (i.e. delivered in meaningful contexts, such as school), and that appropriate peer contact is very effective in modelling and providing feedback in emotional and social competence.

### Treatment

The mainstays of support after ABI are the provision of an informed and optimised educational environment and an empowered family. Helping a family become informed partners in the rehabilitation of, and advocates for, their brain-injured child is highly effective. However, it is also important to plan ahead to the time when the ABI survivor becomes an adult, where the goal will be as much personal independence as possible; a rehabilitation and care package that ties a young person to the family home will not be in his or her long-term interest.

Expert neuropsychological assessment is a vital component of follow-up and support after ABI to allow the parsing of an often complex picture of strengths, and sometimes surprising weaknesses, into a consistent profile of impairments in attention, new learning, executive function, and any other specific sensory or cognitive deficits. Such an understanding is an essential precursor of educational provision.

Psychopharmacological treatment of attention deficit with stimulant medication (e.g. methylphenidate) may be important. Some authorities also advocate the use of carbamazepine and/or valproate for mood-stabilisation effects.

### POST-CONCUSSION SYNDROME AND MILD TRAUMATIC BRAIN INJURY

One in seven children will have post-concussion syndrome for 3 months or more after a mild TBI (Barlow et al. 2010). Post-concussion syndrome (PCS) is a symptom complex with a wide range of somatic, cognitive, sleep and affective features, and is the most common consequence of TBI (Blume and Hawash 2012) making it a significant public health issue because one in five children will sustain a TBI by the age of 16 years (Mckinlay et al. 2008). PCS is associated with significant disability in the child and for his and her family, and yet there are few evidence-based medical treatments available (Gagnon et al. 2005; Moran et al. 2012; Watanabe et al. 2012; Schneider et al. 2013). There is substantial controversy caused by a lack of consensus with regard to diagnostic criteria, the presence of symptoms seen commonly in the normal population, the contribution of sociological, psychological and medico-legal factors to outcomes, and, until recently, a failure to identify any abnormal pathophysiology (Meares et al. 2011).

The diagnostic criteria of the DSM-IV (APA 1994) are as follows: (1) history of TBI; (2) evidence from neurobehavioural testing of cognitive deficits in attention and/or memory; (c) three or more of the following symptoms that appear after injury and persist for 3 months or more: fatigue, headaches, dizziness, sleep disturbance, irritability, apathy or affective disturbance, or personality changes; with (4) symptoms in (2) and (3) starting or worsening after injury; (5) interference with social or occupational functioning; and
(6) symptoms that are not better explained by other mental disorders. The symptom onset must be contiguous with TBI, distinguishable from pre-existing conditions and of a minimum 3-month duration. In practice, the DSM-IV is usually modified because most physicians do not have access to neuropsychological testing, and in any case standard neuropsychological tests are usually normal by 3 months post-injury, even though patients continue to complain of cognitive deficits (Boake et al. 2005; CP Carroll et al. 2012). Furthermore, in our experience, cognitive deficit is not a universal complaint among children and adults with PCS. We have proposed a modified paediatric definition as follows: (1) a history of mild TBI with an onset of symptoms or signs within 72 hours of the injury; (2) the presence of at least three of the following: headache, dizziness, fatigue, irritability, insomnia, difficulty concentrating, memory problems, emotional lability and mood disturbance; (3) symptom duration for at least 4 weeks post-injury; and (4) symptoms that are not better explained by another disorder (Barlow 2016).

Epidemiology
The incidence of PCS varies according to the diagnostic criteria used, time post-injury, age, injury severity, presence of assault and the population studied. PCS incidence rates at 1 month post-injury vary between 24.5% and 52.5% in the A&E population follow-up (Barlow et al. 2010; Pickering et al. 2012). Symptom prevalence decays exponentially with time (Fig. 13.8).

Three months post-injury, 11% of all children and 14–29% of school-aged children remain symptomatic (Barlow et al. 2010; Babcock et al. 2013); 2% remain symptomatic at 1 year (Vanderploeg et al. 2005).

Predictors of Recovery
Many factors are important contributors to symptom persistence, including injury severity, previous TBI, and premorbid sociological and psychological factors, as well as the presence of medico-legal issues (e.g. litigation, assault). Improvements in research methodologies have enabled researchers to gain a better understanding of these factors at various time points in recovery (Satz et al. 1997; McNally et al. 2013).

Injury severity is a significant factor in predicting acute outcomes after mild TBI, that is, up to 3 months post-injury in A&E cohorts (Mittenberg et al. 1993; Barlow et al. 2010; HG Taylor et al. 2010a; McNally et al. 2013). Severity factors include loss of consciousness, amnesia, admission to hospital, degree of the acute symptoms and the presence of other injuries (Barlow et al. 2010; Babcock et al. 2013; McNally et al. 2013). Adolescents are more likely than younger children or adults to develop PCS (Barlow and Minns 2000; Babcock et al. 2013). No predictive genetic factors have been identified (Terrell et al. 2008; Moran et al. 2009; Smyth et al. 2014).

The relative contribution of injury factors to PCS decreases over time and premorbid factors become important factors influencing symptom persistence (McNally et al. 2013; Olsson et al. 2013; Brooks et al. 2014). Some 3–6 months post-injury, premorbid child and family factors, such as school difficulties, parental pre-injury anxiety, coping strategies, adverse life events and stressors, make increasing contributions to persistent PCS symptoms, and injury-related factors are less important. Children with lower IQs and premorbid learning difficulties such as attention-deficit disorder are more likely to be injured and are prone to PCS, perhaps due to differences in cognitive reserve capacity (Fay et al. 2010). Thus, when evaluating and treating children with persistent PCS, clinicians should pay close attention to factors that may elicit symptoms for reasons other than an underlying brain injury (Kirkwood et al. 2008).

Controversies
PCS has been a highly debated and questioned entity for several reasons, including absence of symptom specificity, premorbid influences on outcome, recall bias, and the influence of sociological and psychological factors. The symptoms of PCS are not specific to PCS alone but are present in populations with and without disease (e.g. depression, chronic pain, anxiety) (Chan 2001; Iverson and Lange 2003; Fear et al.
Pathophysiology of PCS

There are relatively few neuroimaging studies to provide insight into the pathophysiology of PCS in children. Conventional MRI is usually normal acutely (80–90% of MR images in acute mild TBI) and almost all conventional MR images are normal in PCS. However, special imaging techniques are beginning to provide objective evidence of cerebral dysfunction. Diffusion tensor imaging (DTI) may reveal abnormalities that correlate with PCS symptoms and cognitive outcome (Wozniak et al. 2007). Common sites of DTI abnormalities are in the corpus callosum, frontal white matter and internal capsule (Henry et al. 2011; Wilde et al. 2011; Shenton et al. 2012). Children and young adults show increased activation of multiple cortical networks during working memory or spatial memory functional MRI tasks, even though the performance on the task is similar to that of a comparison group (Slobounov et al. 2010; Krivitzky et al. 2011; Wilde et al. 2011). This suggests decreased cortical network efficiency and may explain why children with PCS are so fatigued after a full day of school and complain that it is harder to perform cognitive tasks. Transcranial magnetic stimulation (TMS) can measure discrete cortical functional areas, offering non-invasive, painless mapping of motor systems. TMS has demonstrated evidence of acute and long-term cortical excitability in the primary motor cortex neurophysiology (Chistyakov et al. 1998, 2001; De Beaumont et al. 2009).

Clinical Assessment of PCS

A comprehensive assessment is necessary to evaluate a child with PCS and it should pay particular attention to risk factors for poor recovery and mimics of PCS. The differential diagnosis includes headache disorder, cervical injury, anxiety, depression, somatisation, cervical injury, vestibular dysfunction and visual dysfunction.

The history and examination should assess the following:

• Pre-injury details including factors indicating severity of injury, presence of litigation and mechanism of injury (e.g. high velocity/energy insult, elite athlete, assault)
• Medication use (screening for medication overuse), alternative therapies, use of other substances, for example, marijuana
• Current activity, for example, type and amount of exercise especially weight training and boxing
• Past medical history, for example, migraine, exercise-induced headaches, previous concussion and time taken to recover
• Pre-existing traits or disorders, for example, anxiety, depression, current learning difficulties and/or attention deficits
• Family history, for example, migraine, hemiplegic migraine, depression, anxiety
• Psychosocial history, for example, recent stressors such as loss of a family member or friend, change of school, conflicts with friends/family
• Evidence to support cervicogenic headache
• Vestibular dysfunction (using the head impulse test, Dix–Hallpike manoeuvre or a dynamic visual acuity deficit) and balance abnormalities.

Questionnaires to explore current symptoms as well as function are very useful, for example, Post Concussion Symptom Scale (Lovell and Collins 1998) and Rivermead Post Concussion Questionnaire (Eyres et al. 2005). A quality-of-life measure, for example, PedsQL (Zonfrillo et al. 2014), can also be useful to assess overall function. Other useful tools include a headache diary, and questionnaires to explore mood, anxiety and sleep dysfunction.

Investigations do not play a large role in PCS. Laboratory investigations should be considered where there is concern for endocrine dysfunction. After 2–3 months, hypersomnia is unusual and raises concerns for other medical disorders (e.g. hypothyroidism, anaemia, depression, idiopathic hypersomnia). Neuroimaging is generally not warranted. Specialised clinics may offer dynamic balance assessments as well as computerised assessments of vestibular and cognitive function, but their use in persistent symptoms has not been validated.

Management of PCS

PCS is managed somewhat differently from the acute and subacute phases after mild TBI. Rather than a focus on rest, it switches to strategies to improve general functioning, increase ADL and return the child to school. This is done in a graduated fashion, supporting the child/adolescent in his or her environment. Prolonged absence from school is not recommended and should not be longer than 2–4 weeks because this often leads to more problems when the child becomes isolated from his or her peers and loses self-confidence. Often adolescents need significant reassurance and encouragement in this process, especially when their symptoms have been present for several months.

Once the clinician has a clear understanding of the various factors contributing to symptom persistence, it is advisable to address one or two of the most problematic symptoms, and the other symptoms will often improve. Participation in school and social activities should be encouraged while this occurs. Referral to a specialist should be made for children with persistent vertigo and balance problems, or
persistent visual complaints. Peripheral vestibular dysfunction should be treated with specialised physiotherapy initially; migrainous vertigo may be treated with prophylactic agents for migraine (Alsalheen et al. 2010; Schneider et al. 2013). Convergence insufficiency and persistent reading dysfunction may respond to oculomotor neurorehabilitation (Thiagarajan et al. 2014). The most common problems are, however, usually sleep disturbance, headaches, and cognitive and mood disturbances. Addressing sleep disturbance is usually the first step. As sleep improves, children find it easier to cope at school and often the mood disturbance will also improve.

Sleep Disturbance

Although sleep problems are a major concern for children and their parents, there are few studies exploring this (Blinman et al. 2009; Chaput et al. 2009; Schatz et al. 2011). Persistent PCS sleep disturbance is associated with lower sleep efficiency, more wake time and more nocturnal awakenings when assessed using polysomnography (Kaufman et al. 2001). The pathogenesis for sleep disturbance is multifactorial and correlates with increased abnormalities on MRI (Datta et al. 2009; Yaeger et al. 2014). The clinician should always examine other factors that affect sleep including sleep hygiene, pain, anxiety and depression (Gosselin et al. 2010). Medications that interfere with sleep (especially those used to treat any concomitant attention problems) should be examined, as well as the use of illicit substances and caffeine.

Mood Disturbances Following TBI

A range of psychiatric problems can be seen after TBI in children, including anxiety, depression, personality change disorder, post-traumatic stress disorder, ADHD and substance abuse. Mood disturbance is common after any traumatic injury in the first few weeks (Mainwaring et al. 2010), and occurs in up to 36% of children with mild TBI within 6 months of injury. A multidisciplinary team including a psychiatrist is necessary to manage severe depression or anxiety in childhood after mild TBI. Any sleep and pain disorders should be concurrently managed and should not delay psychiatric treatment.

COGNITIVE DIFFICULTIES FOLLOWING TBI

Whether neuropsychological impairment can persist in paediatric mild TBI is still debated. Satz et al. (1997) found no adverse effects on academic–psychosocial outcome across the spectrum of mild TBI in a comprehensive systematic review. However, children who sustain complicated mild TBI may have subtle deficits on long-term follow-up (Babikian et al. 2011). In clinical practice, where the baseline neuropsychological function is not available, the value of neuropsychological testing is unknown. Neuropsychological evaluation is useful for identifying pre-existing learning difficulties and attention problems that were ‘unmasked’ by a mild TBI. Although there is currently little evidence to support the use of stimulants for secondary attention deficits, a trial of stimulants is probably warranted. Drugs such as memantine are not warranted in PCS (especially outside a clinical trial), given the good long-term prognosis.

Return to School

Supporting children as they return to school, regardless of the time post-injury, is key. Parents and adolescents should be encouraged to talk to the school before their child returns and an individual educational plan should be developed. Where possible, exemptions should be made so that the student does not have to ‘catch up’ on all assignments or work missed, but instead priority projects or key areas should be identified. Exemption from examinations and tests should be made during the first phase of return to school, and accommodations such as a quiet environment for taking tests should be arranged. A gradual return to full participation is recommended. Sometimes psychological support is necessary during this time, especially if plans for graduation or university hopes have to be put on hold.

In summary, PCS is a complex disorder involving somatic, mood, cognitive and sleep difficulties. The reasons for persistent symptoms vary considerably among children. The TBI is the initial insult, but many pre-existing or environmental factors influence outcome. Early reassurance is a key part of the rehabilitation process and problematic symptoms should be treated promptly, paying particular attention to sleep, headaches and mood disturbance. Most of these problems will respond well to targeted management strategies.

SPINAL CORD INJURY

Epidemiology

The four main causes of acute paraplegia are as follows: trauma (both non-penetrating mechanisms such as diving into shallow water and penetrating injury typically due to gunshot); vascular (including anterior spinal artery syndrome); inflammatory processes (primary infection, and parainfectious processes such as transverse myelitis and acute disseminated encephalomyelitis); and compression caused by tumours, vertebral disc disease, abscesses or syringomyelia. Tumours and other space-occupying lesions may be intrinsic (arising from the cord substance) or more commonly, extrinsic. Compression resulting from expansion of a paraspinal neuroblastoma through a vertebral foramen is an important cause. Syringomyelia (expansion of the central canal) typically causes a slowly evolving deficit, although it may occur suddenly after...
a cough or the Valsalva manoeuvre (e.g. straining at stool), particularly as a secondary complication of other spinal disease. It is thus an important, potentially reversible cause of further spinal cord injury which requires a high index of suspicion and prompt recognition. The earliest clinical sign of expansion of the central canal is isolated involvement of spinohalamic fibres that cross just anterior, resulting in specific loss of pain and temperature sensation at the affected level, which must therefore be specifically tested for if this is a concern. Anterior spinal artery thrombosis is a relatively important cause of apparently spontaneous, acute-onset paraplegia (in the absence of trauma). The anterior spinal artery, running down the ventral (anterior) aspect of the cord, supplies the ventral two-thirds of the cord. As it descends from the vertebral arteries it is supplemented by a variable arrangement of ‘feeder arteries’. Acute infarction reflects this rather precarious blood supply. Onset is typically spontaneous, over minutes and usually has a very poor prognosis (Sharpe and Forsyth 2013). The sparing of the dorsal parts of the cord (which has a separate blood supply) results in the classic clinical picture of paralysis and loss of spinohalamic modality sensation below that level, with preservation of dorsal column sensation.

The annual incidence of spinal cord injury (SCI) in adults is estimated at between ten and 83 per million population with an estimated prevalence of approximately 200–700 per million living with the consequences of SCI at any time (Wyndaele and Wyndaele 2006). Incidence peaks between the ages of 15 and 30 years with a male excess caused by traumatic SCI sustained in road traffic accidents. A second incidence peak in elderly people is the result of falls, tumour compression, spinal stenosis and vascular ischaemia.

Paediatric paraplegia is more rare and less well described in what is a largely aetiology-specific literature. A national cohort study from Taiwan estimated an incidence specifically of traumatic SCI in those aged <18 years of 5.99 per 100,000 children aged <16 per annum. This is a tenth of the incidence reported by Chien et al. (2012) for trauma alone, but the difference may be partially explained by inclusion of 17- and 18-year-olds in the latter study. In the Sharpe study the aetiology was inflammatory in 67%, oncological in 27%, traumatic in 11% and vascular in 9%.

**OUTCOME**

In adult traumatic SCI, complete injury (of both sensory and motor systems) accounts for approximately 50% of cases and is associated with a poorer prognosis and increased mortality. Cervical cord injury is associated with a better functional recovery than thoracic cord injury, although this may be a reflection of an association between thoracic injury and more severe trauma involving cardiopulmonary dysfunction and impaired perfusion of the spinal cord. Some evidence suggests that children may be capable of better neurological recovery from SCI than adults. This may reflect more clear-cut benefits of greater plasticity in the young spinal cord than the immature brain but adult comorbidities such as hypertension and diabetes mellitus probably also impede recovery. However, it is known that very young children tolerate SCI poorly (Schottler et al. 2012). The complications of SCI, including urinary dysfunction, spasticity, pain syndromes, respiratory insufficiency and psychological sequelae, are especially challenging for children and adolescents, and children who suffer injury before their growth spurt are at an increased risk of developing scoliosis.

A large component of the eventual recovery is seen within the first 3 months, although very slight improvement can continue for up to 18 months (Fawcett et al. 2007). As for adults, prognosis for recovery in children is associated with neurological status at presentation, with better recoveries seen in those with incomplete injuries (Schottler et al. 2012). In the de Goede et al. (2010) study of non-traumatic, non-compressive SCI, complete recovery occurred in >50% of children and fair/poor recovery occurred in >25%. A better prognosis was associated with being aged <10 years, injury at a lumbar spinal level and preceding infection. A worse prognosis was associated with leg flaccidity, urinary incontinence and rapid onset (within 12 hours). In the Sharpe population-based study by Sharpe and Forsyth (2013) of SCI of any cause, 66% made good recoveries with fully or almost independent walking. Bladder involvement at presentation was a poor prognostic sign. Recovery from extrinsic compression is typically good so long as it is promptly recognised and decompressed. Inflammatory lesions usually make reasonable but rarely complete recovery. Vascular injuries (particularly anterior spinal artery syndrome) and severe trauma have the worst prognoses.

**MANAGEMENT ISSUES**

**Emergency Management**

The assessment of a child who has suddenly stopped walking is a neurological–neurosurgical emergency, primarily because of the need to identify and promptly treat spinal cord compression (either medically with steroids or by surgical decompression). The differential diagnosis of this presentation is wide. An important starting point is the distinction of the
child who genuinely cannot walk (due to weakness) from the child who is reluctant to walk because of pain or anxiety (e.g. fear of falling due to araxia). This will require persistence and cajoling.

In children who are genuinely and flaccidly weak, the main differentials are acute inflammatory demyelinating neuropathy (AIDP, Guillain–Barre syndrome) and spinal cord dysfunction. In one study, the two most common causes of acute flaccid paralysis were AIDP (47%) and transverse myelitis (19%) (Morris et al. 2003). Pointers to spinal pathology include back pain (compare leg pain, which commonly accompanies AIDP), the presence of injury at a sensory or motor level, urinary symptoms (frequency, dribbling, retention or priapism) and the absence of cranial nerve signs. Children with AIDP are usually totally areflexic, particularly distally. Urgent MRI (ideally of the brain and spine at one sitting, because of the potential for parasagittal lesions to cause a paraplegia) should be performed if there is any clinical possibility of acute spinal pathology. If imaging shows extrinsic compression then emergency paediatric neurosurgical advice should be sought with a specialist opinion to decompress the spinal cord. MRI demonstration of inflammatory change may reflect vascular or infectious/parainfectious processes. Traumatic injury to the spine can result in remarkably normal cord appearances, an entity known as spinal cord injury without radiological abnormality (SCIWORA).

Medical treatment of cord oedema with high-dose methylprednisolone (e.g. 30mg/kg to a maximum of 1g, followed by infusion of 5mg/kg per hour for up to 18 hours) is widespread. There is some class I evidence to support this in the context of adult traumatic SCI (Bracken 2012). As well as possible decompression, an urgent neurosurgical opinion on the stabiility of the vertebral column should be sought, particularly in the case of traumatic SCI, and temporary immobilisation (e.g. with ‘halo’ traction or other devices) may be required in the short term.

**Early General Management**

High lesions may require ventilatory support. Children require bladder catheterisation and aggressive management of constipation. Early splinting programmes should be instituted to prevent development of contractures (particularly loss of foot dorsiflexion).

**Autonomic Dysreflexia**

This is an important and characteristic feature of complete SCIs above T6. Noxious stimuli below this level (as trivial as a full bladder or constipation, of which the child has no subjective awareness) lead to increased reflex sympathetic activity in the disconnected lower cord, vasoconstriction and sometimes dangerously severe hypertension. This is sensed by the CNS above the lesion, resulting in increased vagal tone and bradycardia, which can be severe. Above the lesion, vasodilatation results in pounding headache, sweating and red blotches on the skin. Emergency treatment involves the relief of the cause (e.g. catheter blockage) and sitting upright. Extreme care must be taken in administering enemas and other potentially noxious stimuli below the level of the lesion.

**Longer-Term Management**

Many longer-term management issues are shared with children with spina bifida, and these clinics (if available) may be best suited to meet the needs of a child with an acquired paraplegia. Motor morbidity may include weakness, spasticity, and the presence of peripheral contractors. Any effect of these on posture must be aggressively managed, with the use of specialist seating if necessary, to prevent late development of scoliosis particularly in children injured before puberty. Some spasticity of the legs may be helpful in so far as it results in the ability to weight-bear and assist with transfers. However, severe spasticity can result in distressing spasms and intrathecal baclofen pumps can be particularly effective in this group. Skin integrity can be jeopardised by impaired sensation; much as in diabetic neuropathy, pressure sores can result from inadequate nursing care and failure to turn regularly. Likewise, ill-fitting footwear or splints can result in breakdown over pressure areas in anaesthetic skin.

Bowel continence can usually be achieved by use of suppository or enema regimens to effect bowel evacuation at appropriate times. Urinary continence is commonly achieved using clean intermittent catheterisation (which results in a much lower urinary infection rate than permanent urethral catheterisation); however, specialist urological input is required to ensure that the urinary system is ‘safe’, that is, that there is no risk of chronic renal impairment developing as a result of obstructive uropathy.

Psychological support is vital, particularly for young people sustaining an SCI in adolescence. Depression and self-harm are well recognised in adolescents and adults. Sexual function is an important issue in adults.

This chapter begins with an account of the clinical features and management of raised intracranial pressure ([ICP] see also Chapter 7) and cerebral oedema before proceeding to consider brain tumours, other intracranial space-occupying lesions, spinal cord lesions and central nervous system (CNS) complications of leukaemia and lymphomas. It concludes with a discussion of pseudotumour cerebri syndrome (PTSC) also known as idiopathic intracranial hypertension.

CLINICAL FEATURES AND MIMICS OF INTRACRANIAL HYPERTENSION

Early Clinical Features

Headache is the most common symptom of intracranial hypertension. Although it may be intense and relieved by vomiting, it is more often mild and may be intermittent and/or relieved by commonly used analgesic agents. Headaches may awaken patients at night or be present on arising but these features are only present in a minority of cases. Persistent headache, especially if it occurs in the morning, must always be considered carefully. Morning headaches associate with raised ICP characteristically recur repeatedly and may be associated with lethargy or general malaise. Headaches with these associated symptoms are ‘red flags’ indicating an increased likelihood of an underlying space-occupying lesion (Wilne et al. 2006).

Vomiting is the second most common symptom of raised ICP. It is usually but not always associated with headaches, even in the case of posterior fossa tumours. Vomiting due to raised ICP is usually unremarkable except by its repetition and persistence and by its frequent morning occurrence. Changes in behaviour and personality are commonly an early manifestation of raised ICP. Irritability or lethargy is especially of concern when associated with vomiting and headache. It is important to ask about educational and/or behavioural difficulties as changes may be a feature of intracranial hypertension (Wilne et al. 2007).

Papilloedema (Fig. 14.1) although a major sign is absent in at least half the children with brain tumours, especially supratentorial tumours. The presence of papilloedema makes an intracranial mass highly probable, but its absence in no way excludes such a diagnosis. Papilloedema should be distinguished from pseudo-papilloedema, a congenital anomaly consisting of excessive gial proliferation at the disk margins, and from drusen of the optic nerve head, which, in children, are usually buried within the disk and produce elevation.
of the nerve head. In such cases there is no vascular congestion or vessel tortuosity and similar abnormalities are sometimes apparent on fundoscopy of a parent. In difficult cases, ultrasound examination (B scanning) may be useful. Fluorescein fundus angiography is a further investigation that will only rarely be needed. In papilloedema (and not in congenital disc anomalies), it showing a proliferation of the capillary network, exudation of fluorescein out of the vessels and persistence of fluorescence at the disk margins.

Papilloedema is, of course, not specific for brain tumours and can be present with increased ICP of other causes as well as in certain conditions in which ICP is usually not elevated, such as polyradiculoneuritis. Papilloedema should be distinguished from the papillitis of optic neuritis. In the former condition, constriction of the visual fields is classically seen whereas in the latter, blindness or scotoma and eye pain are more common.

Less commonly, raised ICP may present with diplopia due to paralysis of the VIth cranial nerve, which may be unilateral or bilateral and may fluctuate. The specific clinical manifestations of intracranial tumours are considered further in later sections of this chapter.

Later Clinical Features including those of Brain Herniation

Raised ICP from tumours, hydrocephalus or other causes is dangerous because it leads to reduction of cerebral blood flow, particularly when cerebral perfusion pressure (the difference between mean arterial pressure and ICP) falls to below 40mmHg and its homeostasis fails. Reduced cerebral blood flow can be responsible for lethargy, coma, and a number of autonomic manifestations generally attributed to brain herniation or ‘coning’. Such manifestations may occur only transiently during the ‘plateau waves’ of ICP and disappear with a decrease in intracranial pressure. Relative hypertension and bradycardia (adjusted for the patient’s age) in an awake and seemingly well patient can be features of critically raised ICP. Prompt investigation and treatment is important.

Mass movements of the brain as a result of asymmetrical or unequal expansion of one brain compartment due to the presence of a mass lesion can produce herniation of the cerebellar tonsils or brainstem through the foramen magnum or of the uncus hippocampi through the tentorial opening. Both types of herniation may induce secondary brainstem dysfunction, by direct compression against the tentorium or by stretching brainstem vessels. Brainstem dysfunction can occur with global downward movement of the brain substance without lateral herniation. This central syndrome of rostro-caudal deterioration is common with bilateral supratentorial masses. It results in progressive functional impairment, involving in succession the diencephalon, the midbrain and upper pons, the lower pons/upper medulla, and finally the medulla, with eventual death. Brain displacements can be demonstrated by magnetic resonance imaging (MRI) (Johnson et al. 2002), and there is a correlation between the magnitude of displacements and the patient’s level of consciousness. Lateral displacement of the brainstem with uncal herniation is more frequent with unilateral masses. The importance of downward displacements is, however, not clear. Herniation is a late phenomenon and the clinical phenomena attributed to herniation may remain reversible for relatively long periods.

Herniations also produce localised signs, especially compression of the IIIrd cranial nerve by the uncus against the tentorial edge with unilateral pupillary dilatation. Often there is compression of the posterior cerebral artery with occipital infarction. Paralysis of the most caudal pairs of cranial nerves may occur with foramen magnum herniation, which can also be responsible for neck stiffness in children with posterior fossa tumours. Stiffness may be paroxysmal and associated with a rigid extension of the body, the so-called cerebellar fit of Jackson. This is often mistaken for a seizure. A lesser degree of chronic herniation may account for the torticollis that is seen in children with posterior fossa tumours.

Symptoms and signs of very high ICP threatening brain perfusion, including those of herniation, are an indication of imminent danger and require emergency treatment (see below).

CEREBRAL OEDEMA

Definition and Clinical Features

Cerebral oedema is defined as an increase in brain volume due to an increase in its water content. Oedema is an important cause of raised ICP. However, localised oedema need not produce intracranial hypertension but may result in focal brain dysfunction.

The diagnosis of brain oedema may be difficult. The clinical manifestations are those of raised ICP and differentiation of brain oedema from cerebral congestion, i.e. increase of cerebral blood volume, may be difficult. Increased blood volume may be caused by epileptic activity, vasoparalysis resulting from asphyxia, head injury, increase in CO₂ content of blood associated with pulmonary or heart disease, venous obstruction, and the effects of drugs such as nitrates, chlorpromazine or halothane.

Cerebral oedema can be detected by imaging. Computed tomography (CT) may show diffuse or localised low attenuation as a result of high water content. On MRI, oedema often presents with intense signal on T2-weighted spin−echo sequences. Diffusion-weighted MRI and diffusion tensor MRI, which allow more precise study of water content and mobility, can give information on the location of oedema in relation to the various cell compartments and be useful for therapeutic orientation (Lu et al. 2004; Sinha et al. 2004). Oedema may be an isolated finding, for example, in patients with diabetic ketoacidosis or following unilateral or focal status epilepticus. It is frequently associated with other entities such as brain tumours and cerebral abscesses.

The symptoms and signs of cerebral oedema are often difficult to separate from those of its causal lesion. The major
consequence of brain oedema is to reduce brain perfusion and produce ischaemia. For this reason the presence of brain oedema, whether in association with other lesions or in isolation, has an important bearing on the understanding and management of the clinical picture.

Types and Causes of Brain Oedema

Cerebral oedema can belong to several types depending on its location and pathogenesis, and each category of oedema is preferentially associated with certain causes.

Vasogenic oedema results from increased permeability of the endothelium of capillaries of the blood–brain barrier, leading to the exudation of protein-rich plasma filtrate into the extracellular fluid. This type of oedema involves most markedly the cerebral white matter in a focal or generalised distribution. Vasogenic oedema is caused by inflammatory processes such as meningitis or abscesses; by brain tumours; by focal lesions that produce an inflammatory response by various mechanisms, such as intracerebral haemorrhages or infarcts; and by disorders that primarily affect the cerebral vessels, such as lead encephalopathy or hypertensive encephalopathy. Oedema that appears in the hours following head trauma probably belongs to this type, as seems also to be the case with focal oedema following partial complex status epilepticus, although, in both cases, more than one cause and one mechanism may be operative. Treatment with corticosteroids is effective only in this type of oedema.

Cytotoxic oedema may coexist with vasogenic oedema. In this type, cellular constituents of the brain, especially astrocytes but also neurons and endothelial cells, undergo rapid swelling as a consequence of dysfunction of the membranes and ionic pumps. The latter is usually due to energy failure and may lead to cellular death, in which case the oedema is irreversible. Hyoxia due to cardiac arrest or to any cause of hypoxic–ischaemic encephalopathy is the most frequent cause, but various toxins and severe infectious processes, and increased ICP itself with decreasing cerebral blood flow, are possible causes. Other mechanisms include neuronal death following status epilepticus and infarction of arterial origin.

Hypotonic oedema is a consequence of osmotic dysregulation between a low osmolality plasma compartment and the higher osmotic pressure of glial cells. Water accumulates within astrocytes. Such occurs with hyponatraemia whether iatrogenic or due to inappropriate antidiuretic hormone (ADH) secretion, in patients with diabetes mellitus during treatment of ketoacidosis, and with the dysregulation syndrome of patients undergoing dialysis for renal failure or other reasons.

Interstitial oedema is caused by the transepipendymal resorption of cerebrospinal fluid (CSF) from the ventricles into the extracellular space in patients with hydrocephalus. This type of oedema is clearly shown by CT or MRI, which demonstrate areas of decreased attenuation in a periventricular distribution, especially around the anterior and posterior horns of the ventricles.

Hydrostatic oedema results when increased intravascular pressure is transmitted to the capillary bed because of a lack of compensatory increase in the vascular resistance, with resulting outpouring of water into the extracellular space. Such an event occurs when the complex mechanisms of brain vascular autoregulation fail.

Intramyelinic oedema is less common. It has been observed mainly following intoxication, for example, with triethyltin and hexachlorophene. The oedema is located between myelin lamellae forming intramyelinic ‘bubbles’. This type of oedema is always diffuse in distribution, involves mainly the white matter, and may affect the spinal cord.

Management of Raised Intracranial Pressure

Raised ICP is a major problem in patients with brain tumours and other expansive lesions, and also in several acute pathological situations such as trauma, brain infections or ischaemia. It is responsible for many complications including mass displacements of the brain and herniation, so its early recognition and treatment are essential. The symptoms and signs that herald impending life-threatening complications are listed in Table 14.1. These are usually attributed to herniation, but high ICP with resulting decrease in cerebral blood flow
should be stressed, however, that it is certainly more important to treat urgently any underlying cause, such as meningitis, than to insert an ICP monitor. Reversal of flow throughout the diastole on Doppler study is usually seen when cerebral perfusion pressure approaches zero, while EEG slowing and low amplitude are correlated with poor perfusion of the brain.

The treatment of raised ICP, irrespective of its cause, includes meticulous avoidance of all factors, such as painful stimuli, which may transiently increase ICP. Crystalloid fluids should be restricted to approximately 60–70% of the age-appropriate requirements, and hypo-osmolar fluids avoided. An adequate circulation must be quickly restored, if necessary with volume expanders and vasopressor agents such as dopamine (10–20µg/kg/min) and then maintained with lower doses (2µg/kg/min) as required. Control of seizures, which increase secondary deterioration, should be vigorously pursued.

It is probably reasonable to administer mannitol (0.25–2mg/kg in 20% solution) as a bolus over 10–15 minutes as an emergency measure temporarily to relieve a spike of raised ICP while other, more sustainable, interventions are initiated. Higher doses have been advised by some (Cruz et al. 2004). Its peak action occurs within 30 minutes and its effect may last from 2 to 6 hours but prolonged use may be associated with rebound intracranial hypertension and aggravation of vasogenic oedema. The use of occasional small (0.25mg/kg) doses in response to acute rises of ICP therefore tends to be preferred to regular doses without ICP monitoring.

Hyperventilation produces cerebral vasoconstriction and decreases cerebral blood volume at least initially. The effect of prolonged hyperventilation is controversial as the vasoconstrictive effect may disappear; haemodynamic responses in the unconscious patient are often altered so that a decrease of CO₂ may be associated with increased cerebral blood flow. Hyperventilation to obtain a PCO₂ less than 25mmHg (3.3kPa) may nevertheless be associated with brain ischaemia even when compensatory mechanisms reduce or suppress this effect and a target arterial PCO₂ pressure level of 5.5kPa is a widely accepted compromise.

Steroids are mainly useful for treatment of the perifocal oedema of tumours or abscesses. Dexamethasone is commonly used. The drug is generally given intravenously at a dose of 0.1–0.25mg/kg body weight initially and may be continued parenterally or orally in a total dose of 0.25–0.5mg/kg/day in four divided doses (Han and Sun 2002). High-dose pulses may be more effective.

Barbiturate coma is not indicated, except perhaps in intractable cranial hypertension and in raised ICP due to status epilepticus. The alleged protective effect of barbiturates on the brain has not been confirmed. Thiopentone is often used in doses of 3–5mg/kg over 10–20 minutes, followed by infusions of 1–2mg/kg at intervals of 1 or 2 hours. This agent seriously interferes with EEG monitoring of cerebral function.

Hypothermia is still used by some clinicians but its role is disputed. External diversion of CSF may be useful for certain neurosurgical patients. Surgical decompression is an exceptional life-saving measure the indications for which are very few.

may be responsible and regression of the symptoms with lowering of pressure can often be obtained.

In chronic situations such as brain tumours, treatment of the cause (removal of mass) is usually sufficient. In acute situations, however, treatment of the cause, although required, may not be sufficient. The most common causes of acutely raised ICP are shown in Table 14.2. For such cases, immediate lowering of ICP is often essential and may dramatically improve the outcome.

The goal of treatment is to reduce ICP to keep cerebral perfusion pressure above 50mmHg to ensure adequate oxygenation of the brain. Since cerebral perfusion pressure equals the difference between mean arterial pressure and ICP, the maintenance of systemic blood pressure is crucially important. ICP can be determined in various ways but a single measure is of little value to guide management. For this reason, continuous ICP monitoring has gained increasing acceptance. It should be stressed, however, that it is certainly more important
Chapter 14  Tumours of the Central Nervous System, Other Space-Occupying Lesions and Pseudotumour Cerebri

FREQUENCY AND AETIOLOGICAL FACTORS OF CNS TUMOURS

Tumours of the CNS are the second most common malignancy of childhood after leukaemia, accounting for 20% of all childhood malignancies. The overall population incidence of intracranial neoplasms varies between one and three per 100,000 in different series (see Baldwin and Preston-Martin 2004). However, the incidence rises to 5.42 per 100,000 for children and adolescents aged 0–19 years of age when benign tumours are included (Ostrom et al. 2014). Approximately 10% of tumours occur in children under 2 years of age, 20% between 2 and 5 years, 25% between 3 and 10 years, and 45% between 10 and 19 years. Overall, supratentorial tumours account for about half the cases (Ostrom et al. 2014) (Fig. 14.2a, b), but their location varies with age. In infants, there is a predominance of supratentorial tumours (especially astrocytomas) over infratentorial neoplasms, (mainly medulloblastomas and ependymomas). In children older than 4 years, infratentorial tumours (mostly cerebellar astrocytomas, medulloblastomas and ependymomas) are the most frequent.

Low grade gliomas represent 40% of all childhood brain tumours and are the commonest solid tumour of childhood requiring active management. Most are sporadic, arising within a single location including hypothalamus, chiasm, optic nerves, cerebellum, cerebral cortex, brainstem and spinal cord, with metastatic dissemination in fewer than 10%. Up to 15% are associated with neurofibromatosis type 1 (NF1). Hypothalamic chiasmatic low grade gliomas most commonly present in the first 2 years of life, the younger the patient, the larger the tumour. Low grade gliomas may occur at any age in childhood in the cerebellum but tend to occur in later childhood in the cerebral cortex, brainstem and spinal cord and this is also true for NF1-associated tumours (Guillamo et al. 2003).

The reasons for the changing age distribution of supratentorial and infratentorial tumours, for the predominance of midline tumours in children compared to adults, the predominance of ventricular tumours and for the predominance of neuro-ectodermal neoplasms in childhood are poorly understood (Bunin 2004). It is becoming increasingly clear that specific genetic mutations in each of the tumour types are associated with anatomical locations as well as the specific tumour type. This regional determination of genetic mutation underlines the anatomical determinant of embryological development that is presumably disordered in tumours that develop within specific regions of the brain during early life (Gibson et al. 2010; Jones et al. 2013; Pajtler et al. 2015).

Genetic Factors

Understanding of the genetics of brain tumours has evolved rapidly over the last 20 years and this is reflected in the appearance for the first time of genetic criteria alongside histological criteria in the classification of tumours of the CNS published by the World Health Organization (WHO) in 2016 (Louis et al. 2016).

From the cytogenetic point of view, the development of cancer is a multistep process in which some cells acquire a series of genetic insults that disrupt their normal development and fate as a result of dysfunction of oncogenes, tumour suppressor genes and stability genes (Vogelstein and Kinzler 2004; Gilbertson 2005). It has long been known that the cells of many tumours contain acquired chromosomal abnormalities that result apparently from new mutations (e.g. deletions of certain chromosomes or part thereof) as they do not exist in the cells of other organs. Such chromosomal abnormalities (e.g. abnormalities of chromosome 22 in acoustic schwannomas) are frequently present in other tumour cells; for example, deletions of 10q, 11 and 17p in medulloblastoma, and deletions of 1p and 19q in certain oligodendrogliomas. Interestingly, these anomalies may differ among different cases of a same tumour type and these differences have a prognostic significance; for example, the presence of the p53 gene (Sung et al. 2000; Pollack et al. 2001) or the amplification of the MYC gene in neuroblastoma.

Molecular genetic studies (Gilbertson 2005) that resulted from the discovery of these chromosomal aberrations have led to breakthroughs in the understanding of the biology of tumours. Some genes have the property of opposing or slowing down their development (tumour suppressor genes or anti-oncogenes), some stabilise signalling pathways, while others favour their growth (oncogenes) or predispose to certain types of cancer.

The mechanisms are illustrated by the case of the retinoblastoma, a retinal neoplasm that usually develops in young children below 4 years of age and often metastasises to the CNS. Retinoblastoma is familial in 40% of cases because of a heritable predisposition to this tumour and others (e.g. osteosarcoma) and sporadic in the remaining 60%. Hereditary predisposition is determined by mutations at a locus within the q14 band of chromosome 13 and sporadic cases have somatic mutations at the same genetic locus. The gene for sensitivity to retinoblastoma normally functions as a dominant suppressor of tumour formation and this function has to be lost in both homologous alleles for a retinoblastoma to develop. In persons who have inherited a genetic mutation, a second, somatic mutation is sufficient to lead to clinical disease (‘two-hit’ hypothesis), whereas two somatic mutations are required for non-genetic cases, a much less likely event.

The genetic characterisation of childhood brain tumour types has been the focus of intensive recent remarkable collaborations by research consortia that share samples and investigative strategies. Examples of the resulting practical consequences are described in the sections that follow relating to particular tumour types and include major revisions of
Figure 14.2a  Distribution in children and adolescents (ages 0–19) of primary brain and central nervous system tumours by site ($n=22,535$), Central Brain Tumor Registry of the United States Statistical Report: National Program of Cancer Registries and Surveillance, Epidemiology and End Results, 2007–2011 (Ostrom et al. 2014).

the understanding of of medulloblastomas, other embryonal tumours, ependymomas, pilocytic astrocytomas and diffuse gliomas. This molecular re-classification will drive future trials of therapy and an increasingly ‘personalised’ approach to therapy by identifying more reliably ‘good players’ requiring less intensive approaches and identifying ‘bad players’ where novel targeted approaches are justified.

Genetic Syndromes Predisposing to Tumours of the CNS

Most tumours of the CNS occur in children without predisposing factors. However, there are a group of syndromes that predispose children to intracranial neoplasms which can be considered either as associations of specific tumour types with underlying genetic syndromes (Table 14.3a) or as associations of genetic syndrome with specific tumour types (Table 14.3b).

The list of these associations continues to expand and become increasingly specific. In some genetically transmitted immunodeficiency syndromes; for example, Wiskott–Aldrich syndrome and ataxia–telangiectasia, the incidence of tumours is also high.

Environmental Factors

The backdrop of brain developmental growth parameters and genetic factors sets the scene for interaction with environmental stimuli that may trigger tumour development. It is clear now that it is difficult to study these factors in isolation from each other. A recent meta-analysis of environmental aetiology for CNS tumours (Walker et al. 2016) has identified the factors for which there is most evidence.

Acquired immune deficiency syndrome (AIDS) complicating infection with human immunodeficiency virus (HIV) is associated with primary non-Hodgkin lymphoma (NHL) of the CNS in around 0.5% of patients with AIDS and 50% of NHL of the CNS is associated with HIV. This risk is reducing in size in North America, Europe and Australia with the introduction of highly active anti-retroviral therapy (International Collaboration on HIV and Cancer 2000).

Ionising Radiation

Ionising radiation is an established environmental risk factor for CNS tumours. Cranial and spinal radiotherapy for cancer, including prophylactic CNS irradiation as part of the treatment for childhood leukaemia, increases the risk of CNS tumours in young people. The predominant tumour types are meningiomas and high-grade astrocytomas. There is also supporting evidence for radiation related to diagnostic imaging including CT for brain tumour. Evidence for a tumorigenic effect of high background radiation is not strong.

Non-ionising Radiation

There is less evidence that exposure to non-ionising radiation such as electromagnetic fields is a risk factor for brain tumours. The absence of a dose–response relationship in most studies makes the results hard to interpret. Epidemiological studies of exposure to radiofrequency emissions from use of mobile telephones suggest that the existence of a substantial risk over a short time of use is unlikely but that there is insufficient evidence regarding the possibility of a small increase in risk or a risk related to longer periods of exposure.

Carcinogens

Intra-CSF (intrathecal) methotrexate with a cumulative exposure more than 70mg/m² is associated with an increased risk of meningioma with a relative risk of 35.6 after adjustment for exposure to radiation (Taylor et al. 2010). N-nitroso compounds (NOCs) are contained in cured meat and tobacco smoke and are known potent carcinogens. Estimation of their effect on the risk of developing a brain tumour is based upon largely unvalidated data for cured meats. There is little evidence of an association between parental smoking, alcohol intake, coffee or tea drinking and CNS tumorigenesis. There is some evidence that parental exposure to pesticides is a risk factor for childhood CNS tumours, but there has been little consistency in studies of other parental occupations (Van Maele-Fabry et al. 2013; Chen et al. 2015).

Birthweight and Fetal Growth Rate

There is some evidence that increased birthweight is associated with enhanced risk for all brain tumours and pilocytic astrocytoma in particular.

Epilepsy and Head Injury

Increased risk of glioma in association with a history of epilepsy has been found in several studies of children and adults. It seems likely, however, that this reflects, at least in part, the fact that epilepsy can be an early symptom of a brain tumour, especially low grade astrocytomas of childhood.

Protective Effects

Many studies have found a protective effect of prenatal vitamin or folic acid supplements against childhood brain tumours. There is a growing body of evidence that past history of allergies, asthma or eczema or certain common viral infections are protective against glioma and meningioma, suggesting immunological mechanisms. The apparent protective effect of female reproductive hormones is consistent with the generally lower incidence of glioma in women compared with men. High levels of physical activity and the presence of diabetes have been found to be protective.

Clinical Manifestations and Diagnosis

Children with brain tumours present with symptoms of increased ICP (considered above), focal neurological deficits or epilepsy. Presentation with symptoms in the absence of

*Previously known as primitive neuroectodermal tumour.

Any abnormal clinical signs on examination is rare except in the case of seizures. Two or more unexplained seizures with focal clinical or electrographic features are, for this reason, a clear indication for cranial imaging in all children. The symptoms and signs differ with the location of the tumour and, to a lesser extent, its histological nature (e.g. depending on the importance of the oedema). The initial clinical symptomatology of intracranial tumours is, however, often nonspecific and may include minor clinical symptoms that may not be different from those in common benign illnesses of children. The occurrence of several such symptoms in combination with each other should raise the clinician’s index of suspicion of a CNS tumour and lower the threshold for cranial imaging correspondingly. The possibility of a CNS neoplasm should always be kept in mind, especially if there is persistence or progression of symptoms, even if the diagnosis only rarely proves to be correct.

A consecutive series of 200 cases of childhood intracranial tumours seen over a 14-year period reported on the relative incidence and duration of symptoms and signs (Wilne et al. 2006). With respect to symptoms, headache was the first reported symptom in around 40% and was the commonest symptom overall, reported by over half of children prior to diagnosis. Vomiting, educational and/or behavioural difficulties each occurred in around 40% of cases at some point and each occurred as the first symptom in around 10% of cases. Seizures occurred at some point in 15% and as the first symptom in around 10% of all cases. With respect to clinical signs, a high rate of abnormalities on examination was evident in the above series with respect to cranial nerve abnormalities (49%), cerebellar signs (48%) and papilloedema while long tract signs were less common (27%). A cranial nerve abnormality and/or papilloedema were the only abnormalities on clinical examination in 20%. Excessive head growth or endocrine problems, including growth failure and/or an abnormal trajectory of weight gain, were less common features although macrocephaly was a common feature in infants. Lower rates of both clinical symptoms and clinical signs were found in a subsequent meta-analysis of 74 reports of clinical features (Wilne et al. 2007) (Fig. 14.3).

In the 2006 report by Wilne et al., the median symptom interval before diagnosis was 2.5 months. The range of symptom intervals was 0–120 months with the longest intervals seen with seizures or endocrine features and a shorter than average symptom interval significantly associated with high-grade tumours and patient age of 3 years or younger. A subsequent similar study of 139 children presenting to four UK centres in 2004–2006 reported a median duration of symptoms prior to diagnosis of 3.3 months and found that longer symptom interval was associated with head tilt, cranial nerve palsies, endocrine and growth abnormalities and reduced visual acuity. More than half of children with brain tumours developed problems, between symptom onset and diagnosis, with vision and more than a third developed motor problems, cranial nerve palsies, behavioural change or nausea and vomiting. Lethargy, weight problems and other features suggesting endocrine dysfunction were highlighted as features whose clinical significance was under-recognised (Wilne et al. 2012).

The UK HeadSmart Be Brain Tumour Aware Campaign (www.headsmart.org), launched in 2011, targeted the medical profession and the public with graded health messages including specific advice on referral versus observation. In this project the tumour groups with the longest total diagnostic intervals were midline supratentorial craniopharyngiomas and intracranial germ cell tumours, presenting with endocrine and visual symptoms and signs, and low grade gliomas presenting with progressive and slowly evolving symptomatology. Twenty per cent of the population indicated some awareness of the project and a significant reduction in total diagnostic interval over a 9-year period coincided in time with the project, suggesting that health systems can be influenced by providing specific guidelines for a rare condition.

Non-focal features of raised intracranial pressure as manifestations of intracranial tumours

These are detailed in the opening paragraphs of this chapter.
Focal neurological features of brain tumours depend mainly on the location of the tumour. The value of careful examination of the cranial nerves, including fundoscopy, is under-recognised. In practice an eye check by an optician is a relatively frequent route of referral for a scan. However, some focal signs are of no localising value in the presence of intracranial hypertension. This applies particularly to paralysis.

<sup>a</sup>Previously known as primitive neuro-ectodermal tumour.

The list of these associations continues to expand and become increasingly specific. In some genetically transmitted immunodeficiency syndromes, e.g. Wiskott–Aldrich syndrome and ataxia–telangiectasia, the incidence of tumours is also high.
of the abducens nerve and less commonly to paralysis of the oculomotor nerve. In general, compression of the oculomotor nerve by a herniated uncus produces only involvement of the pupillary fibres with unresponsive mydriasis whereas complete palsy of the nerve with mydriasis, ptosis and extrinsic ocular muscle weakness is relatively rare. Other false localising signs include involvement of the IVth, Vth and VIIth nerves, which arise as a consequence of compression of the nerve fibres stretched over angular bony structures. Rarely, paradoxical mydriasis of the pupil contralateral to the side of the tumour may be observed.

Ataxia, which is a major manifestation of cerebellar tumours, may also occur with frontal lesions. In this case, there is often no nystagmus, dysmetria or adiadochokinesis, and dysequilibrium is prominent.

Clinical and Radiological Diagnosis and Other Investigations

The current diagnostic approach to a suspected brain tumour is based primarily on neuroimaging. A quick reference guide regarding the clinical features of brain tumours in children in three age bands that can be used to assist in the decision to undertake cranial imaging is available at https://www.rcpch.ac.uk/search/apachesolr_search/Diagnosing Brain Tumours in Children.

MRI is usually the investigation of choice. It provides better anatomical resolution than CT, except for visualisation of intracranial calcification, and is superior to CT for diagnosis and surgical planning in most brain tumours. It is particularly useful in imaging the posterior fossa, small lesions located close to bony structures and for detection of meningeal dissemination. MRI of the brain and spine, pre- and post-contrast, particularly with fluid attenuation inversion recovery (FLAIR) and diffusion-weighted imaging sequences, is now becoming an essential tool for assessment of childhood brain tumours and of sequelae related to their treatment (Chang et al. 2003; Warren 2005).

With the advent of CT, plain X-rays of the skull were largely superseded in the investigation of a patient with a suspected brain tumour except in resource poor settings. Radiological features of brain tumours on skull X-rays include widening of sutures, abnormal digital markings, and rarefaction of the posterior clinoids and lamina dura in the
pituitary fossa. Calcification may be seen in certain tumour types particularly craniopharyngioma. CT has, in its turn, been partly superseded by MRI in the diagnosis of intracranial tumours although it remains the mainstay of emergency and out of hours investigation in many centres. CT is an excellent imaging modality for identification of intracranial calcification (Renowden 2005). It is also fast so young children may avoid the requirement for a general anaesthetic for scanning purposes, and cheaper than MRI, but requires exposure to radiation and this may have long-term implications such as secondary tumours (Mathews et al. 2013).

If only CT is available, it should be performed with and without injection of iodine contrast substance except in patients with allergy to iodine. Unenhanced scans may rarely fail to reveal existing tumours, and the presence and degree of enhancement provides information on the nature of the tumour. Functional imaging is less precise from a morphological point of view but may have specific indications; for example, to localise essential functional areas that must be respected.

Magnetic resonance spectroscopy (MRS) is performed in many centres. It may allow chemical characterisation of paediatric brain tumours (Curless et al. 2002a; Tzika et al. 2002; Tzika et al. 2004). Positron emission tomography (PET), combined with CT or MRI, together provide both precise anatomical information and functional metabolic assessment of malignant tumours. The sensitivity of 18F-fluorodeoxyglucose (FDG) is limited by the high rate of glucose metabolism of healthy brain tissue and more recent studies with PET in brain tumours have investigated the use of radiotracers other than FDG. 18F-fluoroethyl choline (FEC) has, for example, been shown to be an effective metabolically stable radiotracer for imaging cellular metabolism in astrocytic and non-germinomatous germ cell tumours (Treglia et al. 2012; Fraioli et al. 2015; Tsouana et al. 2015) (Fig. 14.4).

Examination of the CSF is usually not essential for the diagnosis. In specific instances the CSF may be indicated for cytology, especially for the detection of meningial spread, and in cases of leukaemia, malignant meningeal tumours or melanomas. The presence of malignant cells in the CSF is not uncommon with malignant tumours such as medulloblastomas or ependymomas. Although false positives are rare, false negative results are fairly common. A search for CSF biochemical markers (e.g. human chorionic gonadotropin or alphafetoprotein) is useful in germ cell tumours.

In most cases where there is evidence of raised ICP, the dangers of lumbar puncture probably outweigh the information provided. How often a lumbar puncture produces or hastens the occurrence of transtentorial herniation is difficult to determine and the literature presents conflicting opinions in this regard. If in doubt, it is safer to refrain from performing lumbar puncture. For example if there is an intracranial tumour and a contraindication to lumbar puncture (Kneen et al. 2012) (see Table 14.4) but also clinical suspicion of CNS infection, it is usually possible to initiate empirical treatment for possible meningitis without undertaking lumbar puncture.

Any decision to proceed with lumbar puncture (or not) will need to take clinical features that might indicate raised ICP into account, whether or not recent cranial imaging is available. In a child who is either sedated or has had clinical signs that are suggestive (but not confirmatory) of raised ICP, this decision should only be made by a clinician experienced in the neurological/neurosurgical aspects of care of children with neurological problems. The advent of CT and MRI has considerably simplified this problem, and CT/MRI should be obtained before lumbar puncture when there is a suspicion of a mass lesion although a ‘normal’ scan does not exclude raised ICP.

The differential diagnosis of brain tumours includes other intracranial mass lesions, hydrocephalus, intracranial haemorrhages and infections and pseudotumour cerebri syndrome (also known as idiopathic intracranial hypertension). The last of these is considered at the end of this chapter.

**CNS TUMOUR BIOLOGY, PATHOLOGY, STAGING AND THEIR RELATION TO MANAGEMENT**

**The World Health Organization 2016 Classification of Central Nervous System Tumours**

The 2007 classification of CNS tumours was replaced by WHO CNS 2016 whose authors stated that a further revision is likely to be required less than nine years thereafter. This classification uses, for the first time, molecular parameters...
Pathological diagnosis may be difficult; some tumours may contain histologically different areas and biopsy diagnosis may, therefore, not give the full diagnostic picture. It is also essential to realise that the clinical prognostic significance of pathological grading and, to a lesser extent, staging may be different from its biological value. A benign tumour that is strategically located, for example, an optic pathway tumour with its risk of causing blindness, may not be removable without worsening the presenting brain injury and so represents a significant risk to the patient. Pathological diagnosis and grading is only one element of interdisciplinary discussion that also needs to consider associated genetic predisposition, age, brain region, precise location, staging and, in some cases, change over time on serial neuroimaging to determine what the likely implications of a tumour are, for a particular patient.

Tumours of the CNS are assigned grades of malignancy based primarily on histological morphology. The WHO has a I–IV grading of least malignant to highly malignant with a specific grade assigned to each tumour entity rather than multiple grades within an entity. The 2016 WHO CNS classification has broken with this tradition in the case of an entity that they now describe as ‘solitary fibrous tumour/haemangiopericytoma’ (Louis et al. 2016). Tumours in this entity are placed in a single group because they share a number of molecular abnormalities but within the group these may be graded I, II or III on the basis of histological features (e.g. number of mitoses per high powered field). This is a further example of the way that molecular characterisation is altering the way that CNS tumours are classified.

CNS tumours are also assigned a stage from I to IV corresponding to localised disease, evidence of malignant cells in the CSF, solid metastasis and widespread metastases respectively. Note that even malignant CNS tumours rarely metastasise outside the CNS; most CNS tumours tend to metastasise along CSF rather than haematogenous pathways (Curless et al. 2002b).

### TREATMENT OF BRAIN TUMOURS

#### General Considerations

The survival rates among children with brain tumours vary with their nature and location. The worst prognosis is for children with diffuse midline tumours predominantly arising in the brainstem (now referred to as diffuse midline glioma H3 K27M mutant) whereas almost 100% of children with cerebellar astrocytoma, and 70–90% of those with low grade hemispheric astrocytoma are alive at 5 years from diagnosis. Children under 2 years of age with tumours have a lower survival rate than older children (see below) and their quality of life is often poor.

Surgery is generally the primary treatment for paediatric brain tumours. Complete macroscopic resection of brain tumours is always the aim of surgery as it is associated with the best results in terms of survival and disease free survival particularly in paediatric tumours. However, this cannot be accomplished in many cases as the associated morbidity/mortality would be unacceptable. In these situations partial resection may be useful to reduce the bulk of the tumour followed by adjuvant treatment in the form of radiation therapy and/or chemotherapy (Exlin 2005). Stereotactic neurosurgery has considerably developed for accurate biopsy of deep seated brain tumours. The use of neuro-navigation has transformed the surgical management of brain tumours in terms of accurate localisation of the craniotomy and the tumour. It is now

Continued
Radiation can be applied to infinitely variable shaped fields involving the primary tumour alone or in extended fields at risk of tumour spread. The total dose is the cumulative sum of radiation fractions delivered to the fields involving the tumour and remote sites. Smaller fractions and hyperfractionated schedules can therefore enable the use of higher doses that are more cytotoxic to the tumour without increasing toxic effects on the CNS. The ratio of tumour cytotoxicity in ‘early reacting’ tissues (e.g. tumours) to that in ‘late reacting’ tissues (e.g. CNS) increases with decreasing fraction size.

Radiation Therapy

Radiation therapy remains the most effective adjuvant therapy for brain tumours. Ionising radiation disrupts DNA replication during cell division leading to cell death and is therefore most effective in rapidly dividing cells of tumours, inspection of the tumour bed for residual following tumour resection, and for skull base tumours. Intra-operative ultrasound allows quick localisation of tumour intraoperatively and is useful for monitoring progress during surgery. Intra-operative MRI is available in a number of institutions and is particularly useful in the management of very large tumours. A good review of the intra-operative adjunctive imaging techniques can be found in Schmidek and Sweet (Quinones-Hinojosa 2012).

seen as standard practice in many units. The use of neuroendoscopy is particularly suited for the management of hydrocephalus associated with brain tumours, biopsy/resection of ventricular tumours, inspection of the tumour bed for residual following tumour resection, and for skull base tumours. Intra-operative ultrasound allows quick localisation of tumour intraoperatively and is useful for monitoring progress during surgery. Intra-operative MRI is available in a number of institutions and is particularly useful in the management of very large tumours. - Teratoma with malignant transformation
- Mixed germ cell tumour

The morphology codes are from the International Classification of Diseases for Oncology (ICD-O) [742A]. Behaviour is coded /0 for benign tumours, /1 for unspecified, borderline, or uncertain behaviour, /2 for carcinoma in situ and grade III intraepithelial neoplasia and /5 for malignant tumours. The classification is modified from the previous WHO classification, taking into account changes in our understanding of these lesions.

**Grading according to the 2013 WHO Classification of Tumours of Soft Tissue and Bone.** PNET, primitive neuroectodermal tumours; EBV, Epstein–Barr virus; IDH, isocitrate dehydrogenase; SHH, sonic hedgehog; NOS, not otherwise specified; ALK, anaplastic lymphoma kinase; MALT, mucosa-associated lymphoid tissue.

Radiation can also be delivered by heavy ions (e.g. carbon ions) or by proton or neutron beams but the use of last of these is limited by serious associated toxicities. Proton therapy, in particular, has recently been the focus of significant development. The use of proton beam radiotherapy also delivers X-rays but offers the theoretical advantage of delivery of the majority of the dose in the last centimetre of a defined path of the particles, known as the Bragg peak, without delivery to tissues distal to the Bragg peak (Fig. 14.5) thus reducing toxicity from the exit dose. Proton beams can, for example, be delivered to the thoracic spinal cord with relatively less irradiation of cardiac tissues (Figs 14.6a and b). However, proton beams can also have limitations when used over large volumes and may also be associated with a greater risk of certain short term toxicities (e.g. over- or under-treatment of the interface between two overlapping fields).

In childhood, the unwanted effects of radiotherapy on the CNS, somatic growth and other tissues are greater the younger the patient. Where the tissue is cortical tissue, cognitive function can be damaged, affecting particularly short term memory, attention span, and processing speed. If this occurs very early in life, it decreases the rate at which new skills can be acquired leading to an apparent ‘drop off’ in IQ because the IQ scale is normalised to the rate of acquisition of new skills in typically developing children. Where the tissues are endocrine the physiological control mechanisms of hormone secretion are affected and result in progressive hormone failure. Radiation also damages blood vessel
The intima and somatic connective tissue’s capacity for growth, leading to increased risk of cerebrovascular disease (Ullrich et al. 2007; Campen et al. 2012) and impaired somatic growth of cranium, spinal column, respectively. Hair follicle function is variably affected after cranial radiotherapy, particularly in regions of scalp receiving boosted doses. Radiation also increases the risk of second tumours, particularly meningiomas and high-grade gliomas, developing in subsequent decades. A few cases of transverse myelitis, possibly due to undetermined viral infection, are on record (Ullrich et al. 2006).

For these reasons radiotherapy is used sparingly in very young children, the balance varies with tumour type and national preferences but extended field radiotherapy is generally avoided in children less than 3–5 years of age. Radiation fields and fractions are carefully calculated and chemotherapy is used in the hope of sustaining a cytotoxic effect on the tumour that will permit reductions of radiation dose or deferral of radiation therapy until the child is older. Currently, increasingly sophisticated prognostic factor analysis is identifying tumour categories that require less cytotoxic therapy for cure and so allow dose reductions and those that have more resistant phenotypes where sustaining maximum tolerated dosing is critical to effective cytotoxicity.

Cytotoxic Chemotherapy

The use of cytotoxic chemotherapy has a long history and is established in both benign and malignant CNS tumours. Its effects on brain tumour are dependent upon the sensitivity of the tumour to the drug’s effect and the tissue levels that can be achieved via oral or intravenous administration. Direct administration to the CSF, tumour cavity or tumour
interstitium can achieve responses with drastically reduced systemic doses and thus avoid unwanted systemic effects. The many and various unwanted effects of chemotherapy on the CNS have been reviewed by Kennedy and Nicolin (2013). Pre- or post-surgery chemotherapy can be used to complement neurosurgery by debulking the tumour. It can also be used either as an adjuvant therapy to consolidate remission and eradicate tumour, or in a continuing schedule to defer irradiation in very young children, or in very high-dose regimes requiring haematological stem cell rescue techniques to achieve transiently elevated drug levels within the brain. However, the systemic toxicity of the latter approach is high and life threatening and its benefit remains unproven. Its neurotoxic effects, especially in conjunction with maximised radiation therapy dosing are not completely understood despite extensive trials (Vivekanandan et al. 2015). The use of intrathecal chemotherapy to control leptomeningeal disease with minimal side effects has an established role in acute leukaemias and is increasing in CNS tumours. Delivering drugs directly to the tumour cavity is also an established technique (e.g. the use of gliadel wafers in high-grade glioma). Experimental approaches delivering drugs interstitially using continuous infusions are under investigation (Lewis et al. 2016).

For systemically administered cytotoxic chemotherapy, unwanted effects are prominent, particularly nausea, vomiting and other gastro-intestinal toxicities, bone marrow suppression and immunodefiency, infertility, particularly in males, neuropathy, cardiac, renal and hearing toxicities. Furthermore, its dose-related DNA damaging effects can contribute to the risk of second tumours such as acute leukaemias, meningiomas, high-grade gliomas and sarcomas.

To date the only cytotoxic drugs licensed for primary CNS tumours in children or adults by the European Medicines Authority (EMA) are lomustine (CCNU), Temozolomide and Gliadel wafers, all in the management of high-grade glioma. In the US the Federal Drugs Administration (FDA) have also licensed Bevacizumab for high-grade glioma. The other drugs in current use are ‘off label’.

**Biologically Targeted Therapies**

The explosion of scientific information about tumour biology offers potential for targeted treatments. In children, this is exemplified by the use of mTOR inhibitors such as Rapamycin, originally developed as immuno-suppressive drugs used in organ transplantation, for treatment of subependymal giant cell astrocytoma associated with tuberous sclerosis. Their mechanism of action is linked to the mutated pathway characteristic of tuberous sclerosis complex (TSC). A randomised trial of Rapamycin has demonstrated tumour response to the drug as well as other beneficial effects on facial tubers and the drug Everolimus is now licensed for children with subependymal giant cell astrocytoma. At the time of writing there are no other drugs with a license for use that target mutated pathways in childhood brain tumours, although a number are the focus of great interest, particularly drugs targeting the mitogen n-activated protein kinase (MAPK) pathway in pilocytic astrocytoma, the commonest benign tumour of childhood. The use of such bio-targeted therapies to tackle malignant tumours has not yet been shown to be effective. The challenge is to test drugs in patient groups with known biological characteristics in sufficient numbers to make observations with sufficient reliability to satisfy licensing requirements. This is difficult in extremely rare conditions in young children. Without licensing, health systems are understandably reluctant to fund the use of these new and frequently very expensive drugs.

**Clinical Trials**

There is an active programme of clinical trials worldwide focused in the larger continents of North and South America, Asia and Europe. Large ‘phase 3’ trials exploring treatment programmes that combine surgery, radiotherapy and chemotherapy have contributed substantially to the progressive improvement in survival rates that has occurred over the last 30 years in childhood cancer generally and, to a lesser extent, in CNS tumours. The associated programmes of biological research have now identified a series of tumour subgroups justifying stratification for future trials. Inclusion in trials and research as part of primary treatment has been demonstrated to enhance standards of care and outcomes but the challenge, increased by more precise delineation of molecular subgroups, is to design trials that will recruit sufficient patients to generate the evidence.

**QUALITY OF SURVIVAL AND NEUROLOGICAL SEQUELAE OF BRAIN TUMOURS IN CHILDREN**

The results of recent advances in therapy have been impressive, especially for certain types of tumours that were often fatal a few years ago, such as medulloblastomas. CNS tumours and their treatments may, however, cause acute and chronic adverse effects. In particular, surgery, cranial irradiation and chemotherapy may induce damage to adjacent healthy tissues leading to neurological damage (reviewed in Bull and Kennedy 2013) for which, once it has occurred, there are few effective treatments. The natural history of healing within the CNS is supported by generic neuro-rehabilitation to promote the processes whereby healing or undamaged areas take over impaired functions. It is difficult to distinguish clearly the morbidities of chemotherapy and those of radiotherapy as the two modalities are often given together and several pathologies are caused by both (e.g. leukoencephalopathy – see below).

Treatment-related injury may appear early or late and may be temporary or permanent. Distinguishing direct effects of tumour those of treatment requires assessment of timing and cranial imaging, including radiation field maps. Adverse effects include neurological, visual and auditory deficits,
seizures, chronic pain including headache, cognitive impairment, neuro-endocrine dysfunction (including short stature due to growth hormone deficiency and spinal irradiation and deficiencies of other pituitary and effector organ hormones leading to hypothyroidism, hypogonadism and reduced fertility), stroke, and secondary malignancies (mostly meningiomas and gliomas, 2–40 years) after irradiation. This was reviewed by Wells and Kennedy (2017) from which some of the material below is drawn. Sequelae that develop or persist more than 5 years after tumour diagnosis, reviewed by Armstrong (2010), are often referred to as ‘late effects’ although the use of this cut-off point between ‘early’ and ‘late’ is somewhat arbitrary. Increased recognition of these problems has led to attempts to reduce or replace radiation therapy with various chemotherapeutic regimens (Kalifa and Grill 2005), to stratify treatment according to the risks of recurrence and of sequelae and by increased surveillance of survivors.

Tools to Assess Sequelae

Assessment tools for use in infants, children and young people have been developed and validated in the fields of oncology, neurology and cognition and are used with increasing standardisation across studies. The WHO Classification of Functioning, Disability and Health (ICF) has been validated in childhood brain tumour survivors (Khan and Amaty 2013) and should remain the context within which outcome measures are placed. For patients receiving treatment on a study protocol, neurological sequelae are reported using Common Terminology Criteria for Adverse Events (current version 4.0; https://evs.nci.nih.gov/ftp1/CTCAE/About.html) which provides standardised grading of adverse effects including endocrine and nervous system symptoms, based on clinician assessments with either a 3- or 5-point severity scale. The Neurological Predictor Scale (Micklewright et al. 2008) was developed to serve as a cumulative index of a child’s exposure to risk factors but is not widely implemented. A degree of consensus has been achieved in both Europe (Limond et al. 2015) and North America (Embry et al. 2012) regarding practicable approaches to assessing quality of survival, including health-related quality of life, that involves administration of not only questionnaires for parents and patients but also short batteries of direct psychometric assessments.

A major advance has been the use of computerised batteries for neurocognitive assessment, including the CANTAB and CogState. The NIH toolbox (Weintraub et al. 2013) and the Patient Reported Outcome Measurement Information System (PROMIS) (Hinds et al. 2013) are relatively newly validated tools for quality of survival assessments. These tools and others are increasingly utilised as quality of survival measures in prospective treatment studies.

IQ testing using the Wechsler Intelligence Scales (WISC), most recently WISC-V (Canivez et al. 2016), has been the most common means to measure neurocognitive deficit in children treated for brain tumours. All the WISC scores are scaled so that the mean and standard deviation of scores in the general population are 100 and 15 respectively. Test scores are constructed in such a way that the IQ is not expected to change substantially over time in that population. The temptation to express neurocognitive outcome as a single number that ‘summarises’ outcome and is known to have a normal distribution in the healthy population is overwhelming for many investigators. There are several limitations of IQ when used in this way. First, IQ may not indicate subtle but important deficits: important neurocognitive deficits may coexist with a normal IQ. Specific deficits in selective attention and executive function with normal IQ, for example, are typical findings in children treated for supratentorial hemispheric pilocytic astrocytomas treated with surgery alone (Aarsen et al. 2009). This problem can be overcome with more sophisticated, in-depth assessment.

Second, IQ score will not capture several important aspects of quality of survival such as ability to live independently. Indeed the difficulty in predicting from IQ scores which individuals with intellectual impairment could and could not live independently provided the impetus for the development of Adaptive Behaviour Scales (e.g. Sparrow et al. 2005) that measure typical abilities in everyday living as assessed by a third party rather than testing intellectual abilities by direct testing. No amount of neurocognitive assessment can avoid this difficulty.

Third, the evaluation of neurocognitive function requires direct assessment by a qualified assessor. This is resource intensive and makes considerable demands on the survivor. Consequently, reports on neurocognitive deficits are typically limited by being obtained only in convenience samples at single institutions or from multi-centre samples with high attrition rates. They are, therefore, of doubtful generalisability. Analysis of a group in which more impaired survivors are selectively retained in a study, for example, may be misinterpreted as a fall-off in ability in individuals in the group.

IQ is itself dependent on underlying core cognitive functions and the structure of the most recent versions IV and V of the WISC were influenced by Carroll’s three stratum theory of cognitive abilities (Carroll 2003) which identifies the core factors that contribute to IQ scores. Full Scale IQ represents a child’s general intellectual ability (g) and, in the WISC-IV and WISC-V, is comprised of four broad domains of cognitive abilities: verbal comprehension, perceptual reasoning, working memory, and processing speed (Canivez et al. 2016). These core cognitive functions provide the foundations of effective learning and retention of information underlying g in Stratum III of the Carroll model and can be mapped on to the eight broad cognitive abilities in Stratum II. These are fluid intelligence, crystallised intelligence, visual perception, auditory perception, general memory and learning, long-term storage and retrieval, cognitive processing speed and reaction speed. Improvements in memory and processing speed together account for almost half of age-related improvements in IQ (Fry and Hale 1996).

By contrast to IQ assessment, other aspects of assessment of quality of survival are more amenable to population-based indirect assessment by questionnaire (Boman et al. 2009a, b;
Packer et al. 2003; Zebrack et al. 2004; Kennedy et al. 2014). These include health status, behaviour, and health-related quality of life (HRQoL). These are conceptually separate from cognitive assessment and do not correlate highly with them although they may nevertheless have a role in screening for the presence of cognitive difficulties (Bull et al. 2015; Hardy et al. 2015). With questionnaires, different raters (self, parent, teacher) provide another dimension of variation and will result in predictable variation in responses with higher levels of agreement on more concrete and observable aspects of HRQoL than on emotional and social function (Morrow et al. 2012). Cross-informant variance should not be equated with informant unreliability but may, on the contrary, indicate that different informants contribute different but valid information.

**SPECIFIC NEUROLOGICAL SEQUELAE OF BRAIN TUMOURS**

The incidence of motor or coordination problems is highest at presentation and during initial treatment. In the acute post treatment period, weakness may result from perioperative injury, oedema or stroke. A large epidemiological study found that 4.6% of long-term survivors developed motor problems at least 5 years after treatment and their relative risk of doing so was 12.5 times that of unaffected siblings with a doubling of risk in those that had received 50Gy or more of radiation to the frontal lobes (Packer et al. 2003). Weakness may also result from myelopathy from spinal radiation therapy or chemotherapy, particularly if intrathecal, and may be accompanied by bowel or bladder dysfunction and sensory deficits, depending on location and severity (Chukwu et al. 2015).

Seizures occur as part of the presentation of a brain tumour in about a quarter of cases, with low grade indolent tumours being the tumour type most likely to present in this way, and continue after primary treatment in about 15% (Van Breezen et al. 2007). New onset or worsening of seizures post treatment may signify tumour progression or recurrence, treatment-related neurotoxicity, low drug levels or metabolic disturbance. Non enzyme-inducing antiepileptic drugs are preferred to avoid interactions with chemotheraphy (Ruggiero et al. 2010). Seizures occurring in the early postoperative period are often transient provoked seizures rather than epilepsy and should not routinely be treated with post-discharge anticonvulsants. The hypothesis that sodium valproate has valuable anti-tumour effects is unproven and should not influence choice of anticonvulsant. Antiplatelet effects of anticonvulsants may be a relative contraindication in some patients because of antiplatelet effects of anti-tumour treatments. A trial of withdrawal of antiepileptic medication is often deferred until a patient has been seizure-free for 2 years but adverse CNS effects of anticonvulsants may lead to important functional deficits when added to the effects of the tumour and anti-tumour treatments.

**Acute Encephalopathy**

The posterior reversible encephalopathy syndrome (PRES) has been reported in association with cisplatin, cytarabine, cyclosporins, cyclophosphamide, methotrexate, rituximab, paclitaxel, and other chemotherapies. Presenting symptoms consist of headache, visual disturbances, seizures which may be intractable and require aggressive acute therapy, nausea and vomiting, altered cognitive status, and, in some cases, focal deficits (McCoy et al. 2011). PRES is usually associated with hypertension or hypotension, sometimes in association with metabolic abnormalities. The neurological deficit is usually reversible upon regulation of blood pressure and withdrawal of chemotherapy. High-dose arabinosyl cytosine (Ara-C), ifosphamide and methotrexate are also known to cause subacute neurotoxicity with headaches, seizures, auditory and visual hallucinations, visual disturbances, pseudobulbar palsy, extrapyramidal signs and paresis.

Another cause of encephalopathy with focal neurological deficit is tumour pseudoprogression resulting from treatment-induced tumour and peri-tumoural tissue oedema. This may present as progressive neurological deterioration with cerebral oedema on imaging, typically 6 weeks to 3 months after radiation therapy. Concurrent treatment with chemotherapy may be a risk factor. When symptomatic, the condition is treated with high-dose corticosteroids. Bevacizumab is increasingly employed for patients who experience rapid deterioration despite corticoids therapy and/or intolerable steroid side effects (Preuss et al. 2013).

The stroke-like migraine after radiation therapy (SMART) syndrome causes acute or subacute focal impairment, often accompanied by encephalopathy and headache. It may be associated with hypointensities on susceptibility-weighted imaging (SWI) and gyriform enhancement on T1-weighted MRI. SWI may help distinguish SMART from other conditions that may have a similar post-contrast MRI appearance (Khanipour et al. 2015). Treatment includes the use of hydration and neuroprotective measures including avoidance of hypotension.

Cerebrovascular complications in childhood CNS tumour survivors include large-vessel vascular injury, stroke, moyamoya (Ullrich et al. 2007), mineralising microangiopathy, cavernomas and other vascular malformations, and stroke-like migraines. The incidence of neurovascular events in childhood brain tumour survivors has been found to be 100-fold higher than in the general paediatric population (Campen et al. 2012). Cranial irradiation, particularly to the circle of Willis, is an important risk factor for stroke and cerebrovascular abnormalities, and the risk is dose-dependent (Bowers et al. 2006; Campen et al. 2012; Mueller et al. 2013). Chemotherapy including methotrexate, anthracyclines, mitomycins, asparaginase (especially venous sinus thrombosis) and anti-vascular endothelial growth factor (VEGF) may also increase risk (DiGiannatale et al. 2014). Asymptomatic radiographic findings include micro-bleeds and superficial siderosis, and all events are more common in children who received whole-brain radiation (Passos et al. 2015). A study
of young adults with radiation induced cavernous malformations (RICMs) found that they occurred within the radiation field on average 12 years after radiation treatment. Compared with non-radiation cavernous malformations, RICMs were more likely to occur as multiple cavernous malformations, to present at a younger age, and were at least as likely to cause symptomatic haemorrhage (Cutsforth-Gregory et al. 2015).

Postoperative cerebellar mutism syndrome, the term preferred in a recent Delphi process to ‘posterior fossa syndrome’ (Gudrunardottir et al. 2016), is discussed in the Posterior Fossa Tumours section.

Leukoencephalopathy after treatment of CNS tumours is a demyelinating process commonly seen after radiotherapy but also in children treated with intravenous or intrathecal methotrexate (Fig. 14.7) when it is related to the cumulative dose of intraventricular treatment although no firm conclusions were drawn about the implications of the leukoencephalopathy for cognitive outcome (Rutkowski et al. 2005). Magnetic resonance spectroscopic evidence of neuro-axonal damage in normal appearing white and grey matter associated with radiation and chemotherapy have also been described (Rueckriegel et al. 2010) and white matter tract volume and anisotropy have been linked to cognitive and motor function in paediatric posterior fossa tumour survivors (Khong et al. 2006; Mabbott et al. 2011; Rueckriegel et al. 2015).

Peripheral Neuropathy

Lower motor neuron weakness may result from toxicity from chemotherapy, in particular vinca alkaloids (vincristine), platinum drugs (cisplatin, oxaliplatinum, carboplatin), methotrexate, and some biological agents, including those with antiangiogenic properties. Chemotherapy-induced peripheral neuropathy may be pure sensory (e.g. diminished temperature and vibratory sensation, burning paraesthesiae, jaw pain), predominantly motor (e.g. foot drop), and/or have an autonomic component that includes constipation and orthostatic hypotension. Symptoms are dependent on the duration and dose of drug therapy and their severity varies from subclinical through mild discomfort to severely debilitating symptoms and signs. The neuropathy is often worse in older individuals. Attempts to prevent or treat have failed, with the exception of medications for hyperaesthesia and pain control. A patient-report rating scale for neuropathy has been validated and is reported to be sensitive to clinical important Vincristine-induced deficits (Lavoie Smith et al. 2015). Platinum drugs also cause auditory neuropathy and audiograms are required to monitor this, often dose-limiting, unwanted effect. Molecular genetic predictors such as alterations in CYP5a enzymes may provide criteria for adapting treatment according to genetic risk to reduce the incidence of drug-induced hearing loss.

SPECIFIC FEATURES OF BRAIN TUMOURS IN INFANTS AND CHILDREN

Brain Tumours in Infants and Children Under 2 Years of Age

These differ in regional distribution, pathology, clinical features and therapy from those of older children. The proportion of all childhood brain tumours occurring at this age may be at least 10%. A significant number of these are definite ‘congenital’ tumours, that is, they produce symptoms within the first 2 weeks of life, or ‘probably congenital’ tumours, that is, they are present or recognised within the first year of life (Sarkar et al. 2005).

The Surveillance, Epidemiology and End Results Data (SEER) USA database would suggest that gliomas represented 42.5% of brain tumours in infants under 12 months of age (Bishop et al. 2012). Of these gliomas, 43% were low grade histology, of which about half were pilocytic astrocytomas, 24% were high grade and 33% were unspecified malignant glial tumours without a documented grade. Medulloblastomas, ependymomas and germinomas accounted for 16.2%, 10.5% and 5.0% of cases respectively. Infants with low grade gliomas had the highest observed survival of 85.6% at 3 years, whereas those with atypical teratoid/rhabdoid tumours (ATRTs) or
primary rhabdoid tumours of the brain had the lowest, with a 1-year survival of 39.7%. Median 3-year survival estimates for other groups were 72% for choroid plexus tumours, 60% for germ cell tumours, 52% for high-grade gliomas, 35% for supratentorial primitive neuroectodermal tumours (PNETs) (termed embryonal tumour with multilayered rosettes in the WHO classification), and 30% for medulloblastoma (Louis et al. 2016).

The clinical features of congenital and early-onset tumours vary with the type and location of the tumour. Macrocraania, delayed milestones and behavioural disturbances are common presenting clinical features. In the case of congenital tumours, fetal deaths and preterm births are frequent. Intracranial haemorrhage can be the presenting manifestation. Vomiting, focal neurological signs, seizures and the diencephalic syndrome of emaciation (see below) may also be early signs. Infantile spasms are an uncommon manifestation.

The diagnosis may be delayed if the significance of relatively nonspecific clinical features, such as delayed milestones or vomiting, is not recognised. Tumours manifested by hemiplegia may be difficult to distinguish from congenital static hemiplegia but brain imaging will resolve any doubt. CSF examination may be misleading as pleocytosis and increased protein are commonly found. CT and MRI will, in most cases, readily permit the diagnosis.

Historically, the prognosis of congenital tumours is poor (Sarkar et al. 2005). Many tumours are malignant. Surgery is difficult because of the large size of many tumours and the small circulating volume of blood. Staged resections may reduce the mortality risk. Radiation is highly dangerous for the very young developing brain and its use has declined since 1979 (Bishop et al. 2012). The power of radiotherapy both to confer substantial benefit to survival rates and also to cause severe long-term sequelae by late effects on the CNS and other organs frequently poses difficult dilemmas in this age group especially as the results of prolonged regimens of adjuvant chemotherapy have been ‘underwhelming’ with a high risk of disease progression at 12–18 months (Bishop et al. 2012). Moreover, the possible late effects of chemotherapy are as yet poorly known. Some role for focal radiotherapy is now being rediscovered following evidence of lack of severe long-term sequelae in the treatment of ependymoma (Merchant et al. 2010).

Quality of life (QoL) for survivors of infant brain tumours is often poor as illustrated by a follow-up study of 27 consecutively treated patients diagnosed in the first year of life in a single centre in Switzerland. Persistent neurological complications occurred in nine out of 11 survivors, endocrine and growth complications in four out of 11, and cognitive deficits leading to school problems/impaired choice of occupation in eight out of ten. Behavioural and psychological adjustment problems were reported by four of six patients and seven out of ten parents. HRQoL as rated by patients and their parents was considerably lower than that of healthy controls. In comparison with healthy controls, social functioning was rated by the patients and the parents as the QoL dimension most affected. HRQoL was lowest for patients with high-grade tumour histology and more intense therapy (Gerber et al. 2008).

**CHARACTERISTICS OF INDIVIDUAL TUMOURS**

The localisation and histology (in the now obsolete CNS 2007 WHO classification) of the major types of brain tumours are shown in Figures 14.2a and 14.2b respectively.

**POSTERIOR FOSSA TUMOURS**

**MEDULLOBLASTOMA**

**INcidence**

Medulloblastoma accounts for 14–20% of childhood intracranial tumours and is second only to cerebellar astrocytoma among posterior fossa tumours. Medulloblastoma is most frequent in the first decade of life and twice as common in boys as in girls. It has been reported in the neonatal period.

**Pathobiology of medulloblastoma**

Medulloblastoma is a malignant and rapidly growing tumour arising from undifferentiated neural cells. The tumour is poorly demarcated from normal tissue. It is very cellular and consists of small round cells without any definite pattern, with frequent mitotic figures. Medulloblastomas usually arise from the cerebellar vermis in the region of the roof of the fourth ventricle but the attachment can extend along the cerebellar peduncles and along the floor of the IVth ventricle. They extend toward the dorsum of the cerebellar vermis and into the lumen of the fourth ventricle thus producing hydrocephalus. Metastases along the CSF pathways are frequent, and imaging of the spinal canal is important to determine the extent of the tumour. Extraneural metastases, which occur only rarely in cases treated surgically, involve spread to bone and lymphoid tissues.

The precise histological classification of medulloblastoma is difficult because of its primitive nature. It is distinct from other embryonal tumours of the CNS and the term primitive neuro-ectodermal tumour has been removed entirely from the histological lexicon in WHO CNS 2016. Histological variants of medulloblastoma (e.g. desmoplastic/nodular, medulloblastoma with extensive nodularity, large cell, anaplastic) relate to molecularly defined subgroupings and to prognosis (Rutkowski et al. 2010; Louis et al. 2016) (Table 14.6). Identification of PTCH1 mutation in sporadic medulloblastoma revealed the role of the ‘sonic hedgehog’ (SHH) pathway mutations.

Genetic disruption of this pathway in medulloblastoma results in inappropriate activation of the signalling cascade and downstream tumourogenesis (Taipale and Beachy 2001). This and other advances in understanding of the molecular variation in medulloblastoma have led to wide acceptance that there are four genetic (molecular) groups of medulloblastoma: WNT-activated, SHH-activated, and the numerically designated ‘group 3’ and ‘group 4’. Some of these histological and genetic variants are associated with dramatic prognostic differences and give rise to histologically and genetically defined ‘integrated diagnoses’ with clinical correlates (Table 14.6) (Louis et al. 2016).

Treatment intensity is now defined by the presence (‘high-risk’ disease) or absence (‘standard-risk’) of histological and genetic and clinical (postoperative tumour residue >1.5cm³) [note that this is a measure of area, not volume] and/or metastatic disease at diagnosis. This stratification currently forms the basis of patient selection into clinical trials (Pizer and Clifford 2009). These ‘disease-wide’, that is, derived from high-, standard- and low-risk cases, biological markers of prognosis in medulloblastoma appear to have a different prognostic significance when applied to standard-risk patients. Specifically, although the favourable prognosis of WNT-activated medulloblastoma was confirmed, better outcomes were observed for other medulloblastoma variants in standard-risk medulloblastoma compared to previous disease-wide clinical trials (Clifford et al. 2015).

In addition to classification on the above schema, single medulloblastoma samples can be characterised into subgroups according to their minimal DNA-methylation signatures. These technologies are transferrable to many diagnostic laboratories. Importantly, the assay is applicable to limited and low-quality samples refractory to array-based analysis, allowing the retrospective unlocking of subgroup status in historical trials cohorts (Schwalbe et al. 2016).

**Clinical features and imaging of medulloblastoma**

The typical clinical presentation is with symptoms and signs of raised ICP in combination with ataxia. Symptoms of raised ICP are prominent and may be isolated. Ataxia is usually truncal or affects both lower limbs, with a tendency to fall backwards or forward. The whole symptomatology develops rapidly in a few weeks and papilloedema is often lacking. Bilateral pyramidal tract signs may be present. Occasionally, multiple cranial nerve involvement, spinal root pain or even paraplegia are seen early, indicating the presence of metastatic dissemination.

The imaging appearance of medulloblastoma on CT and MRI is highly suggestive. The tumour is midline and rounded and has, on unenhanced scans, a density slightly higher than or similar to the surrounding parenchyma. The density often increases homogeneously and markedly on contrast injection. In some cases, small cystic areas, haemorrhages or calcification are visible. Hydrocephalus is usually present (Fig. 14.8).

**Treatment of medulloblastoma**

Therapy of medulloblastoma begins with removal of the tumour, which should leave less than 1.5cm³ of residual tumour.
Figure 14.8 Medulloblastoma: comparison with cerebellar astrocytoma. (In each pairing of images the left-hand scan is from a case of medulloblastoma and the right-hand scan from a case of cerebellar astrocytoma.) (a) Cerebellar medulloblastoma involving the vermis and compressing and invading the brainstem. MRI scan showing heterogeneous enhancement of the mass and hydrocephalus with dilatation of the temporal horns. (b) MRI scan of a different case illustrates the fact that some medulloblastomas can involve the cerebellar hemispheres and make differential diagnosis with cerebellar astrocytoma (a benign tumour) problematic.

The combination of this degree of resection with no metastatic spread to other parts of the CNS prior to surgery and classic histology (Table 14.6) constituting the ‘standard-risk’ profile and is associated with a better outlook than partial removal. It is not clear that complete excision is associated with lower survival rates than that associated with leaving a small residuum of less than 1.5 cm² of residual tumour and it is noteworthy that the increase in incidence of cerebellar mutism coincides with the increase in the proportion of cases in whom complete excision is achieved.

Radiotherapy has a major role in extending survival rates. The use of high-energy sources and increased doses accounts for the recent marked increases in survival. Recommended doses are currently 50–55 Gy to the posterior fossa and 35–4 Gy to the neuroaxis. Chemotherapy alone, with vincristine, cisplatin, nitrosourea or various combinations of alkylating agents such as CCNU, methotrexate, carmustine (BCNU), cisplatin and prednisone, appears to be effective and may be the treatment of choice for some subgroups of children under 2 years of age. Rutkowski (2006) used chemotherapy alone for treatment of young children, with a complete remission rate of 80%, and this method may become the rule for infants and young children.

Outlook of Medulloblastoma

Considering all medulloblastomas diagnosed at age 0–19 years from 1973–2011, 5-year survival was 58% in the US SEER registry and of those in this age range followed up and surviving the first 5 years from diagnosis, 30-year overall survival and cancer-specific survival were also reduced at 70.2% and 80.1% respectively (Frandsen et al. 2015). However, when applying these numbers in the clinic currently, it is important to bear in mind that the 5-year survival rates for children with medulloblastomas have improved during the past two decades to around 80% for standard-risk patients. Patients with high-risk medulloblastoma (age less than 3 years, residual tumour greater than 1.5 cm² of tumour, CSF or solid metastases) had a survival of just 40% despite a far more aggressive treatment regimen (Bartlett et al. 2013).

The quality of survival is often not satisfactory; many children are left with cognitive, behavioural and endocrinological sequelae apparently as a result of radiotherapy in combination with chemotherapy and, in some cases, complications of surgery (Grill et al. 2004; Bull et al. 2007; Kennedy et al. 2014) and problems persist into adulthood (Kieffer et al. 2012). These may vary by molecular subtype (Bull et al. 2014b). Medulloblastoma surgery is complicated by cerebellar mutism syndrome (CMS) (see Cognitive and Behavioural Sequelae of Posterior Fossa Surgery in Children section) more frequently than surgery for any other tumour type and is strongly associated with poorer long-term cognitive outcomes. In some cases this is accompanied by persistent ataxia and dysarthria.

Cerebellar Astrocytoma

Incidence

Cerebellar astrocytomas are about as frequent as medulloblastomas in children.

Pathobiology of Cerebellar Astrocytoma

More than 65% of low grade gliomas in childhood are pilocytic astrocytomas although about 20% are diagnosed clinically without biopsy and are therefore presumptive diagnoses. A very small (and unquantified) proportion of pilocytic tumours is thought to transform to more malignant phenotype later in adulthood but risks factors for this have yet to be identified; currently, this is neither quantified nor are there
Cerebellar astrocytomas may involve the vermis (particularly in younger children), the hemispheres, or both locations simultaneously. Approximately half are purely midline tumours. About 80% are cystic tumours with a mural nodule attached to one part of the cyst wall (Fig. 14.9). Solid tumours are less common. Metastatic leptomeningeal dissemination occasionally occurs (<10%). The majority are pilocytic astrocytomas that are far more benign than most astrocytomas of later life but exceptional cases of malignant cerebellar astrocytoma are on record as recurrences of operated astrocytomas. Histologically cerebellar astrocytomas can be divided into a juvenile pilocytic form, with microcysts, Rosenthal fibres and oligodendroglial fibres that are slowly growing (WHO Grade I) parenchymal tumours and a less common diffuse type (WHO Grade II) with high cell density necrosis and calcification. The latter type has a less favourable outcome than the juvenile type. The classification of diffuse gliomas is further discussed in the section of this chapter on gliomas of the cerebral hemispheres.

Genetic alterations seen in high-grade gliomas such as *TP53* mutation, *MGMT* methylation, epidermal growth factor receptor amplification, and PTEN loss are not found in juvenile pilocytic astrocytomas and no consistent pattern of loss of heterozygosity on 1p or 19q has been identified or shown an association with outcome (Bonfield and Steinbok 2015). Despite this, several studies have identified an aberration in chromosome 7, the vast majority being a tandem duplication resulting in a KIAA1549: BRAF fusion gene. A smaller number of tumours have other BRAF gene alterations or NF1 mutations. All the genetic mutations seen in this tumour type cause alterations in the MEK/mitogen-activated protein kinase (MAPK) pathway, increased transcriptional activity and cellular proliferation, with particular genetic mutations. Pilocytic astrocytoma is therefore considered predominantly a single pathway disease with oncogenic hit distributions that vary with anatomical site (Jones et al. 2012) (Fig. 14.10). However, outcomes do not appear to be influenced by the absence or presence of this alteration. There is also no correlation between the macroscopic appearance of pilocytic astrocytomas and the outcome.

Other genetic associations with low grade glioma in childhood include neurofibromatosis type 2 (NF2) (also associated with acoustic neuroma, multiple spinal ependymoma and peripheral nerve sheath tumours) (see Chapter 4) tuberous sclerosis (see Chapter 4) which presents with subependymal giant cell astrocytoma (SEGA), a benign tumour. Astrocytomas can also present as part of other familial cancer syndromes such as Li Fraumeni Syndrome, constitutional mismatch repair syndrome and familial adenomatous polyposis syndrome (AFP). The Swedish family cancer registry has identified the presentation of low grade glioma in childhood as a marker for nonspecific enhanced family cancer risk (Hemminki and Li 2003).
Clinical features and Imaging of Cerebellar Astrocytoma

The clinical features of cerebellar astrocytomas are similar to those of medulloblastomas but the history is usually much longer and the child less ill so the child often has a prolonged history of symptoms of raised ICP with headaches, vomiting, paralytic squint, ataxia and mobility problems. Papilloedema is frequent because of the long course and slow growth of the tumour and can lead to loss of vision. Delays in diagnosis are common. Occasionally children can die at the time of presentation due to acute hydrocephalus and herniation of cerebellar tonsils. Because tumours may be hemispheric or extend asymmetrically to one hemisphere, unilateral or asymmetrical cerebellar signs are more common than with medulloblastomas. A head tilt away from the lesion is often present.

CT and MRI (Fig. 14.9) usually show large masses, displacing and compressing the fourth ventricle. Low tumour density is mostly due to oedema. On MRI the solid components are typically iso-intense on T1 and hyperintense on T2-weighted images. Contrast injection increases density and can delineate a dense nodule, several pericystic nodules, or a large irregular tumour surrounded by several cysts. Calcification is present in 10–20%. Hydrocephalus of a marked degree is the rule.

Treatment and outlook of cerebellar astrocytoma

Newly diagnosed cases need to be considered by the paediatric neuro-oncology multidisciplinary team. An international consensus has established criteria for case selection for immediate treatment versus observation (Walker et al. 2013). Low grade cerebellar astrocytoma is a surgical disease with excellent long-term results but requiring long-term follow up. Radiotherapy is not indicated in cases of confirmed complete removal nor in the large majority of cases of incomplete removal but is clearly indicated in the uncommon cases of cerebellar glioblastoma. Late recurrences can be treated surgically. In a single institutional series of 100 children, 9% of the children in this study underwent repeated surgery due to progressive tumour recurrence, and 15% were treated for...
persistent hydrocephalus (Due-Tønnessen et al. 2013). However, in a significant proportion of patients for whom resection is reported as ‘complete’ by the neurosurgeon there was evidence of persistence of tumour tissue by MRI within 3 days of surgery, so postoperative MRI surveillance is essential for early detection of residual disease and subsequent imaging at increasing intervals to screen for the appearance/enlargement of residual tumour. Recurrence (or, more precisely, tumour progression) is much more common after subtotal resection although, even in such cases, it does not necessarily occur and recurrences occasionally regress spontaneously (Palma et al. 2004). Sequelea in groups of survivors include specific cognitive deficits and HRQoL that is significantly lower than that of non-tumour comparison groups although significantly higher than that found in medulloblastoma survivors (Aarsen et al. 2004; Bull et al. 2014).

EPENDYMOMA

INCIDENCE
Ependymomas are thought to arise from the radial glial cell, a neural stem cell (Taylor et al. 2005) and account for 6–10% of childhood tumours and 15% of posterior fossa tumours. They have a peak incidence in young children. Sixty per cent of cases occur under age of 5 years. Over 90% of ependymomas arise within the cranium, about two-thirds of them below the tentorium. Ependymomas of the fourth ventricle arise from the floor, the roof or the recesses of the cavity and obstruct CSF flow. Ependymomas in the posterior fossa are commonest in very young children, those in the cerebral hemispheres in adolescence and those in the spinal cord in adults. Ependymomas in a supratentorial location are more likely to be malignant; the latter constituting up to 86% of cases in some series. WHO CNS 2016 recognises five types of ependymal tumours: myxopapillary ependymoma (Grade I – usually a spinal tumour), subependymomas (Grade I), ependymoma (Grade II), anaplastic ependymoma (Grade III) and ependymoblastoma, RELA fusion positive (Grade II or III). The last of these accounts for the majority of supratentorial ependymomas in children (Louis et al. 2016).

PATHOBIOLoGY OF EPENDYMOMA
The histopathological classification and grading of these tumours remains controversial (Ellison et al. 2008). Anaplastic ependymoma has a poor prognosis compared with its differentiated counterpart and clearly anaplastic and differentiated tumours may be distinguished with a high level of agreement. The histological classification and prognostic significance of the intervening histological spectrum of tumours (e.g. focal anaplasia encountered in a largely differentiated ependymoma; high levels of mitotic activity without vascular proliferation; and vice versa) is less clear (Merchant et al. 2010).

Prediction of tumour behaviour has been assisted by molecular subtyping. Chromosomal gains of 1q are commonly associated with ependymoma in children, particularly the intracranial and anaplastic tumour types and genetic imbalances are predictive of tumour site, histological subtype, and age of the patient (Tamburrini et al. 2009; Merchant et al. 2010). Genetic differences in ependymoma may, therefore, be the key to successful risk classification for future clinical trials. The use of messenger RNA profiles in this relatively uncommon tumour type has, however, suggested no fewer than nine ependymoma subgroups (Johnson et al. 2010). Activation of the phosphoinositide 3-kinase (PI3K) pathway, which transduces signals from growth factors and cytokines to alter cell growth, proliferation, and apoptosis, was seen in 72% of 272 ependymoma samples (67% posterior fossa, 22% supratentorial and 6% spinal). That activation was associated with a worse prognosis. The PI3K pathway may, therefore, be a candidate bio-marker to identify patients responsive to therapies targeted against the PI3K pathway (Rogers et al. 2013). It remains unclear to what extent these new discoveries will shape clinical practice.

CLINICAL FEATURES AND IMAGING OF EPENDYMOMA
The main clinical manifestations are signs and symptoms of intracranial hypertension and focal deficits. Seizures are relatively uncommon. The clinical manifestations do not permit distinction from other posterior fossa tumours, although palsies of cranial nerves, torticollis and neck stiffness are more common with ependymomas. Imaging showing a midline mass, often filling the fourth ventricle and associated with hydrocephalus. Tumour signal is usually higher than or similar to that of the brain. Cyst formation and calcification are common, often resulting in mixed signal. Enhancement is typically present. Ependymomas may involve the cerebellopontine angle or extend into the cervical spinal canal and frequently metastasise along the CSF pathways. MRI better demonstrates extension of the tumour into the cerebellopontine angle, the cisterna magna and cervical spinal canal, and is important to determine precisely the volume to irradiate. Local recurrence, subarachnoid spread and ventricular seeding can be demonstrated by neuroimaging. In 15% of low-grade and 50% of high-grade infratentorial tumours, meningeal seeding, mainly to the spinal canal, can be detected by gadolinium-enhanced MRI but only rarely by CSF studies. Neuroradiological appearance is nonspecific. Small multiple intratumoural calcification is frequent.

TREATMENT OF EPENDYMOMA
A systematic review of 182 patients with intracranial ependymoma aged 2.4 months to 18 years sought to quantify the benefits of gross total resection (GTR) versus subtotal resection (STR) and of the addition of external beam radiotherapy (EBRT). Tumour location was supratentorial in 69% – a
substantially greater percentage than would be expected from population-based incidence — and infiltratentorial in the other 31%. Tumour histology was Grade II ependymoma in 63%, Grade III anaplastic in 35%, and unknown in 2%. EBRT was both cranial and spinal in 47% and cranial alone in 53% of those who received it. Overall survival rates were higher with infiltratentorial than with supratentorial tumour location. Progression-free survival rates and time to progression were highest after GTR with supratentorial tumours and after STR + EBRT with infiltratentorial tumours. This held true both for Grade II and Grade III histology. With Grade II tumours, GTR was the treatment with the highest overall survival rate while for Grade III tumours, in contrast, highest survival rates followed STR + EBRT (Cage et al. 2013).

Gross total excision is often technically very difficult as tumours may be adherent to the floor of the fourth ventricle or cerebellar peduncle, encompass cranial nerves and arteries in the cerebellopontine angle, invaginate the brainstem or surround the basilar artery and brainstem perforators. Complete resection is therefore often not possible but it results in the highest rates of event-free and overall survival. Several reports have concluded that the most important prognostic factor is complete resection, achievable in a higher proportion of supratentorial tumours, and, to a lesser extent, the use of radiotherapy (Van Veelen-Vincent et al. 2002; Grill et al. 2003; Merchant et al. 2004, 2009; Cage et al. 2013). The morbidity of aggressive surgery can include deafness and bulbar problems. Many surgeons consider accepting this significant morbidity in order to achieve gross total excision with its associated better survival rate.

Chemotherapy has no proven efficacy (Van Veelen-Vincent et al. 2002; Masimino et al. 2004; Merchant et al. 2004) and has had no impact on the incidence of local recurrences, which are the major threat. It may, however, be used to try to delay radiotherapy to beyond 3 years of age or to reduce tumour vascularity and thus increase the chance of complete resection.

Local irradiation has been clearly shown to improve survival rates and is associated with the highest survival rates when used immediately after surgery (Merchant et al. 2009a). New irradiation techniques, especially conformational, intensity modulated radiotherapy improve the tolerability of this treatment (Merchant 2002). The advent of conformal radiation therapy coincided with improved neuroimaging, neurosurgical navigation, and the systematic use of second surgery before irradiation for patients initially treated with incomplete resection. More effective surgery combined with high-dose postoperative radiation therapy increased local tumour control rates and event-free survival, shifting the pattern of failure from predominantly local to similar numbers of local and distant failures. Long-term sequelae following such treatments in specialist centres have been favourably reviewed (Merchant et al. 2010) and conformal therapy is now part of the first-line management of children regardless of age. Most treatment failures are related to local recurrences with or without spinal recurrence and isolated spinal recurrence is extremely rare. The need for spinal irradiation currently is therefore not generally accepted and is only indicated in malignant posterior fossa tumours with metastatic spread. The advantages of proton beam therapy (discussed in the Treatment: General Considerations section) are particularly pertinent to treatment of ependymomas that require high doses of local radiotherapy and are usually immediately adjacent to critical neural structures.

In summary, treatment includes as complete as possible resection, followed by radiotherapy in children over the age of 3 or 5 years, depending upon local practice criteria. Recurrent tumour is managed with repeat surgical resection if feasible and sometimes by repeat irradiation.

**Outlook of Ependymoma**

The prognosis remains guarded (Packer 2005). The small numbers of cases subdivided between age, location, histopathology, molecular subtype, degree of resection and stage have led to conflicting reports regarding prognostic factors (Tamburrini et al. 2009; Cage et al. 2013). A young age is the most important negative prognostic factor. Reported rates of 5-year survival vary widely from 24% to 82% (Rogers et al. 2013) but survival rates after complete resection have been reported to be as high as 90% (Van Veelen-Vincent et al. 2002). Although survival rates are reported to be poorer for children under 2–3 years, this may simply reflect the fact that a higher proportion of the youngest children have tumours in which complete resection is not achieved. Considering all intracranial ependymomas diagnosed at age 0–19 years in the US SEER registry from 1973 to 2011, 5-year survival was 85% and 30-year overall survival and cancer-specific survival of those in this age range that were in follow up having survived the first 5 years from diagnosis, were 57.3% and 68.6% respectively (Frandsen et al. 2015).

**Other Tumours of the Cerebellum and IVth Ventricle**

**Subependymomas** are rare in children. They are variously interpreted as hamartomatous growths of subependymal cells, or growths of astrocytes or oligoglia. These tumours grow extremely slowly and are often discovered fortuitously, for example at post-mortem examination. Most are located in the floor of the fourth ventricle. They may occasionally be symptomatic and then have a good prognosis. They may also occur supratentorially particularly in the lateral ventricle.

**Cerebellar haemangioblastomas** are rare in childhood. Approximately a quarter of the cases are an expression of the von Hippel–Lindau disease. In such cases the tumour may be discovered at a preclinical stage. Angiography visualises the solid part of these tumours, most of which are cystic with a single mural nodule. CT visualises the cysts, but visualisation of the nodule may be possible only after enhancement.
Solid tumours are rare and mimic meningeomas. MRI with or without gadolinium enhancement gives a characteristic picture with a ring of increased signal surrounding the tumoural cyst. The prognosis following resection is favourable for cystic tumours.

Cerebellar sarcomas are usually located to one cerebellar hemisphere (Oliveira et al. 2002). They run a rapid and severe course. On CT they present as areas of spontaneously increased density with ill-defined limits that become denser after contrast injection.

Schwannomas of the VIIIth nerve are rare in children. They may be unilateral or bilateral. In the latter case, they are usually a component of type 2 neurofibromatosis (Chapter 4). They can be responsible for deafness, often associated with facial paralysis and a contralateral cerebellar syndrome (Verstappen et al. 2005). The diagnosis rests on radiological demonstration of the tumour, which is most effectively visualised by MRI. They may be multiple and may involve the Vth nerve.

Other rare tumours of the cerebellopontine angle include epidermoid cysts and meningeomas. Approximately 30% of posterior fossa meningeomas in children show aggressive characteristics.

Arachnoid cysts are considered in the Arachnoid Cysts section at the end of this chapter.

Dermoid cysts of the posterior fossa are generally midline tumours. They are often associated with a cutaneous fistula piercing the occipital squama. They rarely behave as tumours and are more commonly revealed by meningitis. They may be associated with cervical spinal abnormalities including Klippel–Feil malformation (Muzumdar and Goel 2001). Removal of the cyst and tract is the effective treatment (Caldarelli et al. 2004).

Gangliocytoma of the cerebellum (Lhermitte–Duclos disease) presents as a diffuse increase in volume of several cerebellar lamellae, usually with a predominance on one cerebellar hemisphere. There is diffuse hypertrophy of both the white and grey matter. MRI gives highly suggestive images of localised lamellar hypertrophy with increased signal on T2-weighted sequences (Nagaraja et al. 2004). Lhermitte–Duclos disease is a feature of the Cowden syndrome of multiple hamartomas in at least one-third of cases. Pérez-Núñez et al. (2004) found asymptomatic cases by systematically studying cases of Cowden syndrome seen in a dermatological unit. Cowden syndrome is associated with mutations in the PTEN gene. This gene is also implicated in other hamartomatous syndromes such as Proteus syndrome and activation of the AKT/mTOR pathway (Abel et al. 2005).

Cognitive and Behavioural Sequelae of Posterior Fossa Surgery in Children

Complications of surgery for posterior fossa tumours are common. The presence of hydrocephalus or its development postoperatively is very common and may require endoscopic IIIrd ventriculostomy or shunting. Management of hydrocephalus with an endoscopic IIIrd ventriculostomy prior to tumour removal reduces the incidence of post-resection hydrocephalus (Di Rocco et al. 2013). The occurrence of cognitive, affective and behavioural problems has been recognised only in recent decades. The most striking manifestation is the so-called cerebellar mutism syndrome (CMS). This was originally described in 1984 (Wisoff and Epstein 1984), although the term itself was coined later. CMS was reported with increased frequency in the late 1990s and early 2000s in association with more aggressive surgery to resect posterior fossa tumours, most commonly medulloblastoma. It has been reported to affect 24% of children with medulloblastoma (Robertson et al. 2006) although some centres recognise it in only 5–10% of cases. It is characterised by development of mutism, or more precisely anarthria, in the peri-operative period, often associated with severe distress and transient personality change, emotional lability, decreased initiation of voluntary movements, impaired swallowing, ataxia, weakness and hypotonia. Like the cerebellar cognitive-affective syndrome described in adults (Schmahmann and Sherman 1998), mutism arises in association with damage to the vermis but the precise cause of CMS remains unclear.

Mutism may start within hours of surgery but onset has been reported as long as 9 days post-surgery. It lasts from 1 to 20 weeks. Although the mutism is transient, patients affected by it also have more significant neurological and cognitive deficits at 1 year and more cerebellar atrophy in proportion to the severity of the CMS (Wells et al. 2008, 2010). Dysarthria and ataxia may remain present for years and there is a clear association between postoperative mutism and subsequent cognitive impairment (Wells et al. 2008; Câmara-Costa et al. 2015). Rare cases of this syndrome have been reported following non-surgical insults (haemolytic–uraemic syndrome and cerebellitis) (Mwasaisingh et al. 2003). Reviews have identified associations between CMS and large tumours, pre-operative pontine compression, excessive para-vermian manipulation, damage to the dentate nuclei pathways, and lesions in some supratentorial structures. Ersahin et al. (2002) demonstrated by SPECT the presence of reversible circulatory disturbances. Recent studies have focused on abnormalities in efferent cerebellar pathways including the dentato-thalmo-cortical outflow tracts, detectable on diffusion tensor MRI (Morris et al. 2009; Avula et al. 2015). Bilateral surgical damage to the proximal efferent cerebellar pathways is strongly associated with CMS and it has been suggested that bilateral hypertrophic olivary degeneration after posterior fossa surgery may be a sensitive and, in appropriate clinical settings, reliable MRI indicator of bilateral disruption of the proximal efferent cerebellar pathways and consequently of CMS (Patay 2015). A standardised rating scale is needed to improve identification of the syndrome, risk factors for its occurrence, and means to prevent and treat it.

Resection of posterior fossa tumours is also associated with other cognitive or behavioural difficulties. Rønning et al. (2005) reported on persistent cognitive problems in young
BRAINSTEM TUMOURS

INCIDENCE
Tumours of the brainstem account for 5–11% of all intracranial tumours in childhood and for 13–29% of infratentorial tumours (Ostrom et al. 2014). The peak incidence of diffuse midline gliomas is between 5 and 9 years of age.

PATHOBIOLOGY OF BRAINSTEM TUMOURS
Pilocytic astrocytoma, diffuse midline glioma, H3 K27M-mutant (previously known as diffuse intrinsic pontine glioma) and glioblastoma are the three main histological types in series verified at autopsy or by biopsy. The histological and genetic basis of this classification is further discussed in the Gliomas of the Cerebral Hemispheres section. Histological and anatomical discrimination is critical for prognostication, as low grade glioma of the brainstem can be expected to respond to surgical decompression or debulking and may respond to chemotherapy or radiotherapy. In NF1, brainstem (and cerebellar) tumours are also seen but are generally non-progressive. NF1 associated tumours, which have the capacity for progressive enlargement, particularly affect brainstem (and/or visual pathways considered later in this chapter) and must be distinguished on cranial imaging from non-progressive focal areas of signal intensity (FASI) and neurofibromatous bright objects (NBOs). FASI are iso-intense on T1-weighted images and hyperintense on T2/FLAIR images and frequently affect the cerebellar hemispheres and basal ganglia. NBOs are focal, well-defined areas of high signal change on T2-weighted sequences found in the basal ganglia, brainstem, cerebellum, and occasionally in the subcortical white matter and dentate nuclei. NBOs are reported to proliferate during childhood and involute during adolescence and early adulthood.

Pilocytic astrocytomas tend to occur in the dorsal medulla or cranio-cervical junction and to become dorsally exophytic, growing into the fourth ventricle or the brainstem cisterns, whereas diffuse midline gliomas involve mainly the ventral pons engulfing the basilar artery and producing a diffuse increase in the size of the brainstem while remaining entirely contained within the brainstem parenchyma. A third group is formed by tumours of the tectal plate and peduncles and a fourth group includes tumours involving the medullospinal junction. Meningeal seeding, especially spinal, is not rare. Brainstem tumours are in fact a histologically heterogeneous group that includes cases with different clinical and imaging presentations and, especially, different prognoses and treatments (Jallo et al. 2004). Other variations include diffuse astrocytomas and rare cases of xantho-astrocytomas, which despite the presence of increased cellularity, pleomorphism and necrosis behave in a benign fashion.

CLINICAL FEATURES AND IMAGING OF BRAINSTEM TUMOURS
The history is usually short in the case of diffuse midline tumours. The clinical presentation is usually with multiple palsies of the VIIth to XIIth cranial nerves and ocular motor palsies. The classic clinical presentation is with a combination of ataxia, cranial nerve palsies and long tract signs. These features typically start unilaterally and eventually become bilateral. Symptoms of increased ICP usually appear late, and papilloedema is often absent. However, vomiting, unassociated with evidence of increased ICP, is often present, probably as a result of direct involvement of brainstem centres. Irritability and emotional instability are common. Paroxysmal facial or nuchal itching may be the presenting sign.

Dorsal exophytic gliomas developing posteriorly into the fourth ventricle can produce obstructive hydrocephalus. Tumours of the quadrigeminal plate (Daglioglu et al. 2003) and periaqueductal tumours (pencil tumours) usually present with hydrocephalus or with ocular motor signs, classically with Parinaud syndrome (loss of pupillary reaction to light, loss of voluntary vertical gaze, and eyelid retraction). MRI examination has shown these tumours to be a common cause of aqueductal stenosis. They are usually very slow growing or remain static for long periods, so no primary treatment is required beyond CSF shunting. Such lesions commonly occur with NF1. Brainstem hamartomas are frequent in this disease, usually involve the medulla and are commonly static or slow growing and occasionally regress spontaneously. CSF diversion is sometimes required and careful surveillance is prudent but more aggressive treatment is rarely needed.

Tumours of the cervicomedullary junction commonly originate in the upper spinal cord and grow upwards, or have a bulbar onset and a downward course. They manifest with...
involvement of the lower cranial nerves. Clinical features may include dysphonia, dysphagia, abnormal breathing, vomiting or quadriplegia. Atypical presentations include failure to thrive, acute hemiplegia, a syndrome of the cerebellopontine angle, intractable vomiting and psychiatric symptoms.

The diagnosis of brainstem tumour rests on imaging. CT showing an increase in the anteroposterior diameter of the brainstem with posterior displacement and compression of the fourth ventricle and of the interpeduncular and peripontine cisterns. The lateral and third ventricles are dilated in a quarter of the cases. In most cases, the density of the brainstem parenchyma is altered. Isodense tumours may appear only with enhancement. Hypodense lesions and ring enhancement are associated with a poor outlook and are mainly associated with higher grade glial tumours. Exophytic and dorsal expansion of the tumour, calcification and cysts are associated with lower grade astrocytomas and a better outlook. MRI (Fig. 14.11) gives a precise indication of the vertical extent of the tumour, better defines exophytic components and their relationship to neighbouring structures and allows a clear distinction between focal and diffuse gliomas.

Although tumour biopsy is not necessary for the diagnosis of diffuse midline glioma with typical radiological and clinical features, the case for obtaining additional information at biopsy becomes increasingly strong as better understanding of the molecular pathways of tumorigenesis brings biologically driven new therapies closer to clinical practice.

The differential diagnosis of brainstem neoplasms may be difficult. It includes brainstem encephalitis that may give rise to swelling of the stem and changes in density or signal, multiple sclerosis, haematomas or vascular malformations, parasitic cysts and tuberculomas. The last of these should always be considered, especially in patients from resource poor settings or with increased genetic susceptibility to mycobacteria. Behçet disease has been responsible for midbrain mass. Other mass lesions of that region such as enterogenic cysts or epidermoid cysts are exceptional and their images are very different from those of gliomas.

**TREATMENT OF BRAINSTEM TUMOURS**

Treatment of hydrocephalus with third ventriculostomy or ventriculo-peritoneal shunt may be required. The treatment of brainstem gliomas otherwise depends totally on the type of tumour. In the most common diffuse midline glioma, radiotherapy is often associated with short term remission from symptoms that then reappear and progress inexorably usually after an interval of 6–12 months. These tumours are sometimes surprisingly radiosensitive with dramatic resolution of imaging abnormalities after initial radiotherapy-induced swelling (‘pseudoprogression’) which may be mitigated with steroid therapy. Systemic chemotherapy has not been shown to be of benefit for this tumour type (Hargrave et al. 2006; Khatua et al. 2011).

For focal tumours, surgery, if necessary augmented by chemotherapy or, if this is not effective, irradiation, can be an effective tool. Biopsy is usually necessary to establish a diagnosis and rule out other rare diagnoses with therapeutic implications. Surgical resection of focal tumours, including exophytic tumours and those of the cervicomedullary...
junction, is indicated. These are usually benign, slow-growing tumours. Drainage of cysts associated with tumour may be of great therapeutic benefit.

**Outlook of Brainstem Tumours**

The outcome is correlated with the type, with diffuse gliomas having a younger age at onset and a much worse prognosis (Fisher et al. 2000). Diffuse midline glioma is not radio-curable and the median survival time following diagnosis is 10 months with very few children surviving for 2 years. Longer survival times are seen in a small minority of cases and probably relate to different types of glioma. By contrast, radical excision of focal low grade exophytic or cervicomedullary gliomas is sometimes possible, in spite of surgically uninviting appearance on imaging, and has been reported to give up to 100% survival rate.

**Tumours of the Midline and Base of the Brain**

Several pathologically diverse tumours arise from the midline region of the brain or from nearby structures such as cranial nerves, hypophysis, epiphysis and residua of the notochord. Craniopharyngioma is the most common midline tumour, followed by optic pathway tumours. Most midline tumours may produce, visual impairment, endocrine and metabolic abnormalities, and increased ICP through the development of hydrocephalus.

**Craniopharyngioma**

**Incidence**

Craniopharyngiomas represent about 50% of midline tumours and 4–9% of all tumours in infancy and childhood.

**Pathobiology of Craniopharyngioma**

They arise from small cellular rests that are considered to represent remnants of the embryonic Rathke pouch and may develop either in the suprasellar region or in both suprasellar and infrasellar regions. Purely infrasellar craniopharyngiomas are rare in children. Most craniopharyngiomas are partly or completely cystic. The microscopic appearance is variable with squamous epithelium that may be thickened or degenerate with formation of microcysts. Calcification is a frequent and important feature of craniopharyngiomas. Craniopharyngiomas may manifest at any age from the neonatal period to adulthood.

**Clinical Features and Imaging of Craniopharyngioma**

The clinical features of craniopharyngioma are the result of endocrine abnormalities, interference of the tumour with neighbouring structures, especially the optic pathways and increased ICP secondary to hydrocephalus. Delayed growth resulting from growth hormone deficiency is a common and often the first feature, although it is often found only in retrospect and may be absent in about half the cases. Weight gain due to hypothalamic disturbance may pre-date surgery. Excess weight gain, fatigability and declining school performance are common and may be associated with hypothyroidism. Diabetes insipidus results in excessive thirst and frequent urination. Less commonly, disturbances in fluid and electrolyte balance or abnormalities of autonomic function are present.

Visual disturbances and symptoms and signs of increased pressure are present at the time of diagnosis in a majority of patients and indeed are the most frequent initial manifestation in children. They include visual complaints, subtle alteration of alertness and conscious level, vomiting, bitemporal hemianopia, nystagmus and optic atrophy. Papilloedema is less common. Ataxia is occasionally observed, wrongly suggesting the diagnosis of a posterior fossa tumour. Somnolence, apathy and change of mood are not infrequently present including in patients without increased pressure. Unilateral loss of vision may supervene rapidly, mimicking optic neuritis. Focal neurological signs are uncommon.

Skull X-rays regularly demonstrate erosion of the dorsum sellae or enlargement of the sella turcica or both. Imaging (Fig. 14.12) showing, in most cases, a cystic lesion that is suprasellar or intra- and suprasellar. The suprasellar expansion may be quite large, compressing the third ventricle and reaching the septum pellucidum or even the corpus callosum. Retrosellar expansions are less frequent. The density of the tumour before contrast injection is heterogeneous. Calcification is present in 80% of cases. In rare cases, the tumour may be difficult to visualise or have an unusually dense appearance and extension. MRI is more precise than CT and medial sagittal view are particularly valuable for defining the relationship of the tumour to the optic nerve, chiasm, hypothalamus and brainstem, for the detection of small tumour remnants after surgery, and for exploration of the content of the sella turcica, which is difficult to assess by CT because of the presence of bone artefacts.

Endocrinological studies reveal a deficiency of growth hormone pre-dating surgery in approximately half the patients. Gonadotropic hormones are also low in about 50% of pubertal patients. Diabetes insipidus and deficits in thyrotropin (TSH) and adrenocorticotropin (ACTH) are less common in non-operated patients but appear in most patients following surgery.

The diagnosis of craniopharyngioma is often not made until a surprisingly long period of symptoms has passed. Acute presentation, young age and visual deficits at presentation are clinical features with an adverse prognosis. Once the diagnosis is suspected, other tumours of the region should be excluded. Rarely, a craniopharyngioma may produce the diencephalic cachexia syndrome.
Treatment of Craniopharyngioma

Surgical treatment is generally advised. Surgery combined with postoperative radiotherapy is the commonest protocol. The extent of surgery remains controversial. In general the goals of surgery are to decompress significant cysts and then to remove as much tumour below the hypothalamus as possible. Decompression of cysts can be achieved by open approaches, via a trans-ventricular endoscopic approach or via a stereotactic approach. For the suprachiasmatic and the subchiasmatic solid components there are a variety of approaches and techniques available including an extended endoscopic endo-nasal approach, interhemispheric approach, subfrontal approach, cerebellopontine angle approach, transalamina terminalis approach and a transsylvian approach. The appropriate approach depends on the location of the tumour. It is generally accepted that tumour adherent to the hypothalamus should not be removed. A number of procedures may be required prior to the second stage of treatment with radiotherapy. Attempts to avoid the many problems seen postoperatively (see following paragraphs) have led to a search for different therapeutic methods, including radiosurgery (Kobayashi et al. 2005), neuro-endoscopic surgery (Delitala et al. 2004), intracystic chemotherapy with bleomycin (Mottolese et al. 2001, 2005), and intracystic irradiation with radioactive agents. It is not currently possible to assess these methods fully but they may be of value in some cases.

In most cases, partial excision combined with postoperative irradiation results in a dramatic reduction of the recurrence rate from 75% to 30%, and is generally advised. It can be given as classic radiotherapy, or as proton beam radiotherapy or with stereotactic methods (Kobayashi et al. 2005). With either partial or total resection, the mortality rate has considerably decreased and survival rates are now high (Muller et al. 2004a; Poretti et al. 2004; Stripp et al. 2004). Recurrence rates differ in different studies but do not seem to be grossly higher after partial excision than those obtained with attempted ‘complete’ removal. In a large series of 121 craniopharyngiomas in children and adults, 23% with a suprasellar component, complete removal was achieved in 16 patients and partial removal in 84, while other techniques were employed in other patients including cyst drainage or removal. Radiotherapy was used in about a third of the patients. Survival rates were best in cases of compete removal but were generally high in all (Karavitaki et al. 2005).

Outlook of Craniopharyngioma

The major consideration in the management of craniopharyngioma is now more the quality of survival following treatment...
Part VI Tumours and Vascular Disorders

rather than survival. The avoidance of damage to the hypothalamus is important to the achievement of this end. Complete removal and radiotherapy are fraught with many dangers. They may produce deafness, lowering of IQ levels, endocrinological disturbances and even neurological sequelae. For young children with only partial resection, it may be best to delay irradiation as much as possible because of the greater severity of unwanted effects of irradiation in that age group.

Panhypopituitarism is common postoperatively and poses therapeutic, sometimes life-threatening, problems that require special attention (Theodosopoulos et al. 2012). Diabetes insipidus develops in three-quarters and deficiency of TSH and ACTH of the patients in one-quarter of the patients. ADH deficiency in 9–34% may be masked until ACTH deficiency is corrected. However, a paradoxical growth spurt following surgery has been reported.

Growth retardation can be treated with growth hormone with reasonable success (Muller et al. 2004b). The development of gross obesity in some children, often associated with behavioural problems and loss of neuro-vegetative homeostasis, raises major practical problems and may represent a cardiac threat (Lustig et al. 2003). Unlike endocrinological disturbance, it is not amenable to treatment and seems to be due to surgical injury to the hypothalamus. Prediction of these complications is difficult (Hayward et al. 2004). The current trend, therefore, is to leave some tumour tissue rather than taking these risks.

A variety of neurocognitive deficits are often associated. Epilepsy is present in around 10% of patients and may be intractable medically, especially when of frontal lobe origin, and require surgical treatment. The role of focal radiotherapy in causing epilepsy and in determining IQ in this group of patients with complex problems is debated but newer techniques for delivering radiotherapy to a field with sharply defined margins sparing adjacent neural tissue, discussed in earlier parts of this chapter, offers the promise of reduced morbidity. A long-running longitudinal follow-up study of 261 patients diagnosed before 2000 with childhood-onset craniopharyngioma reports that 20-year overall survival was 84% and 95% in those with and without hypothalamic involvement respectively and that this was not related to degree of resection, sex, age at diagnosis, or year of diagnosis. Progression-free survival was 39%, 52% and 77% in patients aged less than 5 years, 5–10 years and more than 10 years at diagnosis respectively. Hypothalamic involvement led to severe weight gain (+4.59 standard deviations) in the first 8–12 years (with no subsequent further increase) and to impairment of quality of life by obesity, physical fatigue, reduced motivation, dyspnea, diarrhoea and nonoptimal psychosocial development (Sterkenburg et al. 2015).

In summary, the management is complex and controversial and the need for a multidisciplinary approach including all relevant disciplines and with the necessary priority being accorded to quality of survival, essential to the management of all intracranial childhood tumours, is paramount (Hayward et al. 2004).

VISUAL PATHWAY AND HYPOTHALAMIC TUMOURS

INCIDENCE
Visual pathway tumours represent 3–5% of primary intracranial neoplasms in children. A large majority of these are gliomas. Other entities such as nerve sheath tumours, meningioma, and oligodendroglioma and other Grade II tumours of optic radiation are rare in childhood but do occur. Historically these have been appropriately referred to as visual pathway tumours until tissue diagnosis is made. Increasingly, however, biopsy is considered a prerequisite for active management, even in NF1 and/or with characteristic imaging appearances, because molecular genetics is increasingly likely to influence the decision whether to observe or treat and the choice of chemotherapeutic agent. The section below relates to visual pathway gliomas (VPG) only. Ninety per cent of VPGs occur in children.

Approximately 26–36% of VPGs involve the pre-chiasmal portion (optic nerves) and 64–74% involve the chiasm and tracts with or without involvement of the anterior third ventricle. NF1 is present in 10–15% of symptomatic pilocytic astrocytomas and this tumour type affects up to 20% of those diagnosed with NF1 in childhood. These are key observations.

PATHOBIOLoGY OF VISUAL PATHWAY GLIoMAS
Visual pathway gliomas (VPGs) are typical pilocytic astrocytomas consisting of compact fibrillar areas with Rosenthal fibres and looser areas characterised by microcysts, or mixed astrocytomas and oligodendrogliomas. Malignant changes are rare. Molecular biological aspects were considered above, in the account of low grade gliomas of the cerebellum and brainstem.

CLINICAL FEATURES OF VISUAL PATHWAY GLIoMAS
The clinical presentation of VPGs depends on the anatomical location of the lesion. Anterior lesions, confined to the optic nerve anterior to the chiasm, usually present with proptosis, which is often a late sign and monocular visual loss developing over 6–12 months. This may easily be missed in children who adjust to gradual loss of vision. Papilloedema or optic atrophy are present on fundus examination.

In children with posterior lesions involving the optic chiasm or extending further back along the optic radiations, loss of visual acuity is the common presentation. It is often asymmetrical or even unilateral, and in infants aged less than 2 years, may be accompanied by an acquired pendular nystagmus that should not be mistaken for congenital nystagmus. Rarely monocular nystagmus mimicking spasmus nutans may be seen. Sudden visual loss simulating optic neuritis may occur. Visual field loss is variable. A symmetrical bitemporal hemianopia is less common than irregular, asymmetrical field defects or a central scotoma with contralateral impairment of the visual field. Fundoscopic examination generally
showing optic atrophy, although papilloedema is occasionally noted. Papilloedema and nystagmus suggest chiasmatic involvement, whereas blurred discs with visual loss suggest an intraorbital lesion.

With large lesions, there may be compression of the third ventricle with hydrocephalus, and involvement of the hypothalamus may give rise to precocious puberty, diabetes insipidus or obesity or, rarely, to diencephalic cachexia.

Midline location supratentorial tumours typically have clinical features of hypothalamic disturbance, visual symptoms and signs and symptoms of raised ICP. A significant proportion present in infancy and early childhood with the classic features of hypermetabolic diencephalic syndrome (Kilday et al. 2014) of Russell. This is not limited to gliomas of the floor of the third ventricle and is common with optic gliomas and occasionally encountered with craniopharyngiomas and posterior fossa tumours. Conversely, other manifestations such as obesity, diabetes insipidus, hypogonadism and hydrocephalus are frequently encountered. This presentation is often associated with hypopituitarism, signs of accelerated head growth and visual signs or symptoms such as dysconjugate eye movements or nystagmus. The clinical feature of failure to thrive may predominate and indicate the need for brain scanning (Fig. 14.13). In this early age presentation, the tumours can be very large, occupying a significant proportion of the supra-tentorial compartment. When chiasmatic pilocytic tumours present later in life, the tumours are smaller but can still cause significant neurological and endocrine problems and continue to grow.

Hypothalamic tumours predominantly present in the first 5 years and tend to stabilise and stop growing after age 5 years, although there are exceptions.

NF1 and Visual Pathway Gliomas

In cases associated with NF1, tumours can involve one or many sectors of the visual pathways from optic nerves, presenting, with proptosis and optic atrophy, to the chiasm and optic radiations. A study of 84 VPGs in NF1 reported that involvement was confined to the anterior visual pathway in
27% (including 5% with bilateral involvement), to the chiasm only in a further 27%, to one or both optic nerves plus the optic chiasm in 30%, and to chiasm and optic radiations in 6%. The remaining 10% had combined involvement of anterior visual pathway, chiasm and optic radiation (Guillamo et al. 2003). Screening systematically all patients with neurofibromatosis for optic gliomas would probably increase the apparent frequency of these tumours. However, current recommendations based on symptomatic tumours may not be applicable to gliomas discovered by systematic investigation in patients with neurofibromatosis. Therefore, screening is not recommended.

**Imaging of visual pathway gliomas**

Imaging, especially MRI, is of primary importance for the diagnosis of VPGs. High-resolution CT can detect even small tumours in the orbit but is less effective than MRI for assessment of intracranial extensions of optic gliomas (Fig. 14.14). The density of chiasmatic tumours is close to that of the cerebral tissue, and homogeneous enhancement is usually obtained following injection of contrast. Tumoural cysts and calcification may be present. MRI visualises small intracranial tumours extremely well, and multiplanar views are valuable to that effect. Intraorbital gliomas are readily identified on frontal cuts, and it has been reported that MRI identifies perineural arachnoidal gliomatosis characterised by a fusiform area of high signal intensity with a central core of lower intensity in patients with neurofibromatosis. Visual evoked potentials are apt to be more abnormal in patients with chiasmatic gliomas than in those with more anteriorly located tumours and visual evoked potentials may be used to follow up the course of optic gliomas (Trisciuzzi et al. 2004). False positives are, however, common, limiting the usefulness of the technique.

**Treatment of visual pathway gliomas**

The review of the surgical management of these tumours which can be found in the chapter by O’Kelly and Rutka (2008) is recommended. Where surgical resection is not feasible and if the tumour is causing severe symptoms or is progressive and threatens neurological function, primary chemotherapy is currently recommended. The commonest reason for considering non-surgical therapy for low grade glioma is in VPG, where saving vision in the young children who present is a serious concern for parents.

**The history of evaluations of chemotherapy in low grade glioma**

Historically, radiotherapy was used leading in many cases to severe neurotoxicity, affecting the child’s subsequent growth, endocrine and cognitive development and the risk of second tumours (Fouladi et al. 2003a). The introduction of chemotherapy in the 1980s was shown to successfully control tumour progression in very young children with progressive, unresectable tumours. Vincristine and Actinomycin D were used initially. A series of phase 2 trials identified a range of chemotherapy agents with comparable activity when given alone, or in combinations. Where radiotherapy had been used it had produced both symptomatic and imaging responses, saving vision in a significant proportion of cases. Where chemotherapy was used, drug resistance did not seem to occur. Drug selection was driven by seeking to avoid drugs with unacceptable toxicity; for example, cisplatin-induced hearing loss, high cumulative doses of alkylating agents – such as cyclophosphamide, etoposide, CCNU and procarbazine, or genotoxicity, particularly in NF1 – a cancer predisposition syndrome. The most widely used combination of drugs has been vincristine and carboplatin.

Two randomised treatment trials have been reported. A trial of two versus four drugs (vincristine and carboplatin – VCP versus thioguanine, procarbazine, CCNU and vinblastine – TPCV), given over a 12-month period to all post-biopsy patients regardless of their disease progression status, was undertaken by the US Children’s Oncology Group (COG) in USA (Ater et al. 2012). The VCP arm and the TPCV arm included one and three potentially genotoxic drugs, respectively. Allocation to TPCV, not in regular use as a primary treatment, was associated with a superior progression-free survival at 12 months. A European SIOP-E trial found no inter-arm difference in progression-free survival rates associated with random allocation to the addition (or not) of etoposide to a standard VCP induction regimen of chemotherapy (Gnekow et al. 2017).

The experience of these trials has highlighted the need to study children with and without NF1 separately, the need for new targeted agents in those who demonstrate early progression,
and the need to measure vision and neurological symptoms as specific outcome measures in future trials.

The combination of vincristine and carboplatin remains the first-line treatment for newly diagnosed patients with low-grade glioma with progressive disease or at risk of symptomatic disease. Exploring the use of less toxic chemotherapy with fewer side effects in low risk patients; for example, NF1-associated tumours, is a priority in this benign and self-limiting condition. Late or sustained progression after stopping treatment, particularly in younger children with hypothalamic chiasmatic tumours, sometimes requires multiple phases of therapy, including radiotherapy and occasionally surgical resection. Selecting cases for observation versus immediate treatment remains a challenge, a consensus is emerging where immediate treatment is recommended in children when clinical or radiological evaluation suggests that the tumour threatens vision bilaterally there is a history of visual deterioration, or the child is very young so that visual testing is limited (Taylor et al. 2008). Symptomatic proptosis is also an indication for medical therapy if there is the possibility of retaining or saving vision.

Conventional conformal (photon) radiation therapy has a useful role in older children who do not have neurofibromatosis, especially for the treatment of bilateral tumours and chiasmatic gliomas (Merchant et al. 2009b) and proton beam therapy has also been used in this situation. Reduction in size of the tumour and improvement in vision undoubtedly occur.

**Outlook of Visual Pathway Gliomas**

The combination of cisplatin and vincristine, applied according to standardised selection criteria, is associated with 5-year overall survival rates greater than 85% and 80% rate of stabilisation of symptomatic progressive disease in international studies that included Grade I pilocytic astrocytoma in 60% and Grade II diffuse astrocytoma in 40%. The latter group had poorer progression-free survival with the same treatment (Stokland et al. 2010; Gnekow et al. 2012). Progressive disease was seen in up to 30% of cases, predominantly children under 1 year at diagnosis with diencephalic syndrome and hypothalamic tumours. VPGs and other low grade gliomas associated with NF1 had a more favourable prognosis for progression-free and overall survival.

With this experience of chemotherapy responses and the experience of radiation neuro-toxicity, the decision to use radiotherapy is now usually deferred until chemotherapy and surgery has been seen to fail. We can expect 90% non-progression rates at 6 months in children presenting with newly diagnosed VPG. Their natural history is for the most part slow. They are often diagnosed early but tend to remain static in many cases and occasionally regress. However, they are tumours rather than hamartomas and some, particularly in children under the age of 8 years, may have a rapid evolution that is difficult to predict. In general the risk of tumour progression is greatest during the first 3–5 years of life.

In children diagnosed with NF1, surveillance programmes of visual function are in place to identify children with visual changes justifying brain imaging to look for VPGs and screening with imaging is used in some countries (Simmons and Gogi 2010). There is uncertainty surrounding methods for early detection that compound uncertainties surrounding the criteria for selecting patients for observation versus treatment (Opocher et al. 2006; Campagna et al. 2010) as well as the efficacy of treatments to save vision. Furthermore there is an established lack of correlation between changes in imaging appearances and visual function. These factors highlight the need for new, well-designed clinical trials focused upon the impact of treatments for patients at greatest risk of visual loss with new treatments directed at saving vision. The mechanism of nerve injury in NF1 needs to be described so as to help select more effective targeted drugs for the future.

**Tumours of the Pineal Region**

Although tumours of the pineal region are classically considered to be uncommon in children, representing less than 2% of all intracranial tumours (except in Japan and Korea, where they account for 5–10%), their actual frequency may be higher if they are correctly diagnosed. These tumours are a heterogeneous group with both benign and malignant types (Table 14.7) and raise difficult therapeutic problems. Except for astrocytomas, pinealoblastomas and perhaps a few

differentiated teratomas, they are malignant tumours. The clinical features of pineal tumours are described in the account of germ cell tumours below.

GERMINAL CELL TUMOURS

INCIDENCE
Germ cell tumours are by far the most common pineal region tumours. Intracranial germ cell tumours represent a rare and histologically heterogeneous group of predominantly midline neoplasms. Incidence varies substantially across the continents, with an overall incidence of 0.6, 1.0 and 2.7 per million per year in North America, Europe and Japan respectively.

PATHOBIOLoGY OF GERMINAL CELL TUMOURS
Histologically, these tumours are often segregated into three groups: pure germinoma, teratoma, and non-germinomatous germ cell tumours (NGGCTs). Germinomas are the most common tumour of the pineal region, accounting for one-third to one-half of cases. The typical two-cell type germinoma consists of a mixture of large clear cells and small lymphocyte-like cells. Non-germinomatous germ cell tumours are often mixed tumours and can be composed of any combination of yolk sac tumour, embryonal carcinoma and choriocarcinoma. Confusingly, non-germinomatous germ cell tumours can also contain germinoma or teratoma, or both (Murray et al. 2015).

CLINICAL FEATURES AND IMAGING OF GERMINAL CELL TUMOURS
Clinical features are largely determined by their localisation but their histological nature also has a bearing on their symptomatology. The predominant symptoms are related to the effects of increased ICP and hydrocephalus in 90% of patients, including headache, vomiting and lethargy. Partial or complete Parinaud syndrome is present in 50% of cases (Cho et al. 1998). Polyuria and polydypsia are relatively common. Isosexual precocious puberty is a classic finding. Neurological signs at presentation may include ataxia and, sometimes, focal neurological dysfunction.

Imaging features are those of a mass lesion in the pineal region. However, in a significant proportion of germinomas, the tumour is located in the suprasellar region, invading the floor of the anterior third ventricle, even in the apparent absence of a pineal germinoma, the so-called ectopic germinoma. Suprasellar tumours were found in five of 11 cases treated by Janmohamed et al. (2002). These ectopic tumours may be the result of seeding from an undetectable pineal primary.

The neuroimaging features of germinoma are fairly distinctive (Fig. 14.15). They are iso intense or slightly hyperintense to brain parenchyma on T1 and T2 sequences (Liang et al. 2002). The tumour presents as a round mass of slightly higher density than the brain, sometimes with small, spotty calcification. This should be distinguished from physiological pineal calcification, which is never present before age 4, and is found in 3% of 5–8-year-olds, 12% of 9–12-year-olds, and 19% of 13–16-year-olds. After contrast, the density increases homogeneously. MRI showing well-defined lesions with homogeneous enhancement. Thirty percent of pure germinomas are bifocal with an additional suprasellar component. The tumour is highly invasive, and tumour cells are almost always present in the CSF although distant metastases to the spine are rare (2–15%); seeding is mainly along the third and lateral ventricles producing a hyperintense rim around the ventricular cavities on enhanced images. Extraneural metastases are rare.
On neuroimaging, NGGCTs present as heterogeneous masses with areas of high signal due to calcification, haemorrhage, high-protein fluid or fat. A cystic component is present in many cases. Most of them are malignant and the prognosis without therapy is dismal.

**Treatment of Germinal Cell Tumours**

The first steps in management are to treat obstructive hydrocephalus (if present) in the acute setting and to obtain a diagnosis. Concepts regarding treatment of these tumours have changed considerably over the past two decades. Tumour markers (alpha-fetoprotein or β-HCG) may be found in CSF and/or serum (Calaminus et al. 2005). Patients with serum or CSF tumour marker concentrations below national protocol thresholds require surgical biopsy for intracranial germ cell tumour diagnosis, regardless of imaging findings. Conversely, patients with consistent radiological imaging and elevation of serum or CSF tumour markers above nationally defined protocol thresholds do not require surgical biopsy for intracranial germ cell tumour diagnosis. Instead, treatment may be initiated, based on the diagnosis suggested by the markers (Murray et al. 2015). Surgical approaches with irradiation in combination with chemotherapy have become the accepted treatment for some types, whereas irradiation alone or chemotherapy alone tended to be reserved for localised germinomas. Current surgical techniques also include neuro-endoscopic biopsy (Gangemi et al. 2001; Popple et al. 2001) or resection and stereotactic surgery (Hasegawa et al. 2003).

Germinomas are exceptionally sensitive to both radiotherapy and to platinum-based chemotherapy but the GCT-96 trial showed that ventricular recurrences sometimes occurred after local radiotherapy. The regimen used in the subsequent GCT II trial has achieved excellent cure rates with a regimen of whole ventricular irradiation with 24Gy plus a 16Gy boost to the involved field. Comparison of whole-ventricular-plus-involved-field radiation with chemotherapy plus lower dose irradiation to the involved field alone has not yet revealed any difference between these treatment options in respect of long-term neurocognitive function. Irradiation alone is reported to give remission rates of the order of 90%. A 2015 report of a Delphi consensus (Murray et al. 2015) has made a number of statements regarding the contemporary standard of care for germ cell tumours. It states that patients with intracranial germinoma should receive radiotherapy to maximise their chance of cure. Focal radiotherapy fields alone are insufficient localised germinoma, and whole ventricular radiotherapy is required while chemotherapy is accepted as an effective strategy to reduce the dose of radiotherapy. Patients with intracranial germ cell tumours containing malignant non-germinomatous components should have residual disease surgically resected before completion of therapy and receive a combination of chemotherapy and radiotherapy. If they also have metastatic spread, their treatment should include craniospinal radiotherapy. After completion of therapy, tumour markers may be predictive of recurrence before the presence of clinical or radiographic evidence. For NGGCTs, high-dose chemotherapy with haematopoietic stem cell rescue should be employed at relapse with surgery and additional radiotherapy where feasible (Murray et al. 2015).

**Outlook of Germinal Cell Tumours**

Depending on the histological nature, the 5-year actuarial survival rates in the study of Ogawa et al. (2003) were 100% for benign tumours, 68% for those of intermediate severity and 8% for those graded as of poor prognosis. More recent studies, employing treatments as per the consensus views cited above, report 5-year event-free survival rates in excess of 70% for ‘standard-risk’ NGGCTs and good rates of salvage when more intensive therapy is given at the time of relapse (Murray et al. 2015).

**Other Pineal Tumours**

**Parenchymatous Tumours of the Pineal Body**

Account for only a minority of pineal region tumours. Pinealocytomas are benign tumours. Pinealoblastomas are malignant and tend to metastasise along the CSF pathways especially to the walls of the ventricles (Cuccia et al. 2006).

**Astrocytomas of the Pineal Region**

Are mostly benign tumours that run a slow course and may present as detectable masses or more rarely as small ‘pencil gliomas’ of the aqueduct with a picture of apparently pure aqueductal stenosis. Biopsy is not required when there is a classic radiological appearance and hydrocephalus is best managed with an endoscopic IIIrd ventriculostomy. Radiological surveillance is generally the accepted management. An occasional anaplastic astrocytoma may have a malignant course. In most cases, astrocytomas present as isodense tumours of small to moderate size with some enhancement after contrast administration. Very small astrocytomas are best demonstrated by T2-weighted sequences on MRI, which is particularly useful to detect small intrinsic tumours of the cerebral peduncles or quadrigeminal plate. Surgical resection is indicated for extrinsic astrocytomas that are growing.

**Cysts of the Pineal Region**, although they are not really tumours, may present in the same manner. Many of them are fortuitously found on neuroradiological examination and are asymptomatic. Mandera et al. (2003) studied 24 cases, including 17 in female patients. Six required surgical treatment. Monitoring of these lesions is advised as they may be associated with pinealocytoma. No treatment is required but longitudinal follow up is advised. Large symptomatic cysts should be surgically managed. Single or multiple cysts in the pineal region are common in Aicardi syndrome. Ectopic retinoblastoma may involve the pineal body. In association with bilateral ocular retinoblastoma, it is known as ‘trilateral retinoblastoma’.
OTHER TUMOURS OF THE IIIrd VENTRICLE AND SELlar REGION

Adenomas

Pituitary adenomas are rare in infancy and childhood, and the majority of cases are seen in older children and adolescents (Pandey et al. 2005). The clinical features of adenoma include endocrine disturbances and visual defects. The various types encountered in adults can also occur in the paediatric age range.

Most pituitary tumours are non-functioning adenomas. Prolactin secreting adenomas (prolactinomas) are the most frequent functioning adenoma. They usually present in adolescents as delayed growth and puberty, and amenorrhoea (Duntas 2001; Cannavo et al. 2003). Endocrine investigations reveal a very high level of prolactin often with low levels of growth hormone, TSH and ACTH. Cushing disease is a common cause of Cushing syndrome and occurs as a result of ACTH-producing adenoma in the anterior pituitary gland. Growth hormone-producing adenomas are also quite rare in childhood. They may be associated with acromegaly (in adults) or gigantism (in children).

Clinical features and imaging of adenomas

Most patients present with endocrine disturbance or visual field defects such as bitemporal hemianopia from impingement on the optic chiasm. MRI is the imaging investigation of choice for suspected pituitary disease. Occasionally CT may be valuable in identification of the bony anatomy. Adenomas are typically hypodense on T1-weighted sequences, while their appearance is more variable on T2-weighted images. A convex upper margin of the gland and an increased vertical diameter and surface of the pituitary image for age are characteristic.

Treatment of adenomas

Therapy is mainly surgical. The most common surgical approaches are endo-nasal trans-sphenoidal, using either an endoscopic approach or a microsurgical approach to the sella. Occasionally, craniotomy is required for giant tumours. Irradiation is occasionally required although repeat surgical resection is the preferred option. Cabergoline, a dopamine antagonist inhibitor of the synthesis and release of prolactin, may dramatically reduce the size of large prolactinomas and is the treatment of choice for prolactinomas.

An excellent review of the surgical management of pituitary tumours in adults can be found in Schmidek and Sweet’s book (Vaughan et al. 2012). These techniques apply, broadly speaking, to paediatric patients.

Hypothalamic Hamartomas

Pathobiology

Hypothalamic hamartomas are ectopic masses of neuronal and glial tissue that may be small and pedunculated or sessile and relatively large. They arise from the region of the tuber cinereum or mammillary bodies and develop into the interpeduncular cistern. Their histological structure resembles that of grey matter with varying proportions of neurons, glia and fibre bundles. They do not behave as true tumours. Rather, they grow at approximately the same rate as the rest of the encephalon and never produce symptoms or signs of nerve tissue compression. Rare cases are part of the Pallister–Hall syndrome that also includes polydactyly and imperforate anus. Sixteen cases were studied by Boudreau et al. (2005), who found these cases to be of lesser severity on average than isolated cases.

Clinical features and imaging of hypothalamic hamartomas

Clinically, hypothalamic hamartomas may remain asymptomatic. In infants and young children they are often associated with a peculiar epilepsy syndrome. Precocious puberty is the most common clinical manifestation. Its central origin is demonstrated by the increased levels of gonadotropins. The epileptic syndrome associated with hamartomas has an early onset, usually before 2 years of age, and is characterised by the frequently repeated occurrence of attacks of laughter (gelastic fits) (Chapter 16). Epilepsy in hamartomas is rarely controlled completely with drugs (Arzimanoglou et al. 2003; Freeman et al. 2004). The imaging appearance of hamartomas is characteristic, with a well-limited rounded isodense mass surrounded by CSF in the interpeduncular cistern. On MRI the mass is clearly definable in multiplanar sequences. A more intense signal than the surrounding brain is present on T2-weighted sequences in 93% of cases, and a low signal on T1 sequences in 74%. Spectroscopy may show a decrease in N-acetyl aspartate and in myoinositol (Arzimanoglou et al. 2003; Freeman et al. 2004). Small hamartomas may be lateralised, difficult to visualise and require especially careful MRI studies.

Treatment of hypothalamic hamartomas

Resection of the hamartoma is difficult but can control the epilepsy (Polkey 2003), although it does not always result in disappearance of the seizures. Endoscopic approaches to the IIIrd ventricle are often employed. Disconnection of the hamartoma is also effective. Fohlen et al. (2003) reported on 18 cases so treated; nine became seizure-free and marked improvement was obtained in the remaining patients. However, seizures may originate in the hamartomatous tissue, and resection of the tumours may be effective. Gamma knife treatment has also been used (Regis et al. 2004). Callosotomy has been suggested for resistant seizures but is of limited value. (For a more detailed review of surgical treatment options see Chapter 16 and Arzimanoglou et al. 2016.)

Chordomas

Pathobiology

Intracranial chordomas are extra-axial lesions generally located along the clivus. Chondromas, developing from the
spheno-occipital synchondrosis, are indistinguishable from chordomas, unless associated with Ollier disease. Nine familial cases are on record; in one of which a tumour suppressor locus (1p36) was mapped (Miozzo et al. 2000).

**Clinical features and Imaging of Chordomas**

Chordomas, when located anteriorly, may give rise to symptoms and signs similar to those of other parasellar tumours. More posteriorly located chordomas produce palsies of the lower cranial nerve pairs. Plain skull X-rays may show destruction and deformation of the sella turcica and body of sphenoid bone. On CT, chordomas present as well-delineated masses with frequent calcification and contrast enhancement.

**Treatment of Chordomas**

Surgical resection via an endoscopic approach is often performed although complete resection can be very challenging. Proton beam radiotherapy is often given to control tumour growth.

**Other Parasellar Tumours**

- **Colloid cysts of the third ventricle** are very rare in children (see Intraventricular Tumours section).
- **Choroid plexus papillomas of the third ventricle** have been reported (see Intraventricular Tumours section).
- **Paranasal sinus mucoceles** are rare pseudo-tumoural lesions in children, presenting as dilated fluid-filled masses due to the accumulation of mucus and secretions within an occluded sinus cavity (Uren and Berkowitz 2003). All sinuses including the sphenoid sinus may be involved. Mucoceles result from infection (Uren and Berkowitz 2003), trauma, congenital deformity of the ostium, or cystic degeneration of the mucosa. Mucoceles may present with ocular motor palsies, decrease in visual acuity and various eye signs. On CT they present as spontaneously dense areas with possible intracranial extensions.

---

**Tumours of the Cerebral Hemispheres**

**Incidence**

Tumours of the cerebral hemispheres are more common in younger than in older children. Their clinical manifestations are polymorphic with a high incidence of focal neurological symptoms and signs. Most supratentorial tumours are gliomas. Low grade astrocytomas (WHO grades I and II) are the most frequent hemispheric tumours, accounting for 21% of all supratentorial neoplasms in children.

**Gliomas of the Cerebral Hemispheres**

**Pathobiology**

In contrast to the 2007 WHO classification of tumours, WHO CNS 2016 groups all diffusely infiltrating gliomas, whether astrocytomas or oligodendrogliomas, together based not only on their growth patterns and behaviours but also on their shared mutations in the IDH1 and IDH2 genes. Diffuse gliomas therefore now include WHO Grade II and III, Grade IV tumours and the related diffuse gliomas of childhood. Fibrillary astrocytomas, a term dropped from WHO CNS 2016, fall within this group (Louis et al. 2016). The great majority of Grade II and III diffuse astrocytomas are IDH-mutant while the majority of IDH-wildtype diffuse gliomas are glioblastomas. The term ‘gliomatosis cerebri’ has been dropped although the growth pattern to which it referred is mentioned as a special pattern of spread in some diffuse gliomas that is defined by involvement of at least three cerebral lobes with frequent bilateral growth and regular extension to involve infratentorial structures (Louis et al. 2016).

One narrowly defined group of tumours, primarily occurring in children, is characterised by K27M mutations in the histone H3 gene H3F3A or closely related HIST1H3B gene and is termed diffuse midline glioma, H3K27M mutant. Besides their diffuse growth pattern, they typically develop in the midline (thalamus, brainstem or spinal cord). This group includes tumours previously referred to as ‘diffuse, intrinsic, pontine glioma’, another appellation rendered obsolete by the 2016 classification (Louis et al. 2016).

Not included in the above are pilocytic astrocytomas, pleomorphic xantho-astrocytomas and subependymal giant cell astrocytomas all of which have a more circumscribed growth pattern, lack IDH family gene family mutations and frequently have BRAF gene alterations or TSC1/TSC2 mutations. Diffuse astrocytomas and oligodendrogliomas are now therefore classified as being more alike than are diffuse and pilocytic astrocytomas. Pilomyxoid astrocytomas have extensive histological and genetic overlap with pilocytic astrocytomas and may be better classified as Grade I rather than Grade II but are currently ungraded (Louis et al. 2016).

**Low-Grade Gliomas**

**Incidence**

Cortical tumours tend to present later in childhood and early adolescence with focal neurological signs or epilepsy. Their resectability is determined by the eloquence of their anatomical location. Histological grading in cortical location is very
important as their presentation during adolescence raises the possibility of non-pilocytic tumours with the associated risk of subsequent malignant transformation.

**Pathobiology**

The predominant types are pilocytic or diffuse gliomas as discussed in sections on cerebellar and brainstem tumours above. Rare subtypes include SEGA associated with tuberous sclerosis complex, pleomorphic xanthoastrocytoma, cerebral astrocytoma with extensive calcification, mixed neuronal-glial tumours including ganglioglioma, dysembryoplastic neuroepithelial tumour (DNET) and desmoplastic infantile astrocytoma/ganglioglioma (DIA/DIG).

**Clinical features and imaging**

The clinical presentation of parenchymal supratentorial tumours can be due to generalised raised ICP, focal neurological deficit or seizures. The presentation of the focal neurological deficit depends more on the location of the tumour than on its histological nature. Signs of high ICP and focal neurological manifestations may occur in isolation or in various combinations. Headaches, nausea and vomiting may be the presenting manifestations in about 20% of patients, mainly those with malignant tumours.

Epileptic seizures are the most common neurological manifestation, particularly in slowly growing, benign tumours such as low grade astrocytomas and oligodendrogliomas. Seizures are mostly focal. Partial motor and partial complex seizures are the most frequently observed types. Sensory seizures may be especially suspect. On the other hand, uncinate seizures may not be more likely than other types to be due to brain tumours. The occurrence of generalised seizures and of bilateral paroxysmal EEG abnormalities does not exclude the possibility of a tumour (Bourgeois et al. 1999). Long-standing epilepsy used to be frequent in patients with brain tumours but the advent of CT and MRI has led to earlier recognition of the underlying tumour. Epilepsy is the first presenting symptom in around 9% of childhood brain tumours and will occur at some point prior to diagnosis in about 15% of cases. In contrast to other symptoms of a brain tumour, it often occurs without other suggestive symptoms or signs, and the importance of imaging for early diagnosis, especially in those with onset in infancy or with any focal clinical or EEG features, cannot be overemphasised (Wilne et al. 2006).

Localised deficits are less frequently the presenting manifestation of supratentorial diffuse gliomas and are apt to be rather late features. However, hemiparesis, hemianopia and language disturbances may occasionally be the first clinical manifestation, especially with malignant neoplasms.

Although modern neuroimaging techniques have considerably facilitated the diagnosis of supratentorial tumours, the interpretation of images remains difficult as numerous lesions of different origins can give rise to similar radiological pictures. The CT appearance of benign astrocytomas is variable. In a majority of cases, the lesions are well defined and regular in shape. They appear hypodense without contrast enhancement (Fig. 14.16), and their density may increase in a nonhomogeneous manner after contrast injection (Fig. 14.17). Many are cystic with only a small enhancing nodule. False negatives and false positives may occur. Approximately 15% of gliomas are not detected on CT. MRI is more sensitive than CT and gadolinium-enhanced MRI is very effective in the detection of
Figure 14.17 Large pilocytic astrocytoma of the left temporal lobe. T2-weighted showing that the tumour is heterogeneous with a solid central part and cystic formation. The posterior cyst is thin-walled; the anterior cavity has a thick wall with irregular contrast enhancement and pushes the median vessels toward the right. In spite of its huge volume, the histological nature of the tumour was not malignant.

gliomas although scans may be difficult to interpret. In some cases, oedema can give an intense signal identical to that of the mass itself on T2-weighted sequences.

TREATMENT

Surgery is clearly the initial approach, can give excellent results especially in astrocytomas and oligodendrogliomas and can be the definitive treatment for astrocytomas (Fig. 14.16). Progression-free survival at 5 years of over 90% after surgery without, in most cases, radiotherapy has been reported in several series (e.g. Shaw and Wisoff 2003). However, complete excision may not be possible. Adjuvant treatment after partial excision is commonly with radiation, which has some effect on tumour volume, but chemotherapy currently has a major role as an adjuvant treatment as it is effective in children and avoids radiation damage (Fouladi et al. 2003b) and combined treatment with surgery followed by chemotherapy is often employed. Cisplatin and etoposide seem especially effective (Massimino et al. 2002).

The rare subtypes of low grade gliomas listed above are generally treated surgically where possible and the role of chemotherapy has not been extensively studied. SEGAs associated with TSC types 1 and 2 have been identified as being sensitive to mTOR inhibitors. Everolimus has been shown to shrink unresectable SEGAs and contribute to enhanced epilepsy control in patients with tuberous sclerosis in the EXIST trials. There was no association between TSC mutation subtypes and clinical responses (Kwiatkowski et al. 2015).

OUTLOOK

The prognosis of astrocytomas is clearly better in children than in adults. In a series of 71 children with supratentorial low grade astrocytomas, Pollack et al. (1995) found overall survival rates at 5, 10 and 20 years respectively of 95%, 93% and 85%, and progression-free rates of 88%, 79% and 76%. The major predictive factor was the extent of surgical resection. Radiation therapy was not related to outcome. Pilocytic astrocytomas had better prognosis than non-pilocytic gliomas. A generally similar conclusion can be drawn from five prospective trials (four in adults and one in children) that found no significant difference in survival between patients who did or did not receive radiation after surgery, although radiation seemed to reduce tumour volume in adults (Fernandez et al. 2003; Shaw and Wisoff 2003).

Pleomorphic xantho-astrocytomas have attracted some attention despite their rarity. They occur in young children, are almost always supratentorial, are frequently located in the temporal or frontal lobes, and present commonly as isolated seizures. They share many clinical features with the epileptogenic tumours such as ganglioglioma and developmental neuroepithelial tumours (see below) despite their specific histological features (Fouladi et al. 2001; Im et al. 2004).

OLIGODENDROGLIOMAS

PATHOBIOLOGY

These are slow-growing tumours with a strong tendency to calcify and are relatively rare in childhood (about 20% of all supratentorial tumours). As discussed in the Gliomas of the Cerebral Hemispheres section, they are classified as part of the ‘diffuse glioma’ family. They are subclassified as either IDH-mutant and 1p/19q co-deleted or as not otherwise specified. Reports of associations between histological variants of oligodendrogliaomas, partial deletions of chromosomes 1p or 19q, and prognosis in adults are discussed in Aldape et al. (2007). However, these deletions seem to be rare in children (Kreiger et al. 2005).

CLINICAL FEATURES AND IMAGING

The majority of tumours are located in the frontal lobe and 50–70% of cases present with convulsive seizures. The CT or MRI appearances of oligodendrogliaoma are usually characteristic, with hypointensity on T1 sequences and high signal on T2 images. About 40% are calcified and 60% have well-defined margins (Fig. 14.18). Less than half produce a mass effect and less than a quarter of cases enhance with contrast. They may produce thinning of the inner skull table, indicating a slowly enlarging lesion as may also be seen with benign astrocytomas and with dysembryoplastic neuroepithelial tumours. These are described in Chapter 16 as they usually present with isolated epilepsy.
Tumours and Vascular Disorders

Pathobiology
Glioblastoma, IDH-wildtype (about 90% of cases) predominates in patients aged more than 55 years whereas epithelioid glioblastoma, which is a newly recognised variant of glioblastoma, IDH-wildtype, newly recognised in WHO CNS 2016, is more common in children and younger adults. It typically presents as superficial cerebral or diencephalic masses and is often accompanied by a BRAF mutation (Louis et al. 2016). Some of these arise from lower grade pleomorphic xanthoastrocytomas (Louis et al. 2016). Glioblastoma, IDH-mutant also arises preferentially in younger patients corresponding closely to the phenomenon of glioblastoma occurring in the context of a prior lower grade, diffuse glioma (Louis et al. 2016).

Clinical features and imaging
Seizures are the presenting feature in about one-third of patients, but headache, hemiparesis and personality changes are more frequent. Contrast enhancement is common in glioblastoma (Fig. 14.19) but may be absent in anaplastic astrocytomas. Diffusion-weighted MRI and magnetic resonance imaging can be useful in identifying areas of necrosis and oedema, which may not be apparent on conventional T1- or T2-weighted images. PET-CT may also be helpful in identifying areas of increased metabolic activity, which can be used to guide surgical resection.

Figure 14.18 Oligodendroglioma of the left cerebral hemisphere. T2-weighted image showing heterogeneous areas of high signal and faintly visible areas of low signal. CT showed areas of high density indicating the presence of calcification at the periphery of the tumour.

Figure 14.19 Extensive glioblastoma multiforme in 9-year-old girl who had been treated for acute lymphocytic leukaemia at age 3 years and was subsequently intellectually impaired with a leukencephalopathy due to methotrexate and X-irradiation. This is typical of a ‘second tumour’ probably induced by initial therapy.
Tumours of the Central Nervous System, Other Space-Occupying Lesions and Pseudotumour Cerebri

Spectroscopy can help establish the nature of the tumour (Chang et al. 2003). However, large enhancing tumours are not necessarily malignant (Fig. 14.17).

**Treatment**

Surgical treatment is usually followed by radiation therapy. There is currently an increasing tendency to use chemotherapy, which has been found to be effective in improving the overall survival of children with these tumours (Massimino et al. 2005), in contrast to what has been reported in adults. It is also increasingly used to delay or avoid radiotherapy for high-grade tumours.

**Outlook**

Although the prognosis is often more favourable than in adults with histologically similar tumours, it remains poor and even with high-dose chemotherapy, the results are variable and mortality remains significant. The actuarial probability of survival is 32% at 3 years after surgery. An adverse outcome has been found to be significantly correlated with overexpression of the P53 protein in the tumours independently of histology, age and tumour location (Pollack et al. 2002).

**SUPRATENTORIAL EPENDYMO descendants**

As stated in the section of Ependymomas of the Posterior Fossa, the majority of supratentorial ependymomas in children belong to the genetically defined 2016 WHO CNS classification subtype ependymoma, RELA fusion positive (Table 14.5) (Louis et al. 2016). In contrast to posterior fossa ependymomas, the peak age at onset is in adolescence. Metastases from supratentorial ependymomas are mainly intracranial, in contrast with posterior fossa ependymomas in which metastases are predominantly spinal. As discussed in posterior fossa ependymomas, gross total surgical resection appears most clearly to be associated with higher survival rates and to be technically achievable in that minority of ependymomas that are supratentorial in location (Cage et al. 2013).

**OTHER TUMOURS OF THE CEREBRAL HEMISPHERES**

**Dysembryoplastic Neuroepithelial Tumour**

**Incidence**

Dysembryoplastic neuroepithelial tumour (DNET), like gangliocytomas and gangliogliomas, are classified as neuronal and mixed neuronal-glial tumours. Indeed, different investigators may employ any of these terms to describe a particular tumour even though they are different tumour types. Because most of these lesions are highly epileptogenic they are also discussed in Chapter 16.

**Pathobiology**

They include a mixture of neuronal and glial elements, both oligocytes and astrocytes, and appear to be of developmental origin. They may be associated with some oedema of the white matter. However, a few mitoses can be seen. It is likely that a significant proportion of the cases formerly diagnosed as low grade oligoastrocytomas were in fact DNETs. These tumours are located cortically but may encroach on the underlying white matter. The use of the term oligoastrocytoma is ‘strongly discouraged’ in WHO CNS 2016 classification (Louis et al. 2016).

**Clinical features and imaging**

These tumours manifest clinically as isolated epilepsy (see Chapter 16). They are often found in the temporal or frontal lobes of children and adolescents with chronic focal seizures of early onset (Giulioni et al. 2005). They are of mixed density on CT, and only 18% enhance after contrast infusion. A quarter of them are calcified, and one-third produce a focal cranial deformity as a result of erosion of the inner skull table. They give a mixed signal on MRI, usually with low signal on T1-weighted sequences and sometimes high signal on T2-weighted sequences (Fig. 14.20).

**Treatment and outlook**

These lesions have little or no tendency to grow and usually remain stable on repeat examinations. Some of these tumours develop in areas of cortical dysplasia. Surgical removal, even if subtotal, may give good results without recurrences and good seizure control. Irradiation is clearly contra-indicated. When manifesting with seizures, DNETs need to be promptly evaluated by a paediatric epilepsy surgery team (see Chapter 16).

**Gangliogliomas and Gangliocytomas**

**Pathobiology**

These are benign tumours of the cerebral hemispheres that are characterised histologically by the presence of mature neuronal and glial cells and clinically by their isolated epileptic manifestations. These tumours may be intermediate between cortical dysplasias and tumours. Gangliocytomas differ from gangliogliomas, which typically show cyst formation, calcification, contrast enhancement and mass effect. Angiocentric neuroepithelial tumour (Lellouch-Tubiana et al. 2005) was thought to belong to the same spectrum of neuroglial tumours but is classified under ‘other gliomas’ in WHO CNS 2016 (Louis et al. 2016).

**Clinical features and imaging**

Gangliogliomas are particularly apt to present as cases of isolated, intractable epilepsy, usually of a focal type and of
temporal lobe origin. They occur mainly in young children or even in neonates without any sign of increased pressure. The diagnosis is often difficult. CT typically reveals hyperdense cortical lesions with gyriform or serpiginous outlines without marked mass effect. Most lesions are difficult to identify on T1-weighted MRI sequences and may have low, intermediate or increased signal on T2-weighted images. The rare desmoplastic infantile ganglioglioma (Khaddage et al. 2004) is seen almost exclusively below 2 years of age. It presents as a large tumour with a large cystic component and a solid component that takes up contrast on T1 sequences and appears hyperintense on T2 sequences, often with meningeal enhancement (Tamburrini et al. 2003; Trehan et al. 2004). Its main interest is that its diagnosis is difficult and it is often mistaken for a malignant tumour. Yet, resection leads to cure.

**Treatment and outlook**

Surgical removal often results in the cure of epilepsy (see also Chapter 16). Removal of the lesion was associated with relief of seizures in 84% of 184 patients with a median follow-up at 8 years post-surgery (Luyken et al. 2004). The long-term prognosis is favourable: the survival rate at 7.5 years was 97% in that series, even in cases in which the tumour was not totally removed.

**Meningiomas**

**Incidence**

Meningiomas are relatively rare in children at which age the incidence is 0.1 per 100 000 (Sugden et al. 2014), representing less than 2% of intracranial tumours. Their incidence is increased by radiation exposure, increasing with time since and dose of radiation. The issue of screening survivors of childhood brain tumours for meningiomatous second tumours has been aired (Sugden et al. 2014). It is also a frequent tumour in patients with NF2 (Sadetzki et al. 2002; Ruggieri et al. 2005) (Chapter 4).

**Pathobiology**

Most meningiomas are found in the convexity of the brain, but meningiomas found in childhood are characterised by a higher incidence, compared to adults, of location within the lateral ventricles or the posterior fossa, absence of a dural attachment, and cyst formation. Perry and Dehner (2003) reported 13 cases and reviewed the literature extensively. Im et al. (2001) emphasised the large size of many of these tumours, their unusual location, the frequency of calcification and of cyst formation in the gingiva and characteristic radiological appearance. Most meningiomas in childhood are of the fibrous type, consisting of spindles of prominent fibroglia. The angiomatous type is much less common.

**Clinical features and imaging**

Increased ICP is responsible for most clinical manifestations but seizures are the presenting feature in 8–31% of cases. Intraventricular meningiomas are apt to present with signs of intermittent obstruction of CSF outflow tracts. Optic canal or orbital tumours produce central scotomas or variable field defects. They may be difficult to distinguish from optic pathway tumours. Hyperostosis or bone destruction favour the diagnosis of meningioma. CT clearly demonstrates most meningiomas especially after contrast enhancement. The CT picture, however, may be less characteristic in children than in adults. Large cystic formations are frequent, especially in children under 2 years of age. MRI showing a decreased T1 and increased T2 signal, and usually demonstrates heterogeneity of the tumour due to tumour vascularity, cystic degeneration and calcification. It enables better delineation of the limits of the lesion and helps to indicate whether the tumour is intra- or extra-axial.
TREATMENT
Therapy is basically surgical but radiation, especially stereotactic irradiation, may play a role for patients in whom histology suggests a more aggressive course and in recurrent tumours that cannot be resected. The features and management of meningiomas as one type of post-irradiation secondary tumours have been reviewed (Sugden et al. 2014).

PRIMARY CEREBRAL NEUROBLASTOMAS
INCIDENCE AND PATHOBIOLOGY
Primary cerebral neuroblastomas are rare. They occur in the first decade of life in 81% of cases and in 20% before the age of 2 years. Most are primary (Etus et al. 2002; Yaris et al. 2004). A few are cerebral relapses or metastases of peripheral neuroblastoma (Porto et al. 2005a).

CLINICAL FEATURES, TREATMENT AND OUTLOOK
The clinical picture is that of cerebral hemispheric tumours in general. Survival following surgery and irradiation with or without chemotherapy reaches 3 years in 60% of patients and exceeds 5 years in 30%.

TUMOURS OF THE BASAL GANGLIA AND THALAMUS
INCIDENCE
These tumours represent 2–6% of intracranial tumours in children. Most are astrocytomas of various grades, from benign pilocytic lesions to anaplastic astrocytomas and glioblastoma multiforme.

CLINICAL FEATURES AND IMAGING
The most common manifestation is progressive hemiparesis, which may be associated with unilateral dystonia or intention tremor. The majority have signs of corticospinal tract involvement and about 10% present with a movement disorder, most commonly tremor or dystonia. Homonymous hemianopia, nystagmus and hearing loss may be observed. Sensory manifestations are exceptional. Martinez-Lage et al. (2002) studied 20 patients, four of whom presented with acute manifestations: intracranial hypertension was present in 13, motor deficit in eight, seizures in seven, behavioural or cognitive disturbance in five, and abnormal movements in only two patients.

The diagnosis is readily suggested by CT or MRI, when the tumour is hypodense and when contrast enhancement is present (Lefton et al. 2000) (Fig. 14.21). The latter may occur in a ring-like manner. In some cases the tumour is infiltrating and its density does not differ, even after contrast injection, from that of the surrounding brain. In such cases recognition of the mass effect caused by the tumour is the only diagnostic criterion. Bilateral thalamic gliomas may raise a difficult diagnostic problem and usually confer a poor prognosis (Gudowius et al. 2002).

TREATMENT
Complete surgical removal of tumours of the basal ganglia is challenging and may lead to significant morbidity. Stereotactic biopsy is often used as an alternative to attempted resection and blind radiotherapy is best avoided. Irradiation is reserved for malignant tumours.

INTRAVENTRICULAR TUMOURS
Tumours of different histological types can be located within the lateral ventricles. These include choroid plexus papillomas (CPP) and carcinomas, intraventricular meningiomas, central neurocytomas, ependymomas and intraventricular cysts.

CHOROID PLEXUS PAPILLOMAS
INCIDENCE
Choroid plexus papillomas (CPPs) arise from the epithelium of the plexus and are relatively common in infants, about 20%
occurring below 1 year of age, but rare in older children. They are large, cauliflower-like tumours that present the structure of normal choroidplexus with a considerable degree of hyperplasia. Papilloma of the choroid plexus of the fourth ventricle is rare in children, in whom most papillomas arise from the lateral ventricle (Rostasy et al. 2003).

**Clinical features and Imaging**

The usual manifestation of CPP in infants is hydrocephalus (Chapter 7), which is generally rapidly evolving and may be accompanied by papilloedema, an uncommon finding in hydrocephalus arising without an intraparenchymal mass. The diagnosis is easy because papillomas present as large intraventricular masses with massive enhancement after contrast injection (Fig. 14.22). The hydrocephalus usually results from hypersecretion of CSF by the tumour but it may also be due to meningeal fibrosis resulting from haemorrhage from the tumour. In older children, choroid plexus tumours are more likely to be located in the fourth ventricle or the temporal lobe and produce seizures rather than hydrocephalus.

**Treatment**

Excision of the papilloma is the treatment of choice. They are extremely vascular tumours with substantial peri-operative mortality usually resulting from haemorrhage. The risk of this may be increased by proceeding immediately to definitive surgery without first putting interim treatment of hydrocephalus in place. Pre-operative embolisation of the posterior choroidal vessels may reduce the risk of blood loss intraoperatively. Radiation therapy is reserved for tumours having malignant histological patterns.

**Outlook**

Postoperative complications are unfortunately not rare (Nagib and O’Fallon 2000; Kumar and Singh 2005). Hydrocephalus is common despite complete removal of the tumour and a shunt may be required.

**CHOROID PLEXUS CARCINOMA**

**Incidence and Pathobiology**

Choroid plexus carcinoma is a rare, malignant tumour accounting for about 40% of choroid plexus tumours. Neuropathological features include high cellularity, anaplasia and necrosis. Metastatic spread is common.

**Treatment and Outlook**

Complete surgical resection is associated with a higher likelihood of long-term survival. The benefit of radiotherapy and chemotherapy is disputed but a 5-year survival rate of 38% following the intensive ‘Headstart’ chemotherapy regimen has been reported (Zaky et al. 2015).

**CENTRAL NEUROCYTOMA**

**Incidence and Pathobiology**

Central neurocytomas (CNCs) are rare tumours thought to arise from the septum pellucidum. They most commonly arise in the lateral ventricles and in adolescence but are also seen in other locations and in other age groups.

**Clinical features and Imaging**

The clinical presentation is usually with symptoms of raised ICP secondary to hydrocephalus and imaging typically showing heterogeneous masses that are iso-intense or slightly hypointense on T1-weighted MRI and iso-intense to hyperintense on T2-weighted imaging. Contrast enhancement is variable but usually moderate. The presence of cysts, calcification,
haemorrhage or tumour may result in hypo-intensity. CNCs may be misdiagnosed as oligodendrogliomas or ependymomas on the basis of their CT or MRI characteristics. Proton MRS has recently emerged as a promising tool for diagnosis of CNC and showing high glycine, increased choline and alanine and decreased N-acetylaspartate and creatine/phospho-creatine peaks (Patel et al. 2013).

**TREATMENT AND OUTLOOK**

Surgery is the primary treatment for CNC and gross total resection is associated with a favourable prognosis. In patients where this is unattainable, subtotal resection with adjuvant radiotherapy or radiosurgery has been shown to offer better rates of control and survival than surgery alone. Adjuvant radiation treatments have also been shown to be useful in cases of tumour recurrence and may have a role as primary treatments for smaller tumours (Patel et al. 2013).

**COLLOID CYSTS OF THE IIIrd VENTRICLE**

These tumours occur only very rarely in children. They manifest in children, as in adults, with severe headaches that are often paroxysmal in character and are sometimes precipitated by certain positions or movements of the patient. They may be a rare cause of sudden death in children and adolescents (Kava et al. 2003). Nine familial cases are on record (Partington and Bookalil 2004).

**EMBRYONAL TUMOURS OTHER THAN MEDULLOBLASTOMA**

**EMBRYONAL TUMOURS WITH MULTILAYERED ROSETTES**

**INCIDENCE AND PATHOBIOLOGY**

These are rare, highly malignant (WHO Grade IV) neoplasms that occur mostly in young children but cases exist in older children and young adults. The mean age of a series of cases reported from France was 31 months (Horwitz et al. 2016).

Embryonal tumours other than medulloblastoma have been substantially re-classified in WHO CNS 2016 with removal of the term ‘primitive neuro-ectodermal tumour’, previously recognised as an embryonal tumour distinct from medulloblastoma, from the diagnostic lexicon (although, confusingly, it lives on in ‘SIOP-PNET5-MB’, the name of one the current treatment trials for medulloblastoma). Many of these tumours display amplification of the C19MC region on chromosome 19 (19q13.42) and should now be termed embryonal tumours with multilayered rosettes (ETMR). This entity also includes the groups of tumours previously referred to as embryonal tumours with abundant neuropil and true rosettes, and ependymoblastoma. These are now subclassified on molecular genetic features as ETMR, C19MC altered or, in the absence of that genetic feature, as ETMR, NOS (Louis et al. 2016). A further category of embryonal tumours is termed medulloepithelioma, a diagnosis based on histological features. Pineoblastomas have been considered alongside embryonal tumours in some series but are classified separately under pineal region tumours.

The typical histological features of ETMRs include small, undifferentiated cells without observable cytoplasm, and dark oval or irregular nuclei with prominent nucleolus (Ellison et al. 2003; Vogel and Fuller 2003). Numerous mitotic figures and necrosis are often present. Occasional focal areas of differentiation toward neuronal or glial lines may often be recognised. By electron microscopy, the tumour cells have been reported to have similarities to the developing cortical plate of the fetus (Ellison et al. 2003; Vogel and Fuller 2003). The defining feature of medulloepitheliomas is a distinctive pseudostratified epithelium that is arranging in papillary and tubular structures.

**CLINICAL FEATURES AND IMAGING**

Most ETMRs and medulloepitheliomas are located in the cerebral hemispheres but may be found in the posterior fossa (Zagzag et al. 2000). Their clinical features are typically those of malignant supratentorial tumours. Clinical features of raised ICP and focal deficits are more common than seizures. The history is usually very brief. CT may show cystic formation and extensive calcification. Neoplastic meningitis may be the first manifestation.

**TREATMENT AND OUTLOOK**

Treatment is with as complete a resection as possible, followed by irradiation and chemotherapy. Stem cell rescue has permitted the use of increased doses of chemotherapy and/or radiation (Perez-Martinez et al. 2004). With a median follow-up of 70 months, 5-year progression-free survival (PFS) was 40% for all patients and increased to 63% in those patients who received subtotal or total resection and radiotherapy without interruption (Choi et al. 2016). A study of the use of craniospinal radiotherapy with concurrent carboplatin following surgery followed by 6 months of maintenance chemotherapy with cyclophosphamide and vincristine reported 5-year PFS for all patients of 48.7% (62.1% in pineoblastoma and 39.8% in non-pineal tumours). The outcome of this well-tolerated regimen is certainly comparable to those seen with more intensive and longer-duration regimens. Complete surgical resection had a large impact on survival rates (Jakacki et al. 2015). However, for children with a molecularly and histologically well-defined ETMR the prognosis remains poor.

The 1-year overall survival (95% Confidence Interval) in the series reported by the French collaborative group was 45% (31–64%) (Horwitz et al. 2016). On multivariate analysis, complete surgical resection, radiotherapy, and high-dose chemotherapy were associated with a better overall survival (Horwitz et al. 2016).
ATYPICAL TERATOID/RHABDOID TUMOURS

INCIDENCE AND PATHOBIOLOGY

Atypical teratoid/rhabdoid tumours (AT/RT) are rare, constituting 5–10% of childhood brain tumours. Like ETMRs, AT/RTs are Grade IV embryonal tumour occurring predominantly in children aged less than 3 years. The diagnosis is now defined by alterations affecting the SMARCB1 locus on 22q, or, very rarely of BRG1, leading to loss of SMARCB1/INI1 protein expression. In the absence of these genetic alterations it is classified as CNS embryonal tumour with rhabdoid features. AT/RTs show similar histology to ETMRs but with the addition of rhabdoid cells with eosinophilic granular cytoplasm and an eccentric nucleus.

CLINICAL FEATURES AND IMAGING

The history is usually short and usually includes clinical features of raised ICP. The clinical and radiological features otherwise depend on the tumour location. About half of AT/RTs are found in the posterior fossa, either in the cerebellopontine angle or more midline, and half in the cerebral hemispheres.

TREATMENT AND OUTLOOK

Children aged more than 3 years or whose tumour was totally resected have a relative better prognosis. Incomplete resection and metastatic spread via the CSF are more common in younger patients. Postoperative craniospinal irradiation and high-dose chemotherapy improve survival rates but the quality of survival of infants or pre-school children may be severely compromised by these treatments. Two-year overall survival rates of 70% are reported (Chi et al. 2009) and are significantly better for those aged more than 3 years at diagnosis than for younger patients (89 vs 17%) (Tekautz et al. 2005).

DIFFUSE GLIOMA AFFECTING THE CEREBRUM AND INFRATENTORIAL STRUCTURES

INCIDENCE AND PATHOBIOLOGY

The rare neoplastic disorder, involving large parts of the brain in a multicentric or diffuse overgrowth with cells of neuroglial, oligodendrogial or astrocytic lineage (Caroli et al. 2005), is now considered to be the manifestation of a growth pattern found in many types of gliomas, including both IDH-mutant and IDH-wildtype diffuse astrocytic and oligodendrogial gliomas and IDH-wildtype glioblastomas (Louis et al. 2016) (see also the Gliomas of the Cerebral Hemispheres section). The term gliomatosis cerebri has been dropped (Louis et al. 2016).

CLINICAL FEATURES AND IMAGING

Corticospinal tract deficits, dementia/intellectual disability, headache, seizures, cranial neuropathy, raised ICP and spinocerebellar deficit each occur in a third or more of patients. The diagnosis is often difficult as imaging is not characteristic, showing areas of nonspecific (diffusely increased) signal. Atypical clinical presentations have been reported, suggesting meningoencephalomyelitis (Jayawant et al. 2001) or even Rasmussen syndrome because of the presence of epilepsy partialis continua (Shahar et al. 2002). The disorder has also been described in a new born infant whose imaging had suggested lissencephaly.

DIFFUSE LEPTOMENINGEAL GLIONEURONAL TUMOUR

INCIDENCE

Diffuse leptomeningeal glioneuronal tumour (DLGNT) is a rare mixed neuronal-glial tumour, newly defined in WHO CNS 2016 (Louis et al. 2016).

PATHOBIOLOGY

The histological appearance is of monomorphic clear cell glial morphology reminiscent of oligodendroglioma. BRAF fusions and deletions of chromosome 1p and occasionally of 19q, are common but IDH mutations are absent.

CLINICAL FEATURES, IMAGING AND OUTLOOK

DLGNT presents as diffuse leptomeningeal disease with or without a recognisable parenchymal component, commonly in the spinal cord and occurring most often in children and adolescents. These tumours typically show relatively slow growth and cause secondary hydrocephalus (Louis et al. 2016).

METASTASES

Intracranial metastases of extracranial tumours are rare in childhood. Wilms tumours, osteosarcoma, rhabdomyosarcoma, melanoma and neuroblastoma are known occasionally to metastasise to the brain. Curless et al. (2002b) found that neuroblastomas, osteosarcomas, melanoblastomas, Ewing sarcomas and germ cell tumours were responsible for most haematogenous metastases in a review of 2040 tumour cases. Intracranial metastases have no distinctive features. They may be single or multiple and present as areas of hypodensity, which enhance following contrast injection, and surrounding oedema.
A proportion of cases of the opsoclonus–myoclonus–ataxia syndrome (see Chapter 12), a syndrome confined to infancy, are associated with paraspinal neuroblastoma. Imaging of the CNS in this condition is always completely unrewarding as the underlying cause is not to be found there. Rates of survival from the tumour in this clinical setting are very high. The syndrome, although sensitive to immunosuppressive treatment with glucocorticoids, usually has long-term neurocognitive sequelae.

There is a well-known association between ovarian tumours and immune-mediated N-methyl-D-aspartate receptor (NMDA) receptor encephalitis associated with antibodies to those receptors in the blood and/or CSF. This is classically a subacute limbic encephalitis with clinical manifestations including prominent buccal and upper limb movement disorder and disturbance of mood and behaviour. The symptoms can respond to resection of the underlying tumour or to immune-suppression. Recovery can be complete if treatment is given early (see Chapter 12). A high proportion of those patients that are prepubertal do not have an underlying tumour. Paraneoplastic neuropathy and cerebellar syndromes are described in lymphoma but are rare in childhood (see below).

**Lipomas**

**INCIDENCE AND PATHOBIOLOGY**

Lipomas are space-occupying lesions of malformative origin that do not behave as tumours but small, asymptomatic lipomas, particularly in the pineal region, are now increasingly coming to light as incidental findings on cranial imaging (Spallone and Pitskhelauri 2004). The most frequent location of lipomas is the region of the corpus callosum and the quadrigeminal cistern (Gomez-Gosalvez et al. 2003; Yilmaz et al. 2006). The diagnosis is readily made by demonstrating the presence of a mass of fat density, sometimes surrounded by ‘eggshell’ calcification. Lipomas may be associated with total or partial agenesis of the callosal commissure and may communicate through a narrow stalk with an extracranial lipoma in the region of the bregma. They should be distinguished, by using MRI pre-operatively, from dermoid cysts of the anterior fontanel (Aslan et al. 2004), encephaloceles, haemangiomas, lipomas, lymphangiomas and sinus pericranii (extracranial varicoceles).

**CLINICAL FEATURES, IMAGING AND TREATMENT**

Lipomas of the corpus callosum are often asymptomatic and usually do not require any treatment. Epilepsy is the most frequent manifestation of symptomatic lesions.

**Intracranial Cysts and Other Mass Lesions**

The term cyst is loosely applied to a large number of intracranial cavities of multiple pathology and aetiologies such as anoxic necrosis, post-haemorrhagic lesions, vascular accidents, tumours, infections and infestations, and neurodegenerative diseases. Cysts may be of any size from huge lesions to very small, often transient and usually insignificant formations such as subependymal or frontal horn cysts in neonates (Chang et al. 2006). Some rare cystic formations may raise diagnostic problems; for example, rare cases of massive dilatation of the Virchow–Robin spaces whose significance is not fully understood (Rohlfs et al. 2005). This section considers only large primary cysts.

**Arachnoid Cysts**

Most large intracranial cysts are arachnoid cysts. The term designates fluid-filled cavities that develop either within a duplication of the arachnoid membrane or between the arachnoid and the pia mater (Gosalakkal 2002). Arachnoid cysts represent 1% of space-occupying lesions and 60–90% of symptomatic lesions are recognised during childhood or adolescence. Cysts may be an incidental finding in up to 5% of cases in autopsy studies. Arachnoid cysts are most usually malformations and only rarely follow arachnoiditis. Familial cases are rare and causes generally remain obscure (Arriola et al. 2005). Arachnoid cysts may or may not communicate with the subarachnoid space, whether located supratentorially or infratentorially.

**Supratentorial Arachnoid Cysts**

These are the most common type of intracranial cysts. Middle fossa (sylvian) arachnoid cysts have the highest frequency in most series, followed by suprasellar cysts and cysts of the cerebral convexity. Middle fossa cysts are frequently asymptomatic and may be discovered incidentally on cranial imaging performed for various reasons (Fig. 14.23). They may be very large, pushing back the temporal lobe, which is compressed rather than atrophic. When of moderate size and found in later childhood or adolescence, these cysts may not require treatment. The most common clinical manifestations are a large head and temporal bossing. However, some reports challenge the benign nature of these cysts, describing resolution of functional neurological deficits (e.g. difficulties with atten-
tional or language skills) occurring after surgical treatment, as also described in adults (Raeder et al. 2005). Surgery is only clearly indicated when symptoms of raised ICP (e.g. headache) are present and in large cysts.

Symptomatic sylvian cysts can give rise to signs of increased pressure, especially headache and papilloedema, or to seizures, usually focal, or become manifest as a result of haemorrhagic complications. These include haemorrhage into the cyst, which may render the cavity invisible on CT, and subdural haematoma with or without associated intracystic haemorrhage. It seems likely that the ‘juvenile relapsing subdural haematoma’, characterised radiologically by bony changes similar to those of sylvian cysts, is a haematoma complicating a middle fossa cyst. Subdural haematoma may rarely be on the side opposite to the cyst. No treatment is ever indicated in such cases.

The diagnosis of temporal arachnoid cysts is generally easy. Large porencephalic lesions of the temporal pole may superficially mimic arachnoid cysts. Bilateral cysts of the temporal fossa have been reported in children with glutaric aciduria type I but these are also reported as atrophy of the temporal lobe, a term that seems more appropriate than that of cyst, and are not an indication for surgery.

Treatment of a sylvian cyst is best performed by fenestration into the basal cisterns either via an endoscopic approach or an open microsurgical approach. Cystoperitoneal shunting is occasionally required if there is no easy access to the basal cisterns. Drainage of huge cysts in children with closed fontanelles should be cautious as rapid decompression can produce mass brain displacement. It is not indicated for small asymptomatic cases, which are common.

Suprasellar cysts are manifested by hydrocephalus in 90% of cases. Visual abnormalities and ataxia are observed in a quarter of the cases. In some patients they are responsible for a slow anteroposterior to-and-fro movement of the head at a rhythm of 2–3Hz, known as the ‘bobble-head doll syndrome’. Partial hypopituitarism with special involvement of corticotropin secretion is seen in 10% of patients. The full spectrum of endocrinological disturbances may also include precocious puberty and growth hormone deficiency.

The CT or MRI appearance is typical with a large rounded suprasellar mass of fluid density obstructing the foramina of Monro with resulting hydrocephalus (Fig. 14.24). MRI may show that the cyst and the third ventricle are distinct cavities separated by a thin membrane. Treatment may be with endoscopic fenestration of the cyst into the ventricle and then into the preptontine cistern (Decq et al. 1996).

Arachnoid cysts of the convexity can produce focal signs and raised ICP. Interhemispheric cysts may be difficult to separate from dorsal cysts associated with agenesis of the corpus callosum. Cysts in this location are apt to be dysembryoplastic with cuboid or columnar epithelium rather than arachnoidal cells.
OTHER INTRACRANIAL CYSTS

Dermoid cysts are apt to be found in the sagittal plane of the skull. Dermoid and epidermoid cysts can produce compression of intracranial structures. Some of the dermoids are connected
Part VI  Tumours and Vascular Disorders

by a tract to the skin and may give rise to infections. Imaging showing that epidermoids are well-demarcated lesions giving a high signal on T2-weighted images and on water-diffusion MRI (Hakyemez et al. 2005).

Colloid cysts of the third ventricle were discussed in the Intraventricular Tumours section.

Ependymal cysts are rare supratentorial, intracerebral or convexity lesions lined with an ependyma-like epithelium. They are most often located within the frontal lobe and may be associated with complex brain malformations. They do not communicate with the ventricles and probably arise from displaced segments of the wall of the neural tube that correspond to the sites from which the tela choroidea forms.

Huge prepontine cysts may extend from the prepontine region to the posterior and middle fossa. The lining epithelium is thought to be of respiratory origin in some cases.

Enterogenous cysts are also rare and generally found in the spine or posterior fossa but rare supratentorial cysts are on record.

Cysts of the Rathke cleft develop in the suprasellar region and may be associated with endocrine or visual abnormalities.

EMPTY SELLA SYNDROME

The empty sella syndrome is in fact a misnomer as the sella is not completely empty but contains a remnant of pituitary tissue. Although not a cystic formation it is described here as the sella turcica is ballooned and may be mistakenly considered to harbour a tumour or cyst. The aetiology of the condition is often related to raised ICP. Its frequency in childhood is unknown. In some cases the ‘empty sella’ is accompanied by visual or endocrine disturbances ranging from panhypopituitarism to precocious puberty. Visual field defects have been reported, and the condition may occur with microadenomas of the hypophysis. The syndrome may be seen in patients with pseudotumour cerebri, hydrocephalus and CSF rhinorrhoea. Empty sella in childhood may be less benign than in adults, and children with this condition require regular assessment.

SPINAL CORD TUMOURS

INCIDENCE

Spinal cord tumours in childhood are five to ten times less common than brain tumours and may present with symptoms and signs ranging from brainstem signs to systemic upset (Fig. 14.26). Tumours can arise anywhere along the spinal cord. For detailed discussion beyond the scope of this chapter, the account by Hsu and Jallo (2013) is recommended. A majority are intramedullary (i.e. intrinsic to the spinal cord). Spinal low grade gliomas are more likely to present later in childhood and adolescence.

PATHOBIOLOGY

Common tumour types include astrocytomas and ependymomas. Intradural extramedullary tumours include CNS metastatic deposits (for examples from PNET or intracranial PNET), primary intradural ependymomas, schwannomas, neurofibromas and meningiomas. Extramedullary lesions originate from bony elements, adjacent soft tissue or from the dura. Often large masses in the posterior mediastinum or the retroperitoneal region invade through the neural foramina (neuroblastoma) or directly invade the bone (sarcomas).

CLINICAL FEATURES AND IMAGING

Initial signs are often relatively subtle and symptoms may easily be disregarded as trivial complaints. Multiple consultations where the significance of symptoms of spinal origin are not initially appreciated engender delays. The clinical features of spinal cord compression include three groups of symptoms and signs:

1. Back pain and rigidity,
2. Signs of segmental spinal involvement, and
3. Signs resulting from interruption of long tracts within the spinal cord.

The importance of back pain and, especially, of spinal rigidity as an early symptom of tumour of the cord has long been known. Pain may have a radicular distribution but is more often diffuse and is usually predominantly nocturnal. Rigidity is frequently associated with scoliosis. Segmental weakness, hyporeflexia, sensory disturbances and atrophy can result from involvement of the central grey matter or nerve roots. Spasticity evolving into paraplegia, sphincter disturbances and sensory deficits results from long tract involvement.
Disturbances of walking with claudication and stiffness may be present long before other symptoms. The presence of a definable sensory level, which may be difficult to demonstrate in young children, indicates the upper level of compression. Bilateral pyramidal tract signs are present with Babinski sign and/or Rossolimo’s sign (flexion of the toes caused by flicking the tops of the toes from the plantar surface). Back pain in all children, and recurrent abdominal pain in some, should be seen as a potential ‘red flag’ which usually warrants urgent investigation. Initial bladder symptoms are increased urgency followed by retention or incontinence. Sphincter disturbances, especially urinary retention, indicate urgent need for decompression.

Occasionally intradural spinal cord tumours can present with communicating hydrocephalus and children with a new unexplained presentation of communicating hydrocephalus should be considered for an MRI of the spine (Mirone et al. 2011). Other atypical presentations of spinal cord tumours include scoliosis or an acute spinal syndrome mimicking acute transverse myelitis (Chapter 12). MRI should therefore be considered in all patients with a pathological scoliosis.

The diagnosis of spinal cord tumour should be quickly confirmed by MRI because sudden deterioration with complete paraplegia may occur at any time due to compromised circulation in the anterior cerebral artery and its branches. Magnetic resonance clearly demonstrates both intra and extramedullary lesions thus helping in guiding the management plan and has largely supplanted myelography. It is helpful in identifying syringomyelia associated with intramedullary tumours, however, distinguishing a tumour from an area of increased signal due to oedema, haemorrhage or inflammation can be difficult. Gadolinium enhancement helps make such distinctions, and diffusion-weighted MRI may be useful in some cases (Pui et al. 2005). Patients with syringomyelia where no cause is identifiable should have a contrasted MRI scan to exclude a small tumour that may not be easy to see on a plain MRI. CT may be required for patients with extradural tumours to ascertain whether bony destruction or spinal instability have occurred. CSF examination at lumbar puncture, part of the staging process in many paediatric CNS tumours, is contraindicated if there is a tumour compressing the spinal canal but is useful in detection of metastases in patients with PNET or ependymoma.

**Emergency Presentations**

Spinal cord compression is an even more serious emergency than raised ICP, and this possibility must always be present in the mind of paediatricians, while the diagnoses of acute myelitis and of ‘hysteria’ or ‘malingering’ should never be accepted before cord compression has been clearly excluded. If a spinal tumour is diagnosed then the rate of progression of neurological signs must be kept under regular review. The nature of many children’s tumours is that they can progress rapidly. Extra-medullary tumours in particular, such as neuroblastoma, lymphoma or Ewing’s tumour can grow across the spinal canal in a matter of a few days or weeks. Referal, diagnostic biopsy and assessment for possible medical or surgical decompression is urgent and needs to be completed within 24–48 hours. Where spinal cord compression is identified, the use of immediate steroid medication such as dexamethasone in high dose (up to 10mg/m²/day) in preparation for surgical decompression can be critical to the preservation of neurological function. Achieving a histological diagnosis also remains a strong priority and close collaboration with the neuro-oncology team can avert the risk of losing a histological diagnosis of lymphoma, which may melt away under the influence of steroids. The use of steroids in a lymphoma can also precipitate tumour lysis syndrome with the risk of acute renal failure.

**Risk of Delay in Diagnosis**

A useful review of the diagnostic and therapeutic challenges was provided by Wilne and Walker (2010). A population treated in a single Italian centre comprised 134 cases of benign or malignant spinal cord tumours, of 29 different histological types with a bimodal age-specific incidence with peaks in the first 12–18 months and in adolescence. Intradural tumours accounted for 34%, intradural extramedullary tumours 19% and extradural tumours accounted for 40% (of which 60% involved the vertebrae and 7.5% were paravertebral). Tumours of the cervical and dorsal cord predominated but all spinal cord levels were represented. The median time to diagnosis was 5.3 months (range 1 day to 2 years). The most progressive problems at the time of diagnosis were pain, paraparesis, spinal deformity, sphincter problems and hemiparesis (Spacca et al. 2015).

A second single institutional study from the USA reported mean symptom duration of 7.8 months (0.25–60 months). A notable presenting feature they identified was early handedness in those aged less than 3 years. Radiographically homogenous gadolinium enhancement on MRI correlated with low grade histology (Crawford et al. 2009).

A Canadian population-based study of children aged less than 3 years reported three predominant tumour types including low grade astrocytoma (70%), primitive neuro-ectodermal tumour (15%) and rhadoblast tumour (15%). Gait disorder affected over 70% and the next commonest presentations were with developmental delay, abnormal eye movements, seizures, head tilt, vomiting and failure to thrive (Zelcer et al. 2011). Outcomes are significantly worse in malignant tumours (Zelcer et al. 2011) and with less compete tumour resections (Crawford et al. 2009).

**Extradural Tumours**

Approximately two-thirds of the extradural tumours are extradural in origin (Albanese and Platania 2002), originating from bone, soft tissue or the meninges. Neuroblastoma (Fig. 14.27) is the most frequent but other tumours of osseous or soft tissue origin also occur, including rhabdomyosarcoma, Ewing sarcoma (Uesaka et al. 2003), aneurysmal bone cysts, metastases, lymphomas (Daley et al. 2003) or bony deposits of Langerhans Cell Histiocytosis (LCH).

Intradural extradural tumours account for approximately 25% of cases, meningiomas being the most common...
histological type followed by schwannomas (Fig. 14.28). Metastases from intracranial tumours, especially ependymomas and PNETs, are usually multiple and may be especially difficult to identify. So-called ‘sugar coating’ of the spinal cord from PNET metastases is seen.

Extramedullary tumours tend to manifest initially with unilateral pain in segmental distribution, often in association with paraesthesia and weakness. Brown–Séquard syndrome is observed in a small proportion of children with extramedullary tumours. More commonly, there is only predominant weakness, spasticity and deep sensory loss on the side of the tumour, with more marked contralateral loss of pain and temperature sensation. Schwannomas (neurinomas) are more common than meningiomas.

Management of extramedullary tumours requires a histological diagnosis, relief of cord compression to preserve neurological function, removal of tumour if possible and securing spinal stabilisation. It is often appropriate to perform a needle biopsy in the first instance as some tumours such as neuroblastoma are best treated non-surgically. Decompression of the spinal cord and nerve roots and stabilisation may be appropriate when it is not appropriate or possible to completely resect the tumour. Other types of tumour such as Ewing sarcoma may be amenable to en bloc resection if appropriately localised and accessible. Bony destructive extradural tumours will often require instrumented stabilisation to prevent deformity or instability. This can be challenging in very young children.

There is some controversy regarding the role of surgical decompression in tumour related presentations. On the one hand, acute neurological deterioration is reversible with early decompressive surgery, which also offers the opportunity to get tissue for histological diagnosis without the need to access retroperitoneal tissues in the thorax or abdomen. Selection of tissue site for biopsy is critical, especially if it can offer decompression to prevent further progression of spinal injury associated with delayed tumour response to chemotherapy. The significant differences between the treatment programmes justifies the need for tissue for histology and cytogenetics as well as for research purposes. Osteoplastic laminotomy and postoperative replacement of lamina reduces the risk of subsequent spinal deformity linked to delamination but subsequent surgical instability is nevertheless a complication in a few cases. On the other hand, decompression may not be effective in preserving spinal cord function if the neurological injury has been present for more than 24–48 hours. In acute presentations where tissue diagnosis will be delayed for any reason and/or neurological deterioration is observed in spite of steroid therapy, vincristine and cyclophosphamide is used empirically as an interim treatment.

In all cases (except perhaps for simple biopsies) it is best practice to operate with neurophysiological monitoring including somatosensory evoked potential and motor evoked potential monitoring to identify cord compromise that may result in a functional deficit.

INTRAMEDULLARY TUMOURS

Intramedullary tumours are mainly represented by astrocytomas (30%) and ependymomas (60%). Gangliogliomas (Jallo et al. 2004) and haemangioblastomas, which may be part of the Von Hippel–Lindau complex, are rare in children. These tumours are often cystic and commonly extend over considerable lengths in the cervico-dorsal part of the cord. Some of them also involve the lower brainstem.

Intramedullary tumours are frequently associated with cystic cavitation of the central cord (syringomyelia), which may be difficult to differentiate from purely cystic intramedullary lesions. Their presentations are often subacute or diagnosed in patients under investigation for spinal surgery or associated with inherited predisposition states (NF2, NF1 and von Hippel–Lindau). They can produce symmetrical weakness of the limbs and are usually not associated with pain. Intramedullary tumours often do not produce a clear-cut sensory level and some of them may be surprisingly well tolerated for long periods despite a considerable extension (Fig. 14.29).

Some spinal astrocytomas may present with the clinical manifestations of raised ICP without local signs (Mirone et al. 2011). This may result from metastatic disease, meningeal fibrosis due to haemorrhage from the tumour, or decreased resorption of CSF because of its high protein content ‘clogging’ the arachnoid granulations. There are cases, however, in which papilloedema and raised pressure are not associated with ventricular dilatation.

The special features of intra-axial tumours of the cervicomedullary junction were described in the Brainstem Tumours section.
Spinal ependymomas complicating NF2 are often multiple and progressive during adolescence and adulthood. When not associated with NF2 they are uncommon and not infrequently present in the conus medullaris where they often demonstrate myxo-papillary histology. The role of chemotherapy versus radiotherapy has not been studied in low grade astrocytoma. Primary chemotherapy, particularly in younger children, with vincristine carboplatin or other drug combinations are being investigated in clinical trials and in selected spinal cord cases; 70% non-progression rates and 50% response rates can be expected with all drug regimens. As in all CNS tumours, treatment selection by the neuro-oncology multidisciplinary team is the recommended approach (Walker et al. 2013).

Treatment of intramedullary tumours raises special problems (Houten and Weiner 2000). The spinal cord is highly eloquent and any injury often results in catastrophic disability. The guiding principles for the surgeon are to resect as much of the tumour as possible without causing any deterioration in neurological function. Factors to consider when determining if this is possible include the degree of neurological deficit, the location of the tumour, the presence of a syrinx, the presence or absence of a clear plane between spinal cord and tumour and the histological diagnosis. All resection should be performed with neurophysiological monitoring including somatosensory evoked potential and motor evoked potential monitoring. Prognosis is related to completeness of resection.

If removal proves impossible, decompression and irradiation may afford fairly long symptomatic relief in 30–50% of cases. Astrocytomas may be relatively well tolerated for long periods and when removable were reported to have a relatively favourable outcome in the context of a study in which overall long-term survival was around 50% (Townsend et al. 2004). Patients with malignant tumours such as glioblastomas mostly do poorly (Beyer et al. 2016). These tumours are thankfully rare. New forms of chemotherapy, especially cisplatin and vincristine, may improve the prognosis.

OTHER SPINAL COMPRESSIONS

In addition to CNS neoplasms, cord compression may result from leukaemic infiltration, lymphomas, arteriovenous malformations and congenital cysts (Garg and Dormans 2005). Other causes include epidural infections, traumatic or spontaneous haematoma. Spinal arachnoid cysts can produce a slowly progressive myelopathy but, in some cases, symptoms can fluctuate with time and postural changes (Maiuri et al. 2006). Spinal meningeal cysts are a rare cause of cord compression, which is accessible to effective treatment. Extradural meningeal cysts are diverticuli of the arachnoid through a dural opening, extending into the extradural space posterior to the cord. Extradural cysts may be associated with acquired lymphoedema of the lower limbs and lower lid ectropion and distichiasis (double row of eyelashes) in a dominant syndrome.

Other rare causes of spinal cord compression include chronic spinal arachnoiditis, which is a low grade inflammatory
reaction that may follow trauma, shunt procedures or infections, or be idiopathic, and congenital intraspinal lipomas or epidermoid tumours that can be a late consequence of lumbar puncture. Bony compression of the cord is occasionally seen as a result of overgrowth of the bone marrow encroaching on the spinal canal in patients with thalassaemia or, rarely, with other types of haemolytic anaemia or myelosclerosis (Ruo Redda et al. 2014).

**OTHER CONDITIONS RELATED TO CNS TUMOURS**

**NEUROLOGICAL ASPECTS OF LEUKAEMIAS AND LYMPHOMAS**

Complications of leukaemia may result from leukaemic infiltrations of the meninges, brain and cranial nerves, or may be due to haemorrhage, infections, or toxicity of treatments. Which of these is the cause is usually difficult to ascertain clinically.

Meningeal leukaemia may occur at any stage of the disease. One-third to one-half of children are in complete remission when neurological complications appear. CNS leukaemia may present with headache, vomiting and papilloedema but these have become rarer both because non-CNS manifestations of leukaemia are diagnosed earlier and because prophylactic CNS treatment at diagnosis prevents the development of CNS involvement. Leukaemic infiltration primarily affects the arachnoid, and infiltration of the brain tissue is rare. Cranial nerve palsies are frequently present. Retinal lesions including haemorrhages and white exudates sometimes occur with swelling of the disc. Paraspinal masses may rarely present with spinal and radicular compression. Seizures occur in about 10% of patients and may occur as a complication of methotrexate therapy or as a manifestation of venous sinus thrombosis, usually with additional clinical features of increased ICP (Sebire et al. 2005). Rarely, hypothalamic infiltration may lead to increased appetite and weight gain. The incidence of CNS tumours is increased by a previous history of leukaemia or lymphoma reflecting partly a genetic predisposition and partly an unwanted effect of their treatment with radio- and chemotherapy.

CT usually fails to demonstrate the leukaemic infiltrates but MRI with gadolinium enhancement may show the meningeal involvement. Intracranial haemorrhage is uncommon in acute lymphoblastic but more common in other types of leukaemia. Subdural haematoma or subarachnoid haemorrhage usually indicates a poor prognosis. The CSF typically showing an increased cell count with blast cells. Blast cells may, however, be associated with a low CSF cell count. The CSF glucose concentration is low in about 50% of affected children.

Lymphomas may be primary or occur as secondary tumours following leukaemia (Porto et al. 2005a) but are relatively rare in children. Primary non-Hodgkin lymphoma of the CNS is being recognised increasingly as a complication of HIV and AIDS.

Neurological complications of Hodgkin disease are also uncommon in children. Intracerebral deposits may give rise to focal signs, basal meningeal involvement with cranial

nerve palsies, and spinal extradural deposits that can produce paraplegia. These are usually associated with CSF abnormalities. Direct extension of visceral disease into the nervous system may produce compression of the brainstem, spinal roots or brachial plexus. Paraneoplastic manifestations include a cerebellar syndrome and a polyneuropathy but are rare in childhood.

The neurological outlook after lymphoblastic leukaemia is good. A single institutional study that interviewed children and young people at a median interval of 10.2 years after diagnosis at age 0.4–18.6 years of acute lymphoblastic leukaemia reported neurological symptoms in 83% of participating survivors but little symptom-related morbidity or impairment in health-related quality of life (Khan et al. 2014).

**OPPORTUNISTIC INFECTIONS OCCURRING AS A COMPLICATION OF CENTRAL NERVOUS SYSTEM TUMOURS**

These include bacterial, viral, fungal and protozoan diseases that have been described in Chapter 11. There are specific associations between these infections and immunosuppression, as a feature of leukaemia, lymphoma or treatment of CNS tumours. CNS mumps infection is common. A progressive subacute form of measles encephalitis is rare but does occur in unvaccinated individuals and has a poor prognosis.

**PSEUDOTUMOUR CEREBRI SYNDROME (IDIOPATHIC INTRACRANIAL HYPERTENSION)**

Pseudotumour cerebri syndrome (PTCS) is synonymous with the term idiopathic intracranial hypertension (IIH) formerly referred to optimistically as ‘benign intracranial hypertension’. PTCS refers to a syndrome with raised ICP in the absence of a space-occupying lesion or apparent obstruction to CSF pathways. The diagnostic criteria, first defined 80 years ago (Dandy 1937) combine exclusion of mass lesions, cerebral venous sinus thrombosis (CVST) and other underlying causes with combinations of the cardinal features of symptoms of raised ICP, papilloedema or abducens nerve palsy, and elevated cerebrospinal fluid (CSF) opening pressure at lumbar puncture (LP). Although underlying causes, such as CVST, exclude the diagnosis, associated risk factors do not. It has been pointed out that the existence of these risk factors calls into question the designation of intracranial hypertension as ‘idiopathic’.

Visual loss is observed in about 10% of adults with the syndrome. Salman et al. (2001) found that it was also common in children, typically lasting for several months, and questioned the description of this condition as ‘benign’ applied to the condition. Other reports have also established that transient or permanent visual loss does occur in childhood (Orssaud et al. 2001). Therefore, sequential periometry and assessments of visual acuity are in order whenever possible.

A normal MRI study must be obtained before considering the diagnosis of PTCS, as a normal CT scan may not be sufficient to exclude the diagnosis (Said and Rosman 2004). Magnetic resonance venography may demonstrate stenosis of the transverse sinus, sigmoid sinus and/or jugular veins. The syndrome occurs only in children of 2 years of age or more, after the skull has become resistant enough to require sufficiently high CSF pressure to dilate. Before this age, when the skull is more compliant, similar increases in CSF pressure result in hydrocephalus.

A revised set of criteria has been proposed (Friedman et al. 2013). The proposed revised criteria do not include symptoms of raised ICP and thus exclude all cases without papilloedema or abducens palsy, excepting those in whom specific supportive neuroradiological features are identifiable. The revised criteria comprise: signs of raised ICP (papilloedema or abducens nerve palsy), a minimum threshold pressure level above which CSF lumbar opening pressure must lie, and the absence of any other underlying diagnosis (e.g. cerebral venous thrombosis) on CNS imaging or CSF examination. This threshold CSF pressure level was set at 28 cm H₂O in the obese or sedated child and at 25 cm H₂O in all other children – somewhat higher than the previously accepted upper limit of the reference range in the healthy population.

Classification is likely to change as we begin to understand the pathobiology of obesity-related central hormonal metabolism (Batra and Sinclair 2014) that may mediate some cases of PTCS. Understanding of the potential mechanisms of PTCS of other aetiologies, however, remains poor. In particular, we now recognise a group of prepubertal children with PTCS whose clinical characteristics differ from those of post-pubertal children (Rangwala and Liu 2007) in whom such mechanisms are likely to be more important.

PTCS is rare with previous estimates of the annual incidence of 1.0–2.2 per 100 000 in adults. By far the largest study of PTCS in childhood to date is a UK national population-based survey that ascertained 185 cases and calculated an incidence (95% confidence interval) of 0.71 (0.57–0.87) per 100 000 children aged 1–16 years. Diagnostic error was minimised by verifying fundoscopic appearances with ophthalmologic review, excluding CVST by venography, and checking that the clinical diagnosis remained unchanged 12 months later. The incidence increased progressively from 0.17, to 0.75 and to 1.32 per 100 000 in the age bands 1–6, 7–11, and 12–16 years respectively (Matthews et al. 2017). For cases over the age of 6 years, incidence rates in girls were more than double those in boys and the percentage of cases that was either overweight or obese increased with age from 38% of 4–6-year-olds, to 60% of 7–11-year-olds and 86% of 12–15-year-olds. The triad of raised ICP symptoms, papilloedema and elevated CSF pressure, was seen in 83% of cases.
Deficits in vision (i.e. decreased visual acuity and/or restricted visual fields) at diagnosis were reported in 33% of the 98% of cases whose vision was assessed and accompanied by papilloedema in 54 (89%) of those with visual deficits. Specific neuroimaging features of optic nerve hydrops and empty sella turcica were identified and reported in 4% of cases. The median CSF opening pressure was 35.5cH2O (range 12.0–74.0) and was found to be higher in those who were obese and those in whom the procedure of lumbar puncture was done under general anaesthesia. Retrospective application of the revised diagnostic criteria for PTCS (described above) excluded 9% of the cases included on the study’s diagnostic criteria but those excluded did not differ from other cases in their associated clinical features (Matthews et al. 2016).

The study confirms the well-recognised risks of overweight, prior medical condition and use of antibiotics or other medications. It also showing that these factors are present in three-quarters of all cases and that these key factors interact with age and sex to create a risk of PTCS in obese adolescent girls 25-fold higher than that of 4–6-year-olds of healthy weight. Raised ICP is usually the consequence of increased venous pressure in the cranial venous sinuses, as occurs with dural venous thrombosis, or more remote venous obstruction of the superior vena cava. This produces an increase in the volume of the venous compartment of the brain, which explains the small size of the ventricles despite the high CSF pressure. Such increased venous volume is likely to account for a part of the increased resistance to CSF absorption because of the turgescence of the brain tissue itself (Karahalios et al. 1996).

In some patients spontaneous resolution of ICP may occur. Repeated lumbar punctures are often effective for up to a few days and are sometimes followed by resolution of the problem but cannot be repeated indefinitely. In other cases, treatment or removal of the cause can lead to disappearance of symptoms and signs. Weight loss, for example, has an impact on symptoms. Most patients, however, require and receive therapy additional to this although there is no agreement as to the most effective treatment approach (Matthews 2008).

Steroid administration (dexamethasone, 0.1–0.25mg/kg/day, or prednisone, 1mg/kg/day) is commonly used (Salman et al. 2001) and can be given as a 2-week course with rapid taper with relatively few unwanted effects. Longer-term steroids are used only as a last resort because of the frequency and severity of side effects and the benefit of short or longer-term steroids has not been fully assessed in this clinical context. Acetazolamide (30–100mg/kg/day) and furosemide (1–2mg/kg t.i.d.) have been found useful in significantly lowering ICP in a series of cases with no comparison group (Schoeman 1994). A lumbo-peritoneal shunt may be necessary when vision appears threatened but often requires revision and may become infected. Optic nerve fenestration may be indicated when there is evidence of progressive optic neuropathy despite therapy. Jugular venous stenting is a radiological procedure that may have a role in managing this condition.

Cerebrovascular Diseases injuring the developing brain, typically by causing stroke, focal brain damage resulting from the occlusion or rupture of cerebral arteries or veins. Two main ischaemic stroke types are **arterial ischaemic stroke** (AIS) and **cerebral sinovenous thrombosis** (CSVT). In AIS occlusion of cerebral arteries, usually secondary to thromboembolism, results in focal brain infarction in a recognisable arterial territory. In CSVT thrombosis of cerebral veins and/or dural venous sinuses occurs and may or may not result in venous brain infarction. In contrast, **haemorrhagic strokes** involve vascular rupture and are usually subclassified by intracranial compartment (ventricular, parenchymal, subarachnoid, subdural). Ischaemic and haemorrhagic strokes are not mutually exclusive and co-occur in some cerebrovascular diseases: related conditions are covered elsewhere including perinatal stroke, preterm vascular disease, global hypoxic-ischaemic brain injuries in neonates and children (Chapters 1 and 2), as well as traumatic or extra-axial intracranial haemorrhage (Chapter 13).

For this chapter we will define stroke as a focal, vascular disorder occurring in children past the newborn period. The aim is to provide a thorough, clinically-relevant summary of current knowledge informing the care of children with stroke. An evidence-based approach is derived from our review of the literature to June 2014; while growth in childhood stroke research has accelerated in recent years, a paucity of clinical trials persists. We have drawn upon the relevant adult stroke evidence where appropriate, allowing for fundamental differences in the pathophysiology, risk factors, presentations, diagnosis, treatment and outcomes of stroke in children.

Original combined US ischaemic and haemorrhagic paediatric stroke rates of 2.5–2.7/100 000 children/year (Schoenberg et al. 1978; Broderick et al. 1993) are consistent with more recent studies (Fullerton et al. 2003; Agrawal et al. 2009). A recent population-based UK childhood AIS study confirmed a similar incidence of 1.6 per 100 000 and suggested increased risk for Asian and black children (Mallick et al. 2014). The prospective, population-based Canadian Pediatric Ischaemic Stroke Registry estimated combined AIS and CSVT incidence at 2.2/100 000 (1.8 AIS, 0.4 for CSVT) while a population-based Danish study found rates of 1.33 and 0.25 per 100 000 for AIS and CSVT respectively (Tuckuviene et al. 2011). Rarely, studies have suggested rates as high as 10–13 per 100 000 (Giroud et al. 1995; Lynch et al. 2002). An Australian study estimated childhood CSVT incidence at 0.34 per 100 000 children per year (Barnes et al. 2004).

Relative proportions for ischaemic and haemorrhagic strokes in childhood have been less consistent. Some studies report more haemorrhage while others report more ischaemic, suggesting proportions are likely to be equal (Earley et al. 1998; Fullerton et al. 2003). Multiple international studies suggest pediatric stroke rates are increasing (Tuckuviene et al. 2011; Gandhi et al. 2012). Factors possibly explaining an increased incidence include increased availability of sensitive diagnostic tests (MRI) and increased survival in children with at-risk conditions such as congenital heart disease, sickle cell disease and childhood cancers.

The burden of childhood stroke is large, given the substantial prevalence and long-term neurological morbidity in most survivors: compared to adults these consequences are amplified by the decades-long duration of adverse outcomes. Rates of stroke in the young (under 40) appear to be increasing (Kissela et al. 2012) and 20–25% of such individuals are children. Administrative data suggests cerebrovascular disorders are among the top ten causes of death in children (Murphy 2000) although stroke related mortality in young children may be decreasing (Fullerton et al. 2003). Economic costs of childhood stroke are substantial including for the acute and post-discharge timeframes (Lo et al. 2008) while long-term costs are less studied but likely to be substantial. Individualised attributable socioeconomic burdens may be compared to adult stroke when factoring lifelong adverse outcomes in children (Taylor et al. 1996).
Arterial blood reaches the brain via two main arterial systems. The anterior circulation originates from the internal carotid arteries (the ‘carotid system’) while the posterior circulation arises from the vertebral arteries that fuse to form the basilar artery (the ‘vertebrobasilar system’): anterior and posterior communicating arteries bridge these systems to form the Circle of Willis. Paired anterior, middle and posterior cerebral arteries arise from the circle. Anatomical flow dynamics favouring embolism into the left middle cerebral artery (MCA) may explain the left hemisphere predominance of AIS. Perforating arteries originating from the proximal portions of the paired anterior cerebral artery (ACA), MCA and posterior cerebral artery (PCA) vessels including the anterior lenticulostriate and posterior thalamostriate vessels, supply the basal ganglia and thalamus. Posterior fossa circulation arising from the vertebra-basilar arteries includes small perforating arteries supplying the brainstem and medium sized branches supplying the cerebellum (posterior inferior, anterior inferior and superior cerebellar arteries). Variable anastomoses between these arterial beds including distal leptomeningal collaterals may provide circulatory redundancy to support regional brain perfusion during reduced supply. Recognition of these watershed territories can be key in differentiating focal vaso-occlusive stroke from global hypoperfusion with focal watershed injury. Interindividually varying in cerebrovascular anatomy includes various hypoplastic segments and other congenital variations that may be clinically relevant.

Consistent with this anatomical arrangement AIS patterns are often classified as large or small vessel, based on their location within arterial territories. Occlusion of large arteries typically results in wedge-shaped lesions involving the cortex and adjacent white matter in predictable patterns. The MCA carries the largest proportion of blood flow and is most often involved in AIS. Segmental patterns of MCA occlusion are recognizable and include proximal M1 occlusion (complete loss of entire MCA territory), trunk occlusions (loss of anterior or posterior branches with sparing of basal ganglia) or lenticulostriate lesions affecting basal ganglia. Posterior circulation AIS patterns include selective regions of the brainstem, cerebellum, thalamus, occipital and temporal lobes. Recognition of arterial patterns facilitates estimation of aetiology in certain arteriopathies (Chabrier et al. 1998; Askalan et al. 2001; Braun et al. 2009).

The focal ischaemic injury of AIS typically involves thrombotic arterial occlusion. Thrombi may arrive from a distal embolic source or form locally within cerebral arteries. Regional thrombosis may result from local arterial diseases (e.g. inflammation), blood disorders (e.g. prothrombotic state), abnormal blood flow (e.g. high grade stenosis) or some combination of these factors. Thrombotic arterial occlusion may be amplified by endothelial dysfunction which has recently been implicated in in childhood AIS (Eleftheriou et al. 2012). In addition, abnormalities in the hemostatic system including coagulation, fibrinolytic and/or platelet systems can predispose to thrombus formation. In contrast to slow flow venous systems where the coagulation system may predominate platelet activation with platelet-rich thrombi may be a more significant contributor to thrombosis in high flow arterial systems. It is difficult to determine which system predominates and may relate to many variables including flow rates, shear stresses, disrupted endothelium and circulating anticoagulants.

Arterial wall disease may facilitate pathological thrombosis via multiple mechanisms. In-situ cerebral arterial occlusion mechanisms include regional arteriopathies such as vasculitis and dissection. In an injured, inflamed or otherwise diseased arterial wall the normal anticoagulant functions of the endothelium are compromised and exposure of flowing blood to collagen and tissue factor occur, activating both platelets and fibrin formation. Rapid arterial blood flow subjects the arterial wall to increased shear forces also favouring platelet activation: blood stasis or slow flow, such as arterial occlusions or severe stenoses, may favour coagulation system activation. Although precise mechanisms are incompletely understood in childhood stroke, both coagulation- and platelet-mediated thrombotic processes are important and likely to coexist. Important developmental differences in both systems may also be important (Roschitz et al. 2001; Monagle et al. 2006).

Emboli causing AIS are thrombi from the heart or proximal arteries, so-called artery-to-artery thromboembolism. Thromboemboli can also originate in the venous circulation, reaching the brain via leftward intra-cardiac shunts as seen in complex congenital heart lesions. Shunts usually moving left to right may reverse flow direction with changes in intra-thoracic pressure (e.g. Valsalva manoeuvre), resulting in paradoxical embolism. Non-thrombotic embolisation may also occur including infectious endocarditis, atrial myxomas or fragments of material from intravascular medical devices.

Brain damage from focal ischemia may depend on many factors including degree and duration of ischemia timing of reperfusion, collateral blood supply, location, developmental maturational status, metabolic demands and comorbid factors. As blood flow drops ischaemic neuronal dysfunction as demonstrated by evolving international pediatric stroke research initiatives.
occurs but can still be reversible. In transient ischaemic attacks (TIA) drops in blood flow are mild and/or brief enough to avoid permanent damage as defined by absence of lesions on MRI (Albers et al. 2002). In contrast AIS is accompanied by areas of irreversible tissue damage correlating to radiographic confirmation of infarction, however, pathological processes at the cellular level are more complex. A central core zone of permanently infarcted brain is surrounded by a penumbral zone with borderline perfusion containing potentially salvageable tissue. Factors increasing the permanent infarct volume do so by reducing penumbral perfusion or increasing metabolic demand: these include hypotension, hyperthermia, abnormal glucose or seizures. The vulnerable penumbral tissue is the primary target of acute stroke therapy and management.

Focal ischemia leads to regional hypoxia and depletion of high-energy compounds in brain parenchyma. Cerebral perfusion is dictated by mean arterial pressure, intracranial pressure and vascular resistance. Cerebral blood flow (CBF) in adults is ~50mL/100g brain tissue/minute while values for neonates and young children are approximately 20 and 30–50 respectively. CBF increases for children aged 3 to 10 years (~100mL/mg/min) before reaching adult levels by late adolescence. CBF represents 10–20% of cardiac output in infants and adults with a developmental peak >50% in infancy (Wintermark et al. 2004). Autoregulation adjusts cerebral resistance vessels in response to altered flow, carbon dioxide and metabolic factors to maintain perfusion. Cerebral autoregulation is present by term birth but matures through adolescence and may impact regional perfusion in ischaemic stroke.

Depletion of oxygen and glucose rapidly results in neuronal dysfunction with a corresponding shift from oxidative metabolism to glycolysis. Lactate production and acidosis may then further exacerbate injury. Ischaemic brain cell death evolves via two primary mechanisms. Acute necrosis occurs over hours while apoptosis evolves over days or weeks. In paediatric patients with stroke post-mortem tissue analysis has demonstrated that the duration of stroke-induced apoptosis lasts days or longer than adults. Cellular mechanisms are described elsewhere but major components include glutamate excess and receptor activation, calcium-mediated intra-cellular events, nitric oxide and free-radical generation and neuroinflammatory processes likely to also be important (Askalan et al. 2002; Shah et al. 2009). Pharmacological and neuroprotective strategies targeting these mechanisms, while successful in animal models, have been generally unsuccessful in humans. With the exception of hypothermia for neonatal global hypoxic-ischaemic injury none have focused on the developing brain where a paucity of animal models further complicate the development of neuroprotective strategies in paediatric stroke.

**Clinical Presentation in Arterial Ischaemic Stroke**

Diagnosis of stroke in children requires a high index of suspicion. Delays in AIS diagnosis are common and prolonged, often more than 24 hours from initial symptoms (Gabis et al. 2002; Hartman et al. 2009; Srinivasan et al. 2009). Children with acute neurological deficits are usually quickly brought to medical care and the largest component of time delays occur in hospital (Rafay et al. 2009). Factors influencing poor early recognition include lack of awareness by health care professionals, complex neurological symptomology and physical signs, limitations of focal neurological examination in young children, limited access to urgent specific imaging options and a broad differential diagnosis with distracting signs and symptoms (Mackay et al. 2014). Early diagnosis is required to optimise opportunities for acute neuroprotective strategies and initiation of antithrombotic therapies to promote recanalisation and prevent recurrence.

Acute onset of a focal neurological deficit is stroke until proven otherwise. In children, sudden onset of hemiparesis is the most common presenting deficit but carries a broad differential diagnosis with stroke mimics including migraine, seizure (Todd’s paresis), infections and demyelination (Shellhaas et al. 2006; Mackay et al. 2014). Other focal neurological deficits include hemianopia, gaze abnormalities, diplopia, dysphasia, dysarthria, vertigo, nystagmus, ataxia, hemisensory changes and neglect. Stroke syndromes – a constellation of deficits localising to a specific arterial territory – are recognisable but more challenging in younger children in whom the immature brain may not yet manifest certain deficits. Seizures at stroke onset are more common in children compared with adults (Trescher 1992; Delsing et al. 2001). Non-focal neurological signs and symptoms including headache, irritability and behavioural changes are frequent present and potentially misleading (Mackay et al. 2014).

A thorough history, careful examination and judicious use of imaging and ancillary investigations are required to distinguish stroke from the complex differential of stroke mimics (Table 15.1). Adult stroke screening tools may be applicable to children but are likely to require modifications (Yock-Corrales et al. 2011). Stroke signs typically begin suddenly with maximal severity at onset although fluctuations and stuttering also occurs. TIAs are not well studied in children: TIA can be defined as ‘a brief episode of neurological dysfunction caused by focal brain ischemia, with clinical symptoms typically lasting less than one hour, and without imaging (MRI) evidence of acute infarction’ (Albers et al. 2002). A recent administrative data study suggests perhaps half of children with TIA have associated stroke risk factors (Adil et al. 2014). Recognition of TIA is essential to minimise subsequent stroke occurrence.

Clinical elucidation of cause rests on a focused history and examination supported by specific imaging and laboratory investigations. Key historical variables include defining the time of onset and when the child was last seen well, the nature and evolution of current neurological symptoms and any past history of the same. History of recent infection or head or neck trauma including chiropractic neck manipulation should be sought. Relevant past history includes any chronic diseases, especially cardiac, malignancy (including cranial irradiation), child or
Part VI  Tumours and Vascular Disorders

806

family history of migraine and immunisation status including varicella. Medications of interest include oral contraceptives, chemotherapy, sympathomimetics or illicit drugs. Family history screening includes thrombotic diseases, young stroke or heart attack (<50 years), as well as use of anticoagulants.

A complete neurological examination should focus on the presenting complaints while considering the age and cognitive state of the child. The Paediatric NIH Stroke Scale (PedNIHSS) is a validated, age-adjusted tool that rapidly and accurately quantifies stroke severity in children (Ichord et al. 2011). Key additional examination elements include a focused cardiovascular evaluation with blood pressure, peripheral pulses and cranio cervical auscultation for bruits. Fundoscopy findings might include arterial changes or papilloedema. Hypertension may suggest renal artery involvement with fibromuscular dysplasia or moyamoya disease (Kirton et al. 2013) while skin examination could reveal PHACES syndrome, neurofibromatosis or Fabry disease.

Diagnosis in Arterial Ischaemic Stroke

**NEUROIMAGING**

Stroke in children is a clinical and radiographic diagnosis. Efficient use of multiple neuroimaging tools is essential to optimise timing and accuracy of diagnosis, exclude stroke mimics, identify causative mechanisms and guide management.

**Computed tomography (CT) in AIS**

The initial imaging study most often performed in childhood AIS is head CT. Practical reasons include ready availability, short scan times without need for sedation, option for vascular imaging and sensitive exclusion of emergency diagnoses (e.g. haemorrhage). However, early CT is insensitive to childhood AIS and misses the diagnosis in the majority of individuals (Srinivasan et al. 2009; Rafay et al. 2009). CT findings of AIS include focal hypodensity within an arterial territory (see Figs 15.1 and 15.2), while CT can also diagnose clinically...
Figure 15.1  *Focal, transient cerebral arteriopathy.* A 13-year-old girl collapsed in school with left-sided weakness and was transferred to the adult stroke centre within 30 minutes. (a) CT scan at 45 minutes showed loss of grey-white differentiation in the right frontal lobe and a hyperdense right internal carotid artery (ICA) (not shown) while (b) CT angiography demonstrated narrowing and irregularity of the right ICA/middle cerebral artery (MCA). The Paediatric NIH Stroke Scale score was 14 but improved spontaneously to 4 so thrombolytics were not given. (c, diffusion-weighted image) She incurred multiple additional strokes over the next 3 days and was treated with triple antithrombotic therapy and corticosteroids; (d) possible MCA wall enhancement was seen. She then deteriorated with headache, drowsiness and right pupil dilatation. (e) CT showed large haemorrhagic transformation requiring surgical evacuation while (f) conventional angiography confirmed extensive alternating areas of stenosis and dilatation with striae in the ICA, MCA and ACA. Serial MRA showed (g1, g2) worsening from day 3 to 10 with (g3, g4) improvement at 3 weeks and 6 months. At 17, the young lady is well and applying to university.

Figure 15.2  *Moyamoya disease.* A 2-year-old girl presented with acute left hemiplegia after 3 days of gastrointestinal illness. (a) Head CT demonstrated hypodensities in the right parietal and left frontal regions with (b, c) restricted diffusion in both on DWI and ADC. (d) FLAIR MRI demonstrated chronic, small infarcts in the watershed white matter and hyperintensity of the cerebral sulci ('Ivy sign'). (e) MRA suggested severe stenosis or occlusion of bilateral ICA with abnormal collaterals consistent with moyamoya; (f) conventional angiography confirmed same. Bilateral encephalomyosynangiosis was performed and (g) right external carotid injection angiogram 12 months later showed robust cerebral perfusion. At 5 years the child was developmentally normal with stable imaging but occasional hyperventilation-induced transient ischaemic attacks.
important intra-arterial thrombus (‘hyperdense artery sign’), haemorrhagic transformation and malignant cerebral oedema. With injection of contrast CT angiography can image major and early-order branches of the cervical and cerebral arteries with potential aetiology-specific findings (see below). Although risks are low age-related complications of radiation exposure need to be considered in children.

**Magnetic resonance imaging in AIS**

Circumstances permitting, MRI is the investigation of choice for the diagnosis and evaluation of childhood AIS and cerebrovascular disease (Muir et al. 2006). Limitations include sedation in young children, longer scan times and on rare occasions contraindications like implanted metal devices. MRI is significantly more sensitive and specific than CT in paediatric AIS, particularly for small lesions or those in the posterior fossa (Paonessa et al. 2009). Diffusion-weighted MRI (DWI) is exquisitely sensitive and highly specific for acute focal brain ischemia (see Figs 15.1, 15.2 and 15.3). Restricted diffusion with DWI hyperintensity and apparent diffusion coefficient (ADC) map hypointensity in an arterial territory confirms recent (within 7 days) AIS and may also image acute Wallerian degeneration (Domi et al. 2009). Evolution of diffusion, changing over days to weeks, assists in timing stroke occurrence: T2-weighted MRI changes appear within hours and evolve over time while blood sensitive modalities (e.g. susceptibility-weighted) may identify haemorrhagic transformation. Emerging MRI applications include cerebral perfusion and autoregulation, diffusion tensor imaging (DTI), functional MRI (fMRI) and ‘wall imaging’ to explore mechanisms of arteriopathy.

Arterial imaging of the head and neck with magnetic resonance angiography (MRA) should be considered standard in the evaluation of childhood AIS. MRA can often provide images of major first and second order cerebral and cervical arteries (see Figs 15.1, 15.2 and 15.3) but has limited resolution for smaller vessels (Ganesan et al. 1999; Tardieu and Sebire 2002). MRA can identify the distribution and character of cerebral arteriopathies, such as focal stenosis or wall irregularities in contrast to the abrupt cut-off expected with embolic occlusions. Acquired cerebral arteriopathies can be followed over time using MRA (Aviv et al. 2006). Parenchymal MRI sequences can also provide important arterial information such as presence of moyamoya collaterals, the ‘Ivy sign’ on FLAIR suggestive of impaired cerebral perfusion and fat-saturation sequences of the neck to demonstrate dissection. Relying on flow signal, time-of-flight MRA may lose accuracy in areas of turbulent flow which can mimic stenosis or occlusion. This problem may be overcome with gadolinium-enhanced MRA alternatives.

**Conventional angiography in AIS**

Non-invasive angiography with MRI and CT typically provides all required information for initial diagnosis and early management, however, more detailed vascular imaging with Conventional angiography may be required in some cases (see Figs 15.1 and 15.2). Several arteriopathies may only be definitively diagnosed by Conventional angiography including the ‘double lumen’ or intimal flap signs of dissection, the banding or ‘striae’ of transient cerebral arteriopathy (TCA) and diseases of the smaller vessels (Tan et al. 2009). Conventional angiography may still fail to diagnose small-vessel vasculitis where brain biopsy is required (Benseler et al. 2005). Moyamoya disease often requires Conventional angiography for both full characterisation of disease distribution and surgical planning, where additional external carotid system imaging is paramount (Scott and Smith 2009). Conventional angiography should be considered in children with otherwise unexplained AIS with suspicion of an arteriopathic process but inconclusive non-invasive arterial imaging with computed tomography.
angiography (CTA) or MRA. In experienced hands the risk of CAs in children appears to be very low with complication rates <0.5% (Wölfe et al. 2009).

**RISK FACTORS AND CAUSATION OF ARTERIAL ISCHAEMIC STROKE**

Definitive causative mechanisms are poorly understood in childhood stroke. However, many associations have been described, typically considered as ‘risk factors’, some of which satisfy accepted causation criteria with strong biological plausibility and substantial evidence, including case-control and large population-based studies: these include complex congenital heart disease or bacterial meningitis. However, additional associations carry weaker evidence and should not necessarily be considered independently causative. In contrast to adults, stroke risk factors promoting atherosclerosis are not prominent in children: thorough and prompt evaluation of potential AIS mechanisms is essential to determine best management and optimise stroke prevention, with an approach to categorising childhood AIS aetiologies provided in Table 15.2. The following provides a review of childhood AIS risk factors weighted on incidence and evidence and as best possible.

In many children AIS remains idiopathic despite thorough investigation. In single centre studies one possible risk factor is demonstrable in >80% of individuals (Chabrier et al. 2000; deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2000; Lanthier et al. 2000; Ganesan et al. 2003). About half of children with AIS are previously healthy (Ganesan et al. 2003), with the remainder harbouring multiple potential risk factors: therefore, complete evaluations are required even when one factor is found. Risk factors for older adults are uncommon in children including atrial fibrillation and conditions associated with atherosclerosis such as hypertension, dyslipidemia, smoking and diabetes (deVeber 2003). Three major categories of risk factors predominate: arteriopathy, cardiac and haematological.

**ARTERIOPATHIES AS A CAUSE OF AIS**

Diseases of the cerebral arteries are now recognised as the leading cause of childhood AIS. Most importantly, arteriopathies are associated with the highest rates of recurrence and poor outcome (Fullerton et al. 2007b; Goldenberg et al. 2009; Goldenberg et al. 2013). Arteriopathy is present in >50% of childhood AIS (Chabrier et al. 2000; Ganesan et al. 2003; Fullerton et al. 2007b; Amlie-Lefond et al. 2009; Braun et al. 2009; Mackay et al. 2011). The clinical importance of arteriopathy underscores the essential role of arterial imaging for accurate diagnosis and classification (Askalan et al. 2001; Strater et al. 2002; Lanthier et al. 2004; Fullerton et al. 2007; Braun et al. 2009).

Different terminologies and classification schemes have been proposed for childhood cerebral arteriopathies (Sebire et al. 2004). Historical classifications suffer from a limited understanding of disease biology and variable usage of descriptors for possible mechanisms, imaging features and evolution over time. The result is a continued lack of consensus within the paediatric stroke community on how to best categorise arteriopathy to facilitate both research and clinical management (Mineyko and Kirton 2013): fortunately, improved classifications are in development (Bernard et al. 2012). Within these limitations three primary categories of arteriopathy are reviewed here:

1. A syndrome of focal, unilateral and likely to be acquired arteriopathy with possible inflammatory or infectious mechanisms,
2. Arterial dissection, and

Other less common arteriopathies are listed in Table 15.2 including posterior fossa malformations–hemangiomas–arterial anomalies–cardiac defects–eye abnormalities–sternal cleft and supraumbilical raphe (PHACES) syndrome, Alagille syndrome, progeria, primordial dwarfs, childhood fibromuscular dysplasia (Kirton et al. 2013) and COL4A1 mutations (van der Knaap et al. 2006).

**Focal or Transient Cerebral Arteriopathy: Inflammation, Infection or Other?**

A cerebral arteriopathy frequently encountered in healthy young children shares distinctive features of a unilateral disorder of intracranial arteries centred at the internal carotid artery (ICA)/MCA/ACA trifurcation and featuring irregular narrowing or stenosis, often with banding or straie of the vessel wall, AIS typically involves the basal ganglia. The arteriopathy is dynamic but transient, evolving over 3–6 months to a stable residual arterial state, with an example shown in Figure 15.1. Multiple terms have been suggested for this syndrome with slight differences among them in terms of criteria, timing and suggested mechanism. Early descriptions favoured the term ‘transient cerebral arteriopathy’ (TCA) (Chabrier et al. 1998; Sebire 2006) and serial evidence since supports the time-limited, non-progressive nature the label suggests (Braun et al. 2009). As suggested in the original descriptions (Sebire et al. 2004), fewer than 5% of cases progress beyond 6 months and those that do are likely to be a different disorder, such as unilateral moyamoya (Bernard et al. 2012; Susanne Benseler and Pohl 2013).

Despite common occurrence the pathobiology of this arteriopathy is unknown. Acknowledging this uncertainty, others have suggested the more generic term of ‘focal cerebral arteriopathy’ (FCA) for such unilateral stenosing arteriopathy without evidence of an alternative mechanism (Amlie-Lefond et al. 2009). In addition, the most commonly suggested mechanism of this syndrome is vascular inflammation (e.g. primary, post- or para-infectious vasculitis) (Chabrier et al. 1998). Based on this presumption the term ‘non-progressive childhood primary angitis of the CNS’ has

Also been applied (cPACNS) (Elbers and Benseler 2008; Benseler and Pohl 2013). Other possible mechanisms for this syndrome described in the original TCA literature include intracranial dissection, a diagnosis proven for several such individuals by postmortem examination (Dlamini et al. 2011).

A more direct role of infection may also be responsible for this arteriopathy. Post-varicella angiopathy (PVA) shares all the features described in the syndrome above: based on limited studies the primary difference is a history of varicella infection in the preceding 12 months (Askalan et al. 2001; Lanthier et al. 2005). PVA typically affects the same transient, unilateral intracranial arteries with lenticulostriate basal ganglia strokes being most common (Askalan et al. 2001; Lanthier et al. 2005). Post-varicella arteriopathy occurs in adults with ophthalmic zoster (Amlic-Lefond et al. 1995). Viral re-activation from the trigeminal ganglion and trigeminovascular spread to the proximal cerebral arteries may be responsible. Cerebrospinal fluid (CSF) varicella antibodies are typically
normal although polymerase chain reaction (PCR) can also be positive (Gilden et al. 2009). Isolated pathological studies have demonstrated virus in affected vascular smooth muscle cells including in two 4-year-old children who died of PVA-associated stroke (Berger et al. 2000). As varicella vaccination is now routine PVA is expected to decrease and no consistent association with vaccination has been shown (Wirrell et al. 2004; Donahue et al. 2009).

A non-specific role for infection causing paediatric AIS is also becoming increasingly clear, although the causal pathway is not yet clearly related to arteriopathy. Clinical and laboratory evidence of ‘recent viral infection’ have long been associated with childhood AIS (Ganesan et al. 2003), with an international study of 673 AIS children associating viral upper respiratory tract infection with arteriopathy (Amlie-Lefond et al. 2009). A recent large nested case-control study found medical visits for infection in the prior month was associated with childhood AIS (Hills et al. 2012): upcoming evidence from the Vascular effects of Infection in Paediatric Stroke study (VIPS) is expected to advance understanding of this relationship (Fullerton et al. 2011). A unifying link between active or recent infection and vascular inflammation remains to be established.

Additional infections more directly lead to AIS in children. Bacterial meningitis causes both perforating artery and large-vessel diseases resulting in AIS or venous thrombosis: imaging studies have identified such vascular complications in 5–12% of children with meningitis with rates as high as 75% in young infants (Chang et al. 2003). Subarachnoid infection may result in inflammatory thrombophlebitis of neighbouring perforating arteries though late, large artery disease is also described, particularly with streptococcus pneumonia meningitis (Chang et al. 2003). The basilar distribution and chronic, progressive nature of tuberculous meningitis represents an important and aggressive cause of childhood AIS in developing countries (Springer et al. 2009), while paediatric HIV often features arteriopathy leading to ischaemic and haemorrhagic stroke (Kleinschmidt-DeMasters and Gilden 2001). More anecdotal reports have associated childhood AIS with mycoplasma, toxoplasmosis, rocky mountain spotted fever, Lyme disease, cryptococcus, Japanese encephalitis, coxsackie B4 and A9, influenza A, enterovirus, parvovirus B19, chlamydia and others.

Cerebral vasculitis with isolated, non-infectious arterial inflammation can clearly cause AIS in children. Patterns of such vasculitides are increasingly described with more specific diagnostic criteria proposed (Benseler and Pohl 2013): most are isolated to the central nervous system without evidence of systemic vasculitis, so-called childhood primary angiitis of CNS (cPACNS) (Benseler and Schneider 2004; Benseler et al. 2006; Elbers and Benseler 2008; Benseler and Pohl 2013). In contrast to the non-progressive TCA-like subtype of cPACNS a progressive bilateral cPACNS is typically bilateral and involves both proximal and more distal cerebral arteries.

A third form of cPACNS is limited to distal, small cerebral arteries. Such small vessel or angiography-negative cPACNS presents with progressive, multifocal small vessel disease rather than sudden large artery occlusions and generalised, insidious symptoms including headaches, school failure and behavioural changes. MRI appearances vary widely but heterogeneous, multifocal lesions with variable diffusion and enhancement patterns are usually seen (Benseler et al. 2005, 2006; Rafay et al. 2005; Elbers and Benseler 2008): such lesions may wax and wane with disease modifying therapy. Conventional angiography is typically indicated but since usually normal brain biopsy is usually required for pathological diagnosis (Benseler et al. 2005; Aviv et al. 2006; Benseler and Pohl 2013). Although uncommon in children small vessel vasculitis may also occur secondary to other diseases such as collagen vascular diseases, systemic vasculitides and malignancies including Kawasaki disease, Henoch-Schönlein purpura, polyarteritis nodosa, Wegener granulomatosis, systemic lupus erythematosus, Behcet syndrome and others.

Focal arteriopathies are not just intracranial. A recent series described cervical abnormalities in childhood AIS, many of which were not explained by possible dissection (Ganesan et al. 2011). Large arteries can be involved in vasculitides such as polyarteritis nodosa or Takayasu arteritis which commonly involve major aortic branches: the latter presents with absent or asymmetrical pulses, hypertension and stroke (Ringleb et al. 2005). Paediatric forms of fibromuscular dysplasia associated with stroke also feature wide-spread systemic arteriopathy (Kirton et al. 2013).

The possibility of inflammatory or infectious arteriopathy carries important treatment implications and must therefore be considered early and appropriately investigated. Diagnostic testing may include infectious studies (lumbar puncture, serology, virology, PCR) and serum markers of inflammation (ESR, CRP) or vasculitis (ANA, extractable nuclear antigens, complement, etc.). Such testing carries a very low yield in childhood AIS and negative results should not be interpreted as definitive exclusion of an inflammatory mechanism. This is particularly true in cPACNS where laboratory tests are usually negative though small vessel varieties often have mildly abnormal CSF findings (Elbers and Benseler 2008). A recent small series suggests unique inflammatory biomarkers may be seen in children with TCA/FCA arteriopathy (Mineyko et al. 2012).

Dissection and Injury

Dissection represents a disruption of arterial wall integrity, typically with formation of a subintimal hematoma. Cranio-cervical dissection may lead to AIS by multiple mechanisms including frank arterial occlusion at the dissection site by the hematoma, regional thrombosis or both. Artery-to-artery thromboembolism appears to be the predominant mechanism of AIS (Morel et al. 2012) and extension of a dissection in either direction may further exacerbate these mechanisms. Dissection probably accounts for 15–20% of childhood AIS (Fullerton et al. 2001; Chabrier et al. 2003; Rafay et al. 2006). High risk locations for extra-cranial dissection include the proximal portion and skull base regions of the ICA and the C1-C2 segment of the vertebral arteries. Intracranial dissections also occur and may mimic FCA/TCA (169) and have the
potentially added risk of subarachnoid haemorrhage (Dlamini et al. 2011). The relative proportion of intra- to extra-cranial dissections have varied across paediatric studies (Fullerton et al. 2001; Rafay et al. 2006).

Clear risk factors for dissection include trauma to the neck, spine, or retropharynx. More subtle mechanical injuries should also be considered such as external neck manipulation, extreme physical exertion or contact sports (Chabrier et al. 2003; Rafay et al. 2006), while non-accidental trauma should be considered in young children. Many paediatric dissections appear to be ‘spontaneous’ without clear history of trauma beyond normal childhood activity which may suggest inherent abnormalities in connective tissue or other arterial wall structures predisposing to dissection. Clinically evident syndromes are seldom present but in adult case-control studies histopathological abnormalities in connective tissue structure have been reported on skin biopsies in such patients. FMD may also be associated with childhood dissection (Kirton et al. 2013).

Clinical findings suggesting dissection include new head or neck pain, often beginning 7–10 days prior to stroke presentation, ipsilateral Horner syndrome or cervical bruits. Recurrence rates are substantial in childhood dissection, estimated at 20% or higher (Fullerton et al. 2001, 2007b; Chabrier et al. 2003; Rafay et al. 2006) though adult series suggest lower rates (Weimar et al. 2010) The optimal medical management of dissections is uncertain with no randomised clinical trials: current paediatric stroke guidelines suggest consideration of anticoagulation (Monagle et al. 2008, 2012; Roach et al. 2008). A recent meta-analysis in adult dissection combining data from a number of non-randomised studies found no difference between anticoagulation and antiplatelet strategies (Kennedy et al. 2012). Intracranial dissection is a relative contraindication due to risk of subarachnoid haemorrhage, with retrospective studies supporting safety of both approaches. Long-term complications of paediatric dissection including recurrence and pseudoaneurysm require additional study (Tan et al. 2009): which activities should be restricted and for how long are unclear though paediatric stroke experts are reluctant to recommend high impact activities (Bernard et al. 2007).

Trauma without dissection may also be a risk factor for childhood AIS. A history of any head and neck trauma within 12 weeks carries an odds ratio >7 for childhood AIS that is not accounted for by arterial dissection (Hills et al. 2012). Other vascular injuries causing AIS include postradiation vasculopathy (Campen et al. 2012), compression of PCA (or less commonly ACA) from increased intracranial pressure and mechanical trauma from catheterisations and extracorporeal membrane oxygenation cannulation.

Moyamoya Disease

Moyamoya is the progressive occlusion of the cerebral arteries at the Circle of Willis with formation of abnormal collaterals producing a ‘puff of smoke’ appearance on conventional angiography (see Fig. 15.2) (Scott and Smith 2009). Distal internal carotid artery disease is most common but unilateral and posterior circulation variants are also described. Moyamoya disease was the previously idiopathic, predominantly Asian variety now increasingly linked to genetic abnormalities, most notably RNF213 (Camada et al. 2011). Moyamoya syndrome is associated with systemic conditions including sickle cell disease, Down syndrome, neurofibromatosis type 1, postradiation vasculopathy, fibromuscular dysplasia and other arteriopathies (Scott and Smith 2009).

Moyamoya is not a single disease but a recognisable syndrome. Clinical presentation can include classic stroke presentations but also includes unique scenarios such as hyperventilation-induced TIA, alternating hemiplegia and progressive cognitive decline as ‘silent’ infarcts accumulate. AIS is related primarily to regional hypoperfusion, with possible thrombotic occlusion; precipitants include intercurrent illness including dehydration that cause reduced cerebral perfusion pressures. Moyamoya typically progresses slowly over time with such non-specific symptoms including headaches: recurrent AIS accumulate resulting in poor neurological outcomes (Suzuki and Kodama 1983). Onset during infancy and certain genetic abnormalities are associated with more fulminant progression (Kim et al. 2004) and artery-to-artery thromboembolic strokes also occur. Haemorrhagic stroke risk increases with age, arising from the abnormal collateral vessels and possibly predicted by the presence of microbleeds on MRI. Hypertension often occurs in moyamoya and may be a homeostatic compensatory response or relate to renal arteriopathy (Kirton et al. 2013).

MRI findings include small, multifocal AIS, typically in a ‘string of pearls’ pattern in subcortical white matter zones, small flow voids within basal ganglia and signs of pial collateralisation including the ‘Ivy sign’ on fluid attenuated inversion recovery (FLAIR) imaging. MRA carries high diagnostic value for typical moyamoya. However, on time-of-flight MRA studies show that apparently decreased calibre in distal ICA segments can be artefactual. Functional MRI cerebrovascular reserve studies can measure relative at-risk brain and guide surgical planning (Mikulis et al. 2005; Mori et al. 2009). Conventional angiography is usually required to fully define the extent of disease and plan revascularisation surgery (Fig. 15.2).

Moyamoya treatment is multifactorial. Antiplatelet agents are often employed based on a possible thrombotic component, although evidence for stroke prevention is lacking. Risks of increased haemorrhage risk over maturation should be considered. Carbonic anhydrase inhibitors such as acetazolamide have been suggested as vasodilator treatments for moyamoya (Ikezaki 2000), however, the same effect may also cause a ‘reverse Robin-Hood’ effect where healthier reactive arteries dilate and steal blood from the most vulnerable areas, leading to new stroke. Similarly, treatment of hypertension must be very cautious given high risk of drops in perfusion pressure.

Surgical revascularisation is a highly effective treatment (Scott and Smith 2009). In older children with larger calibre arteries direct procedures can be employed connecting
extracranial arteries to distal portions of intracranial vessels, usually the MCA. Indirect procedures are highly effective and likely to be safer, where approximate extracranial branches (e.g. superficial temporal artery) are transferred intracranially to overlie the ischaemic hemisphere. Angiogenesis occurs over months, resulting in neovascularisation of vulnerable areas. Encephaloduralsynangiosis (EDAS) and encephaloduralmyosynangiosis (EDMS) are popular indirect procedures. Comparative studies of different approaches have not been done, with perioperative stroke risks likely to occur 5–10% of the time (Kim et al. 2004). Younger age at onset in moyamoya may carry an increased risk of recurrent stroke and poor outcome as well as earlier surgery may be indicated (Kim et al. 2004). Success of revascularisation surgery can be evaluated with serial angiography and non-invasive imaging. A study of 143 children undergoing pial synangiosis reported >90% with symptom free survival after 5 years (Scott et al. 2004). Follow-up of direct revascularisation over decades suggests very low ischaemic recurrence rates though haemorrhage may still occur. Presence of microbleeds on MRI appears to predict moyamoya collateral haemorrhage and may influence management (Kazumata et al. 2014).

**CARDIAC CAUSES OF AIS**

Heart disease is associated with approximately 10–25% of childhood AIS cases (Chabrier et al. 2000; deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2000; Ganesan et al. 2003; Dowling et al. 2013). AIS is usually the result of cardiogenic thromboembolism with mechanisms relating to abnormalities in heart structure, function including rhythm, valvular integrity, blood flow and viscosity and endothelium. Procedure related stroke is triggered by cardiac surgical or endovascular treatment or circulatory support devices. Recognition of multiple AIS across different arterial territories immediately suggests a proximal embolic source, usually cardiac. Prompt and thorough cardiac evaluation is required in most childhood AIS cases, with a recent international childhood AIS study finding cardiac disorders in 204/667 (30%). These consisted of congenital defects in 60%, acquired in 20%, as well as isolated patent foramen ovale in 15%. Children with cardiac AIS were younger with higher rates of multifocal stroke and haemorrhagic transformation (Dowling et al. 2013).

Children with congenital heart disease frequently harbor silent AIS visible on pre-operatively MRI (see Fig. 15.3) (Miller et al. 2004). A single centre case-control study of >5500 cardiac surgery children found a one in 200 risk of symptomatic perioperative AIS (Domi et al. 2008). Reoperation was a risk factor as was procedure type: in particular post-Fontan stroke rates are 3–19% (Barker et al. 2005) while balloon atrial septostomy is likely to carry an even higher risk (McQuillen et al. 2006). Stroke risk with cardiac catheterisation is estimated at 1 : 600–700, increasing with interventional procedures (Hamon et al. 2006). A large, single-centre, long-term follow-up study found one-third of surviving children with congenital heart disease and stroke suffered recurrence, half of whom were not on therapeutic anticoagulation at the time (Rodan et al. 2012). Factors associated with recurrence included presence of infection at the sentinel stroke, a mechanical valve, prothrombotic condition and shorter time from sentinel stroke.

Patent foramen ovale (PFO) and other atrial septal defects are controversial risk factors for young stroke and poorly studied in children. Paradoxical cerebral embolisation of venous clots can occur across right to left intracardiac shunting when right-sided intracardiac pressures rise transiently (Mas et al. 2001). PFO are common in the general population, especially children where rates are >20–25% while associations have also been reported between cryptogenic stroke and PFO in young adults (Mas et al. 2001) but not necessarily recurrent stroke, suggesting many are incidental findings. A recent randomised trial of PFO closure in young cryptogenic stroke demonstrated no benefit for preventing stroke recurrence (Furlan et al. 2012). Presence of atrial septal aneurysm or prothrombotic conditions may heighten the risk of AIS with PFO.

Acquired cardiac conditions also cause childhood AIS (Dowling et al. 2013). Infective cerebral embolism is common in endocarditis, often resulting in mycotic aneurysm. Endocarditis should be considered clinically when fever, constitutional symptoms, murmur, Janeway lesions and Roth spots are present. Multifocal microbleeds are often seen with susceptibility-weighted MRI (Klein et al. 2009), the long-term significance of which have not been determined. Viral cardiomyopathy, acquired valve disease, arrhythmia and atrial myxoma can all lead to childhood AIS (Hays et al. 2006): in children with end-stage cardiac disease ventricular assist devices have markedly increased survival, however, stroke rates approach 30% (Fraser et al. 2012).

Children with unexplained AIS require prompt cardiac investigation with careful examination, electrocardiogram and echocardiography. Trans-esophageal echocardiograms may be superior in detecting potentially treatable stroke sources in older children and adults (de Bruin et al. 2006) but the thin chest wall of young children improves trans-thoracic sensitivity. Cardiac MRI and rhythm monitoring are poorly studied in childhood AIS. Current guidelines suggest consideration of anticoagulation therapy over antiplatelet strategies in proven or suspected cardiogenic childhood AIS (deVeber and Kirkham 2008; Roach et al. 2008; Paul Monagle et al. 2012). Predominance of coagulation system-mediated thrombosis in cardiac stroke favours acute anticoagulation, most often with low molecular weight heparin (LMWH).

The duration of anticoagulation requires consideration of multiple factors including status of primary risk factor (ventricular function, completeness of surgical correction), whether the AIS was procedure-related and the presence of additional risk factors such as thrombophilia, as well as others. New comprehensive guidelines for secondary stroke prevention and other thrombotic complications of congenital heart
disease are now available to support consensus across specialists and define directions for research (Giglia et al. 2013). A recent international workshop on paediatric cardiac-related stroke has created a road map for future research.

**PROTHROMBOTIC AND HAEMATOLOGICAL DISORDERS CAUSING AIS**

Abnormalities of the coagulation, fibrinolytic or platelet systems may predispose to pathological thrombus formation. Childhood stroke thrombophilia studies are challenged by developmental hemostasis, limited evidence and variable laboratory methods, however, the association between prothrombotic disorders and childhood AIS has been repeatedly demonstrated (Barnes and deVeber 2006; Mackay and Monagle 2008).

Inherited or acquired coagulation disorders are identified in 20–50% of children with AIS (deVeber et al. 1998; Barnes and deVeber 2006). A 2010 meta-analysis summarised associations with first childhood AIS and thrombophilias (Kenet et al. 2010): the highest odds ratios were for protein C deficiency (11.0/9.13–23.59), antiphospholipid antibodies or lupus anticoagulant (6.95/3.67–13.14) and lipoprotein (a) (6.53/4.46–9.55). Modest associations were noted for factor V Ledien and prothrombin gene 20210A mutations while other factors showed minimal or no association (protein S, antithrombin III, MTHFR). These studies are generally consistent with the primary studies that drove the analysis (Chan et al. 2000; Kenet et al. 2000; Strater et al. 2002; Ganesan et al. 2003; Barnes and deVeber 2006) differing slightly from a previous systematic review (Haywood et al. 2005). MTHFR mutations have unclear significance in childhood AIS since they are common in the general population. Prothrombotic states also independently increase AIS recurrence risk (Strater et al. 2002; Ganesan et al. 2006; Rodan et al. 2012) including lipoprotein and other abnormalities (Goldenberg et al. 2013). Additional prothrombotic factors of interest include abnormal levels of plasminogen, fibrinogen, plasminogen activator inhibitor (PAI), coagulation factors (VIII, IX, XI) and an increasing number of genetic polymorphisms. Studies of platelet dysfunction have been limited in childhood AIS.

Coagulation testing should be considered in all children with AIS since these disorders are common, synergistically increase AIS recurrence risk and are potentially treatable with anticoagulation. In particular, children with idiopathic AIS and those with chronic high-risk conditions such as heart disease should have thorough investigation (Rodan et al. 2012). An experienced laboratory with established age-appropriate normative values is required for accurate interpretation. Testing is typically done at diagnosis or off anticoagulants following resolution of active thrombosis: diagnosis of a pro-thrombotic disorder requires appropriate education and counseling, ideally with thrombosis experts for future prevention.

**Sickle Cell Disease**

Sickle cell disease (SCD) increases the risk of childhood AIS 400-fold. Approximately one-quarter of SCD children incur cerebrovascular complications including large and small vessel AIS, moyamoya and haemorrhage: most strokes are ischaemic but haemorrhagic rates increase with age and mortality is substantial (Manci et al. 2003). Large vessel SCD cerebrovascular disease affects major Circle of Willis arteries in a moyamoya pattern, while extracranial carotid disease is also described. SCD also affects small caliber end arteries, leading to an accumulation of subclinical white matter injuries. Mechanisms relate primarily to vascular occlusion potentiated by abnormal flow rates, endothelial damage by sickle red cells, low hemoglobin levels, proinflammatory genetics and hypertension (DeBaun et al. 2012).

Transcranial Doppler is an effective screening test in SCD and MCA flow velocities >200 cm/s predict stroke risk, guiding primary prevention treatment (Adams et al. 1992; Adams et al. 1998). Annual TCD screening from age 3 is routine, often accompanied by serial MRI for those with neurological symptoms, previous stroke or moyamoya (Fig. 15.8). MRI detects silent infarcts while MRA can survey changes in large vessel disease (Zimmerman 2005): the STOP trial found that regular transfusions lowering hemoglobin S below 20–30% resulted in a 90% relative risk reduction in stroke and stroke recurrence for children with abnormal velocities (Adams et al. 1998). Stroke risk appears to return when transfusions are stopped (Adams and Brambilla 2005): the SWiTCH trial was stopped early as a result of increased stroke risk (and no difference in iron overload) in children switched from transfusions to hydroxyurea and (Ware and Helms 2012). The effectiveness of transfusions for small vessel disease is under investigation in clinical trials but such injuries do occur despite transfusion therapy (Hulbert et al. 2011). The STOP trial has translated into better screening and fewer strokes (Fullerton et al. 2004; Armstrong-Wells et al. 2009). Transfusions remain the standard of care despite substantial morbidity to families (Roach et al. 2008; Paul Monagle et al. 2012), while the supplementary roles of antiplatelet agents, hydroxyurea and nocturnal oxygen remain to be determined. Revascularisation surgery can be effective in SCD moyamoya (Fryer et al. 2003). Lower risk cell-based transplant therapies are increasingly employed definitive treatments for SCD though long-term effects on cerebrovascular disease are not fully elucidated.

Iron deficiency anaemia has emerged as an independent, easily treatable AIS risk factor in older infants with AIS, with this association now supported by case-control evidence (Maguire et al. 2007) Iron deficiency anaemia may be present in up to 40% of childhood AIS (Ganesan et al. 2003), however, it has not been determined how such anaemia leads to AIS. A study comparing acute imaging in SCD to other anemic children found high lesion rates in the non-SCD children where iron deficiency was prominent (Dowling et al. 2012): children with low hemoglobin and microcytosis should have
iron studies and prompt correction with supplementation or even transfusion if severe.

Additional conditions associated with childhood AIS are categorised in Table 15.2. Migraine is associated with young stroke (Bousser and Welch 2005) but true migrainous infarction diagnosed according to international headache society criteria is uncommon in children. Special treatment considerations include calcium channel blockers (e.g. flunarizine) and avoidance of vasoconstricting triptans or sympathomimetics. Reversible cerebral vasoconstriction syndrome (RCVS) is reported in children (Kirton et al. 2006) and may warrant similar treatment. Potentially treatable inborn errors of metabolism including homocystinuria. Fabry disease and mitochondrial diseases may feature stroke-like episodes as well as actual ischaemic stroke. Modifiable metabolic and lifestyle factors prominent in adult stroke such as diabetes, hypertension, dyslipidemia, smoking and obesity are less commonly addressed in childhood AIS since atherosclerosis is not a significant cause for childhood AIS, however, these factors are still of concern in some children (Ganesan et al. 2003). Medications and illicit drugs may increase AIS risk, particularly oral contraceptives.

**TREATMENT IN ARTERIAL ISCHAEMIC STROKE**

Multiple consensus-based guidelines for childhood stroke have been generated in the past decade. These include current *Chest* (Monagle et al. 2012) and the American Heart Association (AHA) (Roach et al. 2008), publications that predominantly agree with each other though content and recommendations differ in some areas. Complementary stroke best practice guidelines from organisations such as AHA and the Canadian Stroke Network, the latter including paediatric recommendations also provide guidance. The following provides a chronological overview of general management issues for childhood AIS, referencing guidelines and other supportive evidence. Discussion of long-term treatments including stroke prevention and rehabilitation follow in the Outcomes section.

Emergent: Neuroprotection

‘Time is brain’ certainly applies to children with stroke. Rather than a ‘magic bullet’ medication neuroprotection refers to supportive therapy to optimise survival of at risk brain tissue: principles include optimising cerebral perfusion to deliver oxygen and glucose to the penumbra and reducing neuronal metabolic demand. Though randomised trials may never exist fundamental attention to physiological variables and prompt supportive measures to correct them may ultimately improve neurological outcome. Most children require management in paediatric intensive care units (Fox et al. 2012). Once stable, children with stroke should be promptly transferred to a tertiary care paediatric centre for management, ideally one with cerebrovascular expertise: the number and capacity of such Paediatric Stroke Centres is increasing (Bernard et al. 2014).

Blood pressure and intracranial pressure determine cerebral perfusion, while maintenance of adequate systemic blood pressure is important to maintain penumbral perfusion. Optimal blood pressure values are undetermined but targeting the upper range of normal (50–95 centile) may be reasonable. Mild hypertension may be a normal auto-physiological response to brain ischemia and blood pressure can be decreased with short acting agents (e.g. labetolol) or increased with fluids and pressor agents to achieve these parameters. Low and high glucose levels are associated with worse outcome in adult stroke (Yager and Thornhill 1997) and critically ill children (Srinivasan et al. 2004) which suggests normoglycaemia is optimal, however, insulin use in acute adult stroke carries complications and no paediatric studies exist. Supplemental oxygen remains controversial in adult stroke but maintenance of normal oxygenation and ventilation seems prudent. Guidelines support aggressive treatment of fever including regular anti-pyretics and body cooling if needed. Induced therapeutic hypothermia has not, however, been studied in childhood stroke and trials are essentially negative in paediatric traumatic brain injury (Hutchison et al. 2008) and adult stroke. Seizures commonly occur acutely in childhood AIS and are frequently subclinical (Abend et al. 2011): since these significantly increase neuronal metabolic demand and are likely to worsen brain injury in acute AIS close monitoring and active anticonvulsant treatment are recommended. Correction of severe anaemia in both sickle and non-sickle patients appears prudent.

Emergent: Recanalisation

A child presenting with acute stroke is a stressful medical emergency. Initial management rests on first principles including clinical assessment, airway breathing and circulatory support, and neuroprotective care. Intravenous thrombolytics and other emergency recanalisation procedures lack evidence in children and are, therefore, not recommended in current guidelines. In particular, endovascular device use is not advisable given that such devices are designed for adults and risks in children are unknown. Accordingly, the following discussion aims only to educate and in no way represents recommendations for such interventions.

Thrombolytic agents such as tissue plasminogen activator (tPA) are standard of care in adult stroke. Given within 4.5 hours, intravenous thrombolytics improve neurological outcome across a wide-range of stroke patients with a number needed to treat of 7–8 years or better balanced by a low risk of intracranial haemorrhage.

However, in children thrombolysis safety and efficacy are not known. Child-specific considerations include differences in stroke mechanisms, hemostasis and coagulation and others. An international observational study of nearly 700 children with AIS found that 2% received intravenous or intra-arterial thrombolytics (Amlie-Lefond et al. 2009) while violations of adult tPA protocols were common. Comparison of these ‘real-world’
cases to the existing case-report literature found a publication bias toward normal outcomes. An administrative data study also found low (<1%) but increasing rates of children with stroke receiving thrombolytics with haemorrhage and mortality rates comparable to adults, although stroke diagnoses were uncertain and not validated. Using adult selection criteria, up to 10% of children with stroke may be eligible for thrombolytics (Lehman et al. 2011).

Development of emergent recanalisation strategies in children faces numerous challenges. Diagnostic delays are a key barrier although hospital arrival times are often within eligible timeframes (Ichord et al. 2007). The paediatric modification of the NIH Stroke Scale (PedNIHSS) provides a quick, valid assessment of stroke severity (Ichord et al. 2011) while the Thrombolysis in Paediatric Stroke study (TIPS) was a safety and dose-finding trial of intravenous tPA within 4.5 hours in children 2–18 years of age. TIPS was recently stopped as a result of lack of recruitment but generated important data on the development of acute paediatric stroke treatment programs (Bernard et al. 2014). Potential benefits of intervention thrombolytic or mechanical therapies continue to be investigated in adult stroke while only anecdotal experience is reported in children (Amlie-Lefond et al. and Members of IPSS 2007) with additional challenges of smaller patient size and decreased availability of paediatric neurointerventional facilities and specialists. A summary of 34 published cases of endovascular paediatric AIS treatment (Ellis et al. 2011) found wide ranges of time to treatment, recanalisation rates and outcomes: among 28 with data recanalisation was either absent or only partial in over half (15) and (eight) had procedure related complications (Amlie-Lefond et al. 2007). The authors recommend that only children with severe deficits (NIH Stroke Scale > 10) be considered for treatment and then only by interventional teams with specific paediatric experience and paediatric stroke neurologists.

Urgent: Antithrombotic Therapies

Pathological thrombus is a primary therapeutic target in childhood AIS. Accordingly, antithrombotic therapies are an urgent consideration to prevent early recurrence or propagation and possibly promote recanalisation. Two strategies are typically considered early: heparins targeting the coagulation system or antiplatelet agents, typically acetylsalicylic acid (ASA). Based predominantly on theory, anticoagulation approaches are favoured for mechanisms such as cardiogenic stroke, high grade (low flow) stenosis or severe thrombophilic states while ASA may be preferred for many arteriopathies where endothelial disruption may favour platelet-rich thrombogenesis. Agent selection for other circumstances, such as dissection, remains controversial. No randomised controlled trials exist and choices of antithrombotic therapy vary widely among paediatric stroke experts (deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2000; Fullerton, deVeber and IPSS investigators 2007; Goldenberg et al. 2009), with published guidelines slightly discordant (Roach et al. 2008; Monagle et al. 2012). These two approaches (antiplatelet, anticoagulant) are not mutually exclusive and may change over time as stroke mechanisms are better understood and in individuals as recurrent events necessitate. Withholding early antithrombotic treatment is not currently supported by the combination of substantial safety data for all agents and high risk of early recurrence (deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2000; Strater et al. 2001).

Guidelines currently support anticoagulation as a possible first line therapy in childhood AIS (Monagle et al. 2012). An international study of 661 children found anticoagulation was consistently given to children with cardiac and dissection aetiologies (Goldenberg et al. 2009). Anticoagulation is safe in children with arteriopathy (Bernard et al. 2009) while effects of anticoagulation on haemorrhagic transformation of childhood AIS appear minimal (Beslow et al. 2011; Schechter et al. 2012): relative contraindications include intracranial haemorrhage, uncontrollable hypertension or haemorrhage diathesis. Age-dependent hemostasis differences need to be considered in young children, with duration of therapy depending on clinical indication. Two primary alternatives exist for early anticoagulation.

Unfractionated heparin (UFH) inhibits coagulation pathway enzymes. Age-specific dosing guidelines for childhood AIS range from 28 units/kg/hr in infants to adult doses of 18 units/kg/hr in older children (Monagle et al. 2012). Risks of heparin include haemorrhage and heparin-induced thrombocytopenia in <4% although rapid reversal of heparin effects with protamine may be advantageous in select circumstances. Monitoring by activated partial thromboplastin times (APTT) and heparin levels may be challenging: LMWHs are subcomponents of heparin. LMWH differences include subcutaneous dosing, more predictable pharmacokinetics, less frequent monitoring and lower risk of thrombocytopenia. These differences, and the substantial nature of childhood AIS safety data (deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2000; Bernard et al. 2009) have resulted in LMWH becoming a treatment of choice at many centres for acute anticoagulation of childhood AIS. Dosing and monitoring guidelines are available (Monagle et al. 2012) and typically involve once or twice daily injections as well as monitoring of antifactor Xa levels: parents can be taught to administer LMWH, usually with favourable tolerability. Oral anticoagulation with warfarin (vitamin K antagonist) is typically reserved for those requiring long-term treatment, complex congenital heart diseases being most common. Paediatric administration guidelines (Monagle et al. 2012) typically target an INR of 2.0–3.0 (2.5–3.5 for mechanical heart valves) while relative contraindications include infants and young children with unpredictable vitamin K levels, children with gastrointestinal disorders or those playing contact sports. New oral anticoagulants currently being tested in children have not yet been evaluated for paediatric stroke prevention but appear favourable in adult populations. New guidelines for antithrombotic therapy in children with complex congenital heart disease should also be accessed (Giglia et al. 2013).
Guidelines also currently support antiplatelet agents as first line therapy for non-cardiogenic childhood AIS including headaches, while altered level of consciousness must be reacted to immediately as waiting until later signs including pupillary dilatation may reduce good outcomes. Management includes stabilisation, emergent imaging (CT) and measures to reduce intracranial pressure (sedation, paralysis, manipulation of pCO2 and osmotic therapy). Randomised trial evidence supports a net benefit of decompressive hemicraniectomy in adult stroke (Vaheki et al. 2007), while studies of malignant cerebral oedema in childhood AIS have been limited but suggest outcomes are favourable, including quality of life measures and those with dominant hemisphere lesions (Ramaswamy et al. 2008; Smith et al. 2011).

Anti-inflammatory treatment with steroids as is used for definite CNS vasculitis may have a role in transient cerebral arteriopathy with a presumed inflammatory basis. There are no definitive clinical, imaging or laboratory biomarkers to confirm active inflammation in acute unilateral arteriopathy of the TCA subtype. Steroids have modest side-effect profiles in acute stroke in adults and they may modulate the arteriopathy reducing the severity of eventual arterial stenosis and risk of early recurrent stroke: based on the natural history of TCA with stabilisation by 3 months a short course of corticosteroids could be considered (Benseler and Pohl 2013), while some evidence supports the use of such immunomodulatory therapy in small vessel cPACNS (Hutchinson et al. 2010). TCA in the context of either active varicella infection or possibly post-varicella angiopathy could warrant antiviral therapy. Additional treatments targeting adult stroke complications that should be considered in children include aspiration prevention, feeding and nutrition, skin care and deep vein thrombosis prophylaxis. The benefits for outcome facilitated by the development of stroke units in adults will hopefully be realised as more specialised paediatric stroke centres develop (Bernard et al. 2014).

OUTCOMES AND CHRONIC MANAGEMENT IN ARTERIAL ISCHAEMIC STROKE

Survivors of childhood stroke typically experience neurological morbidity including moderate to severe deficits or epilepsy in >50% (Ganesan et al. 2000; deVeber et al. 2000; Delsing et al. 2001) while mortality rates are 5–10% (deVeber et al. 2000; Delsing et al. 2001). Comprehensive rehabilitation targets physical, occupational, language, cognitive/behavioural and psychosocial consequences for both child and family (Paediatric Stroke Working Group 2004). Lessons from evolving evidence-based guidelines for adult stroke rehabilitation are applicable: while the ‘enhanced plasticity’ suggested to improve outcomes from early brain injury is an oversimplification age is one of many complex variables that must be considered. Evolving understanding of developmental plasticity and brain reorganisation are providing new strategies to promote recovery (Kirton 2013).

Hemiparesis and motor disabilities are a leading sequela of childhood AIS with major functional consequences (deVeber et al. 2000; Ganesan et al. 2000). The upper extremity is often most affected because of MCA involvement but leg and gait problems are also common: damage to basal ganglia or cerebellum may lead to additional movement disorders or ataxia, while post-stroke hemidystonia can emerge months after basal ganglia infarction and be disabling. Neuroimaging may allow some prediction of motor outcomes at diagnosis (Boardman et al. 2005; Domi et al. 2009) and physical as well as occupational therapies remain the mainstay to optimise motor recovery though evidence specific to childhood AIS is sparse (Dobkin 2004). Programs combining strength and aerobic conditioning, task-specific training and promotion of an active lifestyle are recommended. Constraint induced movement therapy (CIMT) pairs restraint of the unaffected limb with therapy to promote hemiparetic limb function. Evidence supports marked long-term CIMT effectiveness in adult stroke (Taub et al. 1998; Taub et al. 2002; Wölf et al. 2006, 2008) with emerging evidence in perinatal stroke paediatric populations (Taub et al. 2004; Sung et al. 2005; Charles and Gordon 2006; Taub et al. 2007), however, trials in childhood stroke are required, while bimanual therapy approaches may compliment CIMT (Charles and Gordon 2006). Non-invasive neuromodulation such as transcranial magnetic stimulation (TMS) now has substantial randomised trial evidence in adult stroke motor rehabilitation (Hsu et al. 2012). A small randomised trial in childhood AIS demonstrating favourable tolerability and possible benefit on motor function requires replication (Kirton et al. 2008).

Peripheral electrical stimulation recommended in some adult stroke rehabilitation guidelines are untested in children, however, robot-assisted rehabilitation and virtual reality strategies being advanced in adult stroke may be applicable. Spasticity and dystonia limit function in children with AIS. Selective use of botulinum toxin can alleviate tone top enhance function though issues of cost, frequency and tolerability must be considered. Assistive devices such as ankle-foot orthoses or hand splints may facilitate positioning and function in adult stroke while in growing children with disability attention to musculoskeletal health including bone density and scoliosis is important. For all rehabilitation needs, emerging evidence combining orthopaedic and physical medicine physicians, occupational, physical and speech therapists, child psychologists and educational specialists as well as other parties is required. Morbidity-targeted interventions should include objective, blinded pre- and post-interventional outcome measures focused on function and participation whenever possible.

Neuropsychological impairments limit academic success and psychosocial health (Friefeld et al. 2004; Nass and Trauner 2004). On average, children with AIS have moderately impaired global intellectual function (Hetherington et al. 2005; McLinden et al. 2007) that is difficult to predict by age,
lesion size, side or location. Verbal learning and memory are often impaired in children following stroke (Lansing et al. 2004; Max 2004; Studer et al. 2014) while language dysfunction is common (Hertz-Pannier et al. 2002) and associated with dominant hemisphere lesions (Nass and Trauner 2004). Formal neuropsychological testing is often required to optimise educational planning including serial measures as deficits may emerge across development (Westmack et al. 2007; Westmack et al. 2009). Potentially treatable, attention-deficit–hyperactivity disorder rates are increased (Max et al. 2004) while emotional and behavioural disorders including depression, anxiety and impaired social function may also develop (Mosch et al. 2005), impacting health-related quality of life and peer relationships (Neuner et al. 2011).

Given high recurrence rates, secondary stroke prevention is a key medical issue. Stroke and TIA recurrence risks range from 7% to 35% (deVeber et al. 2000; Lanthier et al. 2000, 2004) with population-based data suggesting 5-year rates of 20% (Fullerton et al. 2007b): risk is heavily weighted to children with arteriopathy (Chabrier et al. 2000; Lanthier et al. 2004) with rates >65% (Fullerton et al. 2007b). There are no randomised trials but observational data demonstrates recurrence rates are higher in children not on antithrombotic therapy (Lanthier et al. 2004) while ASA (1–5mg/kg/day) is most often employed (Goldenberg et al. 2009), consistent with published guidelines (Roach et al. 2008; Monagle et al. 2012): select conditions including certain cardiac conditions may indicate long-term anticoagulation (Giglia et al. 2013). Other prevention treatments include immunomodulation for vasculitis, transfusions for SCD, revascularisation surgery for moyamaya, removal of medications and treatment of medical conditions (e.g. iron deficiency). Good arterial health should be emphasised including balanced nutrition, regular exercise, avoidance of smoking and drugs, as well as surveillance for hypertension and dyslipidemia.

Remote symptomatic epilepsy occurs in 15–20% of childhood AIS survivors (deVeber et al. 2000; deVeber and Canadian Paediatric Ischaemic Stroke Study Group 2001; Fitzgerald et al. 2007). Most are focal, arising from perilesional areas, though bilateral EEG abnormalities and epileptic encephalopathies can occur (Fitzgerald et al. 2007; Kirton et al. 2008). Concerns that ongoing clinical seizures or even subclinical pathological electroencephalographic activity can adversely affect plastic neurodevelopment and recovery in children after stroke are theoretical but important: predictors of epilepsy may include cortical involvement (deVeber et al. 2000) as well as younger age and seizures at presentation and careful historical screening for seizures as well as judicious use of electroencephalography is required. Treatments follow fundamental principles of anticonvulsant use in children: as a focal injury in a previously healthy brain, children with AIS can be excellent epilepsy surgery candidates (Wyllie et al. 2007).

Headaches are more common in childhood stroke, occurring in one third of patients (deVeber et al. 2000). Risks include underlying diseases such as moyamoya, comorbid primary headache problems (e.g. migraines) as well as psychological factors. Worsening headaches may indicate disease progression or recurrence in certain disorders including cPACNS or moyamaya. Most established headache interventions are safe in children with AIS with exceptions including effects of non-steroidal anti-inflammatory medications on ASA effectiveness and vasoconstricting triptans in children with migrainous infarction or other vasculopathy.

Complete psychological and social support of child and family is essential. Family-centred care allows identification of the complex psychosocial challenges faced by most families. Effects on quality of life occur in most survivors and their family (Gordon et al. 2002) and relate to both neurological and psychosocial factors (Friefeld et al. 2004). Coping strategies may improve adult stroke outcome but are unstudied in children. Treatment should consider the lifestyle of the individual child, goals and level of functioning and be integrated into the school and home environments (Paediatric Stroke Working Group 2004), while parental guilt may also be an educational target (Bemister et al. 2014). Families require guidance in interpreting the many unproven therapeutic options presented to them, including those with legitimate potential (e.g. stem cells) and none at all (Rosenbaum 2003). Educational and supportive organisations are increasing on a global scale (IAPS 2014).

CEREBRAL SINOVENOUS THROMBOSIS

Cerebral sinovenous thrombosis (CSVT) represents thrombosis within the cerebral venous system. Only about 50% of children will have parenchymal involvement with venous infarction, which is often haemorrhagic. Estimates of CSVT incidence range from 0.25 to one in/100 000 children/year, accounting for about 25% of paediatric ischaemic strokes (Barnes et al. 2004; Mallick and O’Callaghan 2009). In neonates, who are at greatest risk, diagnosis has improved but is often still missed (Golomb et al. 2009): evidence rests on a seminal population-based study of 160 consecutive paediatric CSVT (deVeber et al. 2001) and more recent large patient series (Heller et al. 2003; Kenet et al. 2004; Sebire et al. 2005; Jordan et al. 2010). As a treatable condition with high mortality clinical awareness of neonatal and childhood CSVT is essential.

Anatomy, Physiology and Pathobiology of CSVT

A network of veins and sinuses drains blood from the brain with patterns generally flowing medially towards midline channels then posteriorly. CORTICAL veins feed the superior
sagittal sinus in the superficial system, with internal cerebral, medullary, thalamic and other deep system veins converging at the Vein of Galen and straight sinus in the deep system: these two systems join the torcula before draining into bilateral transverse and sigmoid sinuses that empty into the internal jugular veins. Other recognisable venous territories include cavernous and petrosal sinuses, large superficial veins (e.g. Trolard, Labbe) and a venous network draining the posterior fossa. The sinuses are passive venous channels existing between layers of the dura mater. A fixed lumen allows slow, potentially reversible flow sensitive to impaired venous return. In supine infants the occipital bone may mechanically compress the superior sagittal sinus (Tan et al. 2011); as most CSF re-absorption also occurs in the sagittal sinus thrombosis (see Fig. 15.4). Coagulation cascade activation and fibrin-rich thrombosis predominates in CSVT over platelet-mediated processes. The importance of prothrombotic conditions or states, both acquired or inherited, therefore, have greater impact. Virchow’s triad describes alterations in blood composition, flow or the vessel wall as promoters of thrombosis and provides a practical framework to consider CSVT mechanisms and risk factors. Anticoagulant mechanisms may differ in the venous system compared with the arterial system where endotelial thrombomodulin levels are increased (Lin et al. 1994); venous wall injury may relate to infection or inflammation, trauma, surgery or compression (Deitcher et al. 2004; Tan

Figure 15.4 Cerebral sinovenous thrombosis (CSVT). A 16-year-old boy with active inflammatory bowel disease had diarrhoea, mild dehydration and iron deficiency anaemia. He presented with sudden onset left leg weakness and several days of diffuse new headache. (a) Head CT demonstrated focal hypodensity in the right frontal lobe (open arrow) and possible hyperdensity in the superior sagittal sinus (closed arrow) while (b) CT venogram confirmed multiple filling defects in the superior sagittal sinus diagnosed as CSVT; (c) MRI showed bilateral, parasagittal oedematous lesions with (d) only the inner portion having restricted diffusion. After 3 months of anticoagulation the young man had mild leg weakness with (e) full recanalisation of the venous sinuses and chronic infarcts with hemosiderin staining on MRI.
Mechanisms are not mutually exclusive and many children with CSVT will harbour multiple risk factors across these elements.

CSVT obstructs venous flow, increasing venous and tissue pressure within brain parenchyma. Consequences will depend on the location and degree (complete or not) of blockage and range from focal changes in a discrete venous territory to global drainage impairment with increased intracranial pressure. Initially, increased regional tissue pressure results in vasogenic oedema, producing neurological symptoms without infarction. Variable alternative venous drainage pathways and collaterals may mitigate this process. Further increases in venous pressure will eventually exceed incoming arterial pressure leading to infarction. MRI may distinguish these states of parenchymal disease, comparing diffusion sequences to T2 (see Fig. 15.4), however, restricted diffusion lesions may sometimes reverse.

Clinical Presentations of CSVT

CSVT must be recognised quickly to minimise poor outcomes. Diagnosis is challenging, particularly in infants who account for ~50% of paediatric CSVT (Carvalho et al. 2001; deVeber et al. 2001). In contrast to AIS a gradual onset of diffuse neurological signs and symptoms is more typical: common presentations include headache, nausea and vomiting and markers of signs of increased intracranial pressure (papilloedema, VIth nerve palsy). Childhood CSVT often mimics idiopathic intracranial hypertension (IIH) while seizures are more common, compared to both childhood AIS and adult CSVT, occurring in 40–90% (deVeber et al. 2001; Wasay et al. 2008): focal deficits can occur acutely but are more common in older children (Rivkin et al. 1992; Carvalho et al. 2001; deVeber et al. 2001). In the largest published study, proportions of presenting features included headache (54%), seizure (48%), altered consciousness (49%), focal signs (53%) and papilloedema (22%) (deVeber et al. 2001).

Diagnosis of CSVT

Neuroimaging

Childhood CSVT diagnosis requires timely use of appropriate neuroimaging. Imaging diagnosis shares the challenging nature of clinical recognition and is often missed or delayed with many mimics and pitfalls (Shroff and deVeber 2003). Illustrative imaging-based reviews of childhood CSVT diagnostic approaches and challenges are available (Bracken et al. 2013). Parenchymal imaging can be diagnostic, however, the principal required approach involves clear imaging of the venous system to demonstrate filling defect(s). CSVT distribution ranges from diffuse major sinuses to discrete single veins: multiple sinuses or veins will be involved in about half of patients (deVeber et al. 2001) while thrombus location, extent and degree of occlusion are likely to determine parenchymal injury. Infarct patterns correlate with affected venous drainage territories in children (Teksam et al. 2008) with the superficial system most commonly affected. Deep system CSVT is most diagnostically challenging where even a small thrombus in a critical location such as the straight sinus may have catastrophic consequences, however, modern neuroimaging has greatly improved the accuracy of childhood CSVT diagnosis.

CT without contrast cannot exclude CSVT (Bousser and Russell 1997). Focal hyperdensity of veins or sinuses can be observed but a significant false positive rate is seen, particularly in young infants with higher hematocrits, slower flow and relatively hypodense brain tissue (Davies and Slavotinek 1994). Subdural haemorrhage layering over the tentorium in young infants or trauma patients can mimic transverse sinus thrombosis. Imaging showing a hyperdense straight sinus, thalamic stroke and/or intraventricular haemorrhage are recognisable, life-threatening presentations of deep system CSVT (Linn et al. 2009). Contrast-enhanced CT venography (CTV) is a highly sensitive and specific diagnostic test for childhood CSVT: filling defects in venous structures are diagnostic and thinner slices with multiplanar reformations improve diagnostic accuracy (Figs 15.4 and 15.5) while contrast outlining luminal thrombus may result in an ‘empty delta’ sign at the torcular. Combining CT and CTV across multiple imaging intervals warrants concern given repeated radiation exposure in children.

MRI is often indicated in childhood CSVT. Advantages over CT including better assessment of brain parenchyma and lack of radiation are countered by the need for sedation in young children. MRI can differentiate venous congestion and vasogenic oedema (FLAIR sequences) from cytotoxic oedema and infarction (restricted diffusion) as well as from haemorrhagic transformation (blood-sensitive sequences) (Fig. 15.4). MRI can also characterise the extent and nature of the thrombus itself, often appearing hyperintense on T1 and T2 images (Fig. 15.6) although many mimics exist (Leach et al. 2006). Susceptibility-weighted MRI may be more sensitive for small cortical vein thromboses. Restricted diffusion of a thrombus may predict slower recanalisation (Favrole et al. 2004) (Fig. 15.6). MRI venography (MRV) is often comparable to CTV, however, with important differences: options include time-of-flight and gadolinium-enhanced venograms. Time-of-flight studies are subject to flow artifacts (Ayanzen et al. 2000) mimicking filling defects and must be interpreted with caution. Enhanced MRV appears superior to time-of-flight in adults and has similar utility in children (Farb et al. 2003). Careful interpretation is essential and CTV may be required for confirmation.

RISK FACTORS AND CAUSATION OF CSVT

Associations with reasonable biological plausibility of a causative role can be defined in most children with CSVT. Associated factors vary by age, with neonates and young infants...
Figure 15.5  Cerebral sinovenous thrombosis (CSVT). A 6-year-old boy with vomiting and diarrhoea for 4 days due to gastroenteritis presented with new onset headaches and personality change. Examination revealed a dehydrated, encephalopathic child with papilloedema while laboratory studies found severe microcytic anaemia and iron deficiency. Head CT demonstrated (a) bifrontal hypodensities with haemorrhagic transformation and (b, arrows) CT venogram showed a large burden of thrombus throughout the superior sagittal sinus. Treatment including anticoagulation resolved the thrombosis by 3 months: at 2 years, (c) the child has extensive encephalomalacia with global delays, behavioural disorder and symptomatic epilepsy.

Figure 15.6  Cerebral sinovenous thrombosis (CSVT). A 7-year-old boy was undergoing induction chemotherapy for acute lymphoblastic leukemia including L-asparaginase. He developed recurrent, paroxysmal complex visual hallucinations and new headache. (a) MRI demonstrated hyperintense signal throughout the superior sagittal sinus (SSS) on T1 consistent with CSVT. (b) A parasagittal image demonstrated a focal lesion with restricted diffusion and subacute haemorrhage in the visual association cortex consistent with venous infarction. (c) Thrombus in the SSS and a cortical vein also demonstrated restricted diffusion.

more likely to be idiopathic. About two-thirds of children harbour multiple risk factors (deVeber et al. 2001) that combine to cause disease, suggesting a thorough evaluation is required in most patients even when one potential factor has been identified. The largest population-based study of childhood CSVT described the following proportions of risk factors: prothrombotic disorders (41%), dehydration (25%), systemic infection (9%), head and neck infection (18%), other head and neck disorders (12%), haematological disorders (12%) and malignancy (8%). Most studies to date have categorised major risk categories of infection, prothrombotic states, as well as both acute and chronic diseases.

Infection is commonly associated with childhood CSVT. Septic CSVT occurs in the context of head and neck infections including otitis media, mastoiditis, sinusitis, meningitis and others. Septic CSVT is likely to account for up to 50% of patients (deVeber et al. 2001; Sebire et al. 2005; Wasay et al. 2008): mechanisms include direct spread of infection from tissue sites into neighboring venous sinuses resulting in thrombophlebitis. In addition, infections may promote CSVT via more systemic mechanisms such as dehydration in gastroenteritis, systemic inflammatory responses and septic coagulopathy. Human necrobacillosis causes Lemierre syndrome with pharyngitis and neck pain progressing to jugular
Prothrombotic disorders have long been associated with childhood CSVT, reported in 20–80% of series (Ganesan et al. 1996; deVeber et al. 1998; deVeber et al. 2001). This prevalence appears larger than adult CSVT where estimates are only 15–20%: a systematic review and metaanalysis childhood CSVT patients described the following odds ratios for prothrombotic conditions: antithrombin III deficiency (18.41, 3.25–104.29), protein C deficiency (6.30/1.56–25.40), protein S deficiency (5.27/1.53–18.21) and factor V Leiden (2.74/1.73–4.34), while multiple other thrombophilias did not reach statistical significance. The largest single prospective case-control study of 149 children found coagulation abnormalities in 56% compared with 21% of controls (Heller et al. 2003). A metaanalysis of genetic factors in adult CSVT confirmed associations with FVL and PTG20210A that appeared stronger than in childhood CSVT (Marjot et al. 2011). Recurrence of CSVT has been associated with prothrombotic conditions (Kenet et al. 2007) although results from the metaanalysis above were inconclusive. Novel prothrombotic states associated with adult CSVT such as factor XII C46T are untested in children: D-dimers may be a serum biomarker of CSVT in adults and are currently being studied in children. Given these associations and the common occurrence of multiple risk factors a prothrombotic evaluation is typically required for children with CSVT.

Many underlying medical conditions increase the risk of CSVT. Dehydration is a common, recognisable and immi- nitently treatable factor. Chronic systemic diseases commonly co-occur in older children with CSVT: inflammatory bowel disease (Fig. 15.4) confers multiple risks including systemic inflammation, diarrhoea-induced dehydration and iron-deficiency (Standridge and de Los 2008). Risk is increased in children with lupus anticoagulant and antiphospholipid antibod- ies in systemic lupus erythematosus. Malignancies and their treatment may create prothrombotic states such chemotherapy side-effects (L-asparaginase), immunocompromised states and resultant infections, cerebral involvement of cancer and interven- tional procedures (Deitcher et al. 2004). CSVT may complicate 1:200 childhood acute lymphoblastic leukaemia patients (Santoro et al. 2005) while nephrotic syndrome may deplete coagulation factors to increase CSVT risk (Fluss et al. 2006).

Iron deficiency anaemia is an independent, treatable risk factor for childhood CSVT (Sebire et al. 2004; Maguire et al. 2007). Cardiac disease is present in <10% of children with CSVT and may relate to surgery, instrumentation or other factors (deVeber et al. 2001; Sebire et al. 2005). Traumatic head injury with direct damage to venous sinuses causes CSVT: of 131 children requiring CT for head injury 6% had CSVT (StiefeI et al. 2000). An all ages study of nearly 1000 patients with trauma and head CT found CSVT in >10% with risk approaching 35% when fractures approximated a sinus (Rivkin et al. 2014). Mechanical compression of the sagittal sinus in infants also predisposes to CSVT (Tan et al. 2011).

**TREATMENT AND OUTCOMES IN CSVT**

Two current paediatric stroke guidelines provide evidence-based recommendations for CSVT management (Roach et al. 2008; Paul Monagle et al. 2012). An additional European consensus guideline on paediatric CSVT treatment was also published in 2012 (Lebas et al. 2012). Finally, AHA guidelines for diagnosis and management of CSVT including children are also available (Saposnik et al. 2011): evidence across these sources is modest, resting predominantly on uncontrolled but clinically relevant paediatric and adult studies. First principles of acute care and neuroprotection described above remain a priority.

Promotion of endogenous thrombolytic mechanisms with anticoagulation to prevent thrombus progression and promote recanalisation is the primary medical intervention in CSVT. Best available evidence comes from a large single-centre study of 162 infants and children with CSVT treated by anticoagulation protocol (Moharir et al. 2010). Of 79 children, 56 (71%) received anticoagulation with significant haemorrhage reported in 5% and was not associated with worse outcome. Perhaps most importantly, propagation of thrombus within the first week occurred in nearly 30% of children who were not anticoagulated when using serial imaging compared to 5% who were: such propagation was associated with new infarction and worse outcome. Additional support for anticoagulation in childhood CSVT is provided by multiple adult clinical trials and cohort studies, smaller paediatric studies and paediatric trials in extra-cranial venous thrombosis. Multiple adult CSVT trials have provided evidence supporting improved survival and outcome with anticoagulation while meta-analysis confirms favourable safety and probable efficacy in reducing death and disability (Stam et al. 2003). Large cohort studies have confirmed the safety of anticoagulation in adult and paediatric CSVT (deVeber et al. 1998; Dix et al. 2000; deVeber et al. 2001; Sebire et al. 2005; Mallick et al. 2009).

The current consensus guidelines (Roach et al. 2008; Saposnik et al. 2011; Lebas et al. 2012; Paul Monagle et al. 2012) are in general agreement with each other regarding the indications, contraindications and duration of anticoagulation therapy. ‘Major’ cerebral or systemic haemorrhaging is a consistently stated relative contraindication to anticoagulation. If acute anticoagulation is not started repeat imaging within 5–7 days is suggested given risks of propagation (Moharir et al. 2010) while initial anticoagulation options include LMWH and UFH with relative risks and benefits as outlined above: paediatric dosing guidelines for each are available (Monagle et al. 2012). Anticoagulation duration parallels adult recommendations, usually given for 3 months (or 6 weeks in
neonates) followed by reimaging, with an additional 3 months (or 6 weeks in neonates) given if full recanalisation has not been achieved. If risk factors have been minimised or removed therapy is typically stopped at 6 months (3 months for neonates) regardless of the completeness of recanalisation. Despite this evidence practice patterns across paediatric stroke experts appear to vary widely (Jordan et al. 2010).

Additional therapeutic considerations for childhood CSVT include the following. Emergent recanalisation interventions are described for adult CSVT, however, must be considered experimental in children: limited adult evidence suggests possible efficacy of endovascular thrombolysis but a high rate of poor outcomes (Stamm et al. 2008). Paediatric experience consists of isolated patients (Prasad et al. 2006; Wasay et al. 2008): one single-centre case-series of 21 children with CSVT described thrombolytic therapy in four patients who had experienced severe thrombus progression despite initial anticoagulation (Mallick et al. 2009), with regional thrombolytics and guide wire manipulation accomplished without major complications. Decompressive hemicraniectomy has been performed with good outcome in isolated patients (Coutinho et al. 2009): increased intracranial pressure must be detected and monitored closely for attendant optic nerve damage and visual loss. At-risk children may require regular ophthamological examinations, serial visual field testing and imaging and though evidence is lacking treatment options include carbonic anhydrase inhibitors, serial lumbar punctures, lumbarperitoneal shunting or optic nerve sheath fenestration. Infection-related CSVT requires aggressive antibiotic therapy and, in some patients, surgical intervention (e.g. mastoidectomy). Corticosteroids are possibly harmful in adult CSVT and not recommended unless targeting a specific systemic inflammatory diseases: additional modifiable risk factors include hydration, restoration of iron stores, removal of jugular venous lines and modifying chemotherapy regimens.

Multiple cohort studies have defined outcomes after paediatric CSVT although few have used standardised outcome measures. Most lack long-term follow-up and shorter observation periods for young children may underestimate long-term developmental consequences. Consistent with this, 25% of children in the Canadian Paediatric Ischaemic Stroke Registry-Toronto outcome study showed increased severity of deficits over time (deVeber et al. 2001). Long-term, comprehensive neuropsychological studies are yet to be completed: children with CSVT require the same family-centred approach to rehabilitation, education and support as outlined above.

Rates of favourable outcome range widely from 26% to 75%, demonstrating a generally worse outcome than adult CSVT (Wasay et al. 2008) and mortality rates of 4–25% have been reported though primary causes of death is often not described. The largest population-based childhood CSVT study with mean follow-up 1.6 years reported 35% with deficits, 20% with epilepsy and 9% mortality (5% attributable to CSVT) (deVeber et al. 2001). A prospective single-centre study of 162 infants and children found no mortality in children older than 1 month but unfavourable outcome in 47% with 63% considered mild or normal (Moharir et al. 2010): intracranial hypertension, hydrocephalus and visual complications occur in up to 30% (Sebire et al. 2005; Mallick et al. 2009). Across adult and paediatric studies factors associated with poor outcome include coma at presentation, intracranial haemorrhage, bilateral infarction and deep system involvement (deVeber et al. 2001; Wasay et al. 2008): recurrence is uncommon but does occur, particularly in children with chronic risk factors. The largest study reported recurrence of cerebral or systemic thrombosis in 13% of children with CSVT (deVeber et al. 2001), a rate comparable to adults: ongoing risk factors must therefore be screened for and managed when possible. Incomplete recanalisation is common in children (Sebire et al. 2005; Vieira et al. 2009) but any influence on outcome is not well understood (Moharir et al. 2010).

HAEMORRHAGIC STROKE

Haemorrhagic stroke is a cerebrovascular event characterised by rupture of cerebral blood vessels often associated with neurological injury. Extravasation of blood occurs into intracranial compartments, the names of which are used for haemorrhagic stroke classification. Intracerebral (i.e. intraparenchymal) haemorrhage (ICH) is most common (50–75% of patients) and carries the greatest morbidity (Giroud et al. 1995; Lanthier et al. 2000). Subarachnoid haemorrhage (SAH) accounts for <25% of paediatric patients with aneurysms being most common. Intraventricular haemorrhage (IVH) usually represents an extension of ICH (Kumar et al. 2009): location influences differential diagnosis but haemorrhaging across multiple compartments is common. Haemorrhagic stroke is a neurological emergency with a high mortality rate, both acutely and later due to a high recurrence risk. Haemorrhagic stroke incidence is probably comparable to ischaemic stroke in children, estimated at one to five out of 100 000 children/year (Mallick and O’Callaghan 2009): compared to ischaemic stroke, there is increased need to find a specific aetiology, surgical treatment, mortality, chance of good outcome and recurrence in haemorrhagic stroke. (Fullerton et al. 2007a; Lo et al. 2008) Conditions predisposing to both ischaemic stroke and haemorrhagic stroke include moyamoya, sickle-cell, infectious and non-infectious vasculitis and certain congenital vasculopathies.

A number of single centre, retrospective cohort studies and case series have contributed to our understanding of paediatric haemorrhagic stroke (Livingston and Brown 1986; Lin et al. 1999; Lanthier et al. 2000; Blom et al. 2003; Lo et al. 2008; Kumar et al. 2009): these are presented in Table 15.3. To date, published paediatric stroke consensus guidelines

focus on ischaemic stroke and do not address haemorrhagic stroke (deVeber and Kirkham 2008), with adult guidelines for haemorrhagic stroke management available and cited below where appropriate (Morgenstern et al. 2010). This section provides a general summary of clinical presentations, diagnostic imaging, treatment and outcomes followed by discussion of select childhood haemorrhagic stroke aetiologies. Related topics addressed elsewhere include preterm and perinatal haemorrhagic stroke (Chapter 1) as well as extra-axial subdural and epidural hematomas (Chapter 13).

Anatomy, Physiology and Pathobiology of Haemorrhagic Stroke

Major cerebral arteries within the subarachnoid space send perforating branches to the brain parenchyma. Rupture of large arteries at the Circle of Willis spills blood directly into the subarachnoid space and with forceful ejection blood may also directly enter brain tissue. A major complication of SAH is vasospasm of regional arteries and it can also introduce blood product into the CSF, potentially causing obstructive posthaemorrhagic hydrocephalus. The size and location of the ruptured artery influences what will likely be the cause and consequences of haemorrhagic stroke although predicting mechanism by location is less accurate in children. Most haemorrhagic stroke are supratentorial, however, further distinctions of cortical versus subcortical used in adults are not well-defined in children (Blom et al. 2003; Meyer-Heim and Boltschauser 2003; de Ribaupierre et al. 2008).

There are multiple potential mechanisms of brain injury in haemorrhagic stroke. Intraparenchymal hematomas or ‘jets’ of arterial blood can directly injure brain tissue though tissue may often just be mechanically displaced rather than irreversibly damaged; impaired regional perfusion may compromise oxygen and glucose delivery, as well as brain metabolism. Blood–brain barrier compromise generates cerebral oedema and further increases mass effect. Many of the immediate life-threatening complications relate to rapid increases in intracranial pressure and herniation: depending on hematoma location herniation patterns include direct transtentorial, cerebellar, central and subfalcine syndromes as well as intracranial pressure complications secondary to obstructive hydrocephalus.

Clinical Presentations of Haemorrhagic Stroke

Sudden, severe, ‘thunderclap’ headache, particularly accompanied by neurological symptoms, is haemorrhagic stroke until proven otherwise. Headache with nausea and vomiting is the leading presenting symptom in children, reported in >50%, however, in one large series, although headache was reported in nearly 80%, only 30% had ‘sudden’ in onset (de Ribaupierre et al. 2008). Acute presentations are more typical of SAH and aneurysms than arteriovenous malformation (AVM) where symptoms can be subacute or chronic (Meyer-Heim and Boltschauser 2003). Warning or ‘sentinel’ bleed symptoms may resolve quickly but require careful attention and evaluation especially if associated with altered level of consciousness and focal neurological deficits. Seizures occur at presentation in 15–37% (Livingston and Brown 1986; Meyer-Heim and Boltschauser 2003; Lo et al. 2008; de Ribaupierre et al. 2008; Kumar et al. 2009), often leading to other diagnostic considerations and delaying haemorrhagic stroke diagnosis. Subtle and slowly progressive clinical presentations of haemorrhagic stroke in children are described in nearly half of patients (Livingston and Brown 1986; Meyer-Heim and Boltschauser 2003) while bulbar signs, ataxia and rapid-onset coma are typical of posterior fossa bleeds. Hypertension is common at presentation but may be a reactive, physiological response (Lo et al. 2008).

Similar to AIS, diagnostic delays are common in childhood haemorrhagic stroke, possibly related to lower index of suspicion in primary care physicians and less specific signs and symptoms, particularly in young children (Meyer-Heim and Boltschauser 2003; Lo et al. 2008; de Ribaupierre et al. 2008): following immediate stabilisation, thorough examination may suggest the underlying cause. Cranialbruits, skin lesions such as telangiectasias or purpura, infective endocarditis signs or genetic syndromes may be clues, while fever and meningismus may occur with subarachnoid blood but infection requires exclusion. A recently developed Paediatric ICH imaging score using variables of haemorrhage volume, hydrocephalus, herniation and posterior fossa location demonstrated clinically useful prognostic utility (Beslow et al. 2014). All children with suspected haemorrhagic stroke require continual vital signs monitoring, intensive nursing, frequent re-assessment and urgent neuroimaging.
Part VI  Tumours and Vascular Disorders

Figure 15.7  Aneurysm. A healthy 13-year-old girl presented with thunderclap headache and loss of consciousness. (a) Head CT demonstrated large intraparenchymal haemorrhage with intraventricular extension, effaced sulci and cisterns as well as enlarged temporal horns. (b) CT angiography demonstrated a large, complex aneurysm of the left middle cerebral artery with (c) conventional angiogram confirming same (left) with complete resolution following surgical repair (right). The child was well 2 years later with very mild hemiparesis and mild psychological morbidity.

Figure 15.8  Sickle cell moyamoya haemorrhage. (a, left) A 14-year-old girl with large vessel sickle-cell arteriopathy in a moyamoya pattern suffered bilateral watershed strokes as a young child. (a, right) After being stable for years on transfusions her last annual MRI demonstrated a small microbleed in the left basal ganglia on susceptibility-weighted imaging (arrow). (b) MRA showed otherwise stable severe arteriopathy with absent internal carotids. She developed a new headache that progressed over 2 hours to sudden vomiting and loss of consciousness, with (c) head CT demonstrating acute haemorrhage in the right thalamus with intraventricular extension and effaced cisterns. She required emergent intubation and extraventricular drain insertion; early recovery was good but she incurred multiple complications.

Diagnosis of Haemorrhagic Stroke

Neuroimaging

CT imaging should be completed without delay in children with suspected haemorrhagic stroke. The high risk of imminent mortality in haemorrhagic stroke would very seldom be outweighed by the very small lifetime risk of radiation in young children (Brenner and Hall 2007). Adult studies of SAH report CT sensitivities of 92–100% within 24–48 hours, 85% at 72 hours and 50% at 1 week (Edlow et al. 2008), while sensitivity and specificity of CT within 6 hours are 97–100% (Perry et al. 2011). In children given the lack of such evidence, adult data are extrapolated: acute blood is hyperdense on CT though at active haemorrhaging sites signal varies (see Figs 15.8 and 15.10). Immediate interpretation with attention to markers of mass effect and impending herniation is essential: quick volume estimation methods such as ABC2 or ABC/XYZ provide prognostic information in children (Beslow et al. 2010; Kleinman et al. 2011). Acute CTA may be diagnostic of a root cause such as aneurysm or AVM (Fig. 15.7) while presence of a 'spot sign' or contrast extravasation on CTA also predicts early hematoma expansion in adults (Thompson et al. 2009). Serial CT may be required as early haematoma expansion may occur in >30% of childhood haemorrhagic stroke (Beslow et al. 2014).

Combined clinical and radiographic decision-making tools are in development to eliminate the need for lumbar puncture in some suspected haemorrhagic stroke patients with normal CT, however, these tools have not and will likely never be validated in children. Therefore, a child with clinically suspected haemorrhagic stroke and normal CT usually requires lumbar puncture to exclude xanthochromia. Time required for xanthochromia to develop in children is unknown but adult estimates of 6–8 hours appear reasonable (Edlow et al. 2008). Serial dilution of red cell counts across tubes is unreliable (Shah and Edlow 2002).
Occasional false negative conventional angiography may result from vasospasm, thrombosis or haemorrhage effects while another study of paediatric SAH suggests conventional angiography and MRA have comparable clinical utility (Fasulakis and Andronikou 2003). When a clear alternative aetiology has not been found children with haemorrhagic stroke should undergo conventional angiography to definitively exclude vascular pathology. Given the need for anesthesia combined diagnostic and interventional procedures may be indicated.

MRI applications in paediatric haemorrhagic stroke are several but not usually in the acute setting. Advantages include improved characterisation of parenchymal injury and vascular aetiologies with both MRA and MRV (Figs 15.7, 15.9 and 15.10). One childhood haemorrhagic stroke study found MRI was diagnostic of aetiology in 65% with only a 6% false negative rate (Liu et al. 2006). Blood-sensitive MRI sequences such as susceptibility-weighted imaging can detect small microbleeds suggestive of diagnoses such as non-accidental trauma, familial cavernomas or endocarditis (Figs 15.7, 15.9 and 15.10) (Klein et al. 2009; Santhosh et al. 2009). Conventional angiography is often required and remains the criterion standard (Fig. 15.7), with achieving a definable aetiology much higher in children undergoing conventional angiography: 97% versus 80% (Al Jarallah et al. 2000). However, two-thirds or less undergo conventional angiography (Livingston and Brown 1986; Lin et al. 1999; Al Jarallah et al. 2000; Meyer-Heim and Boltshauser 2003). Occasional false negative conventional angiography may result from vasospasm, thrombosis or haemorrhage effects while another study of paediatric SAH suggests conventional angiography and MRA have comparable clinical utility (Fasulakis and Andronikou 2003). When a clear alternative aetiology has not been found children with haemorrhagic stroke should undergo conventional angiography to definitively exclude vascular pathology. Given the need for anesthesia combined diagnostic and interventional procedures may be indicated.

**RISK FACTORS AND CAUSATION OF HAEMORRHAGIC STROKE**

A cause can be defined for 85–90% of children with haemorrhagic stroke, with differential diagnoses outlined in Table 15.4.
Disorders of the blood vessels themselves as well as haematological factors must be considered. Inherent vascular disorders predominate (Livingston and Brown 1986; Lin et al. 1999; Lanthier et al. 2000; Blom et al. 2003; Meyer-Heim and Bolthausen 2003; Lo et al. 2008; de Ribaujepierre et al. 2008; Kumar et al. 2009). The primary diseases of AVM, cavernoma and aneurysm are discussed in detail below including specific management: preceding that is an overview of additional aetiologies and review of general management principles and outcomes.

Numerous congenital arteriopathies leading to childhood haemorrhagic stroke are described. Hereditary haemorrhagic telangiectasia (HHT) (also known as Osler-Weber-Rendu) leads to systemic vascular malformations of the lung, liver and brain (Kring et al. 2005). Mutations in multiple transforming growth factor (TGF)-b signalling superfamily genes are dominantly inherited (Govani and Shovlin 2009). Management strategies including serial imaging and familial screening are available (Faughnan et al. 2011; McDonald et al. 2011) while inherited disorders of connective tissue such as COL4A1 predispose to recurrent haemorrhagic stroke (van der Knaap et al. 2006). Unique paediatric varieties of fibromuscular dysplasia predispose to childhood HA (Kirton et al. 2013) while a rapidly growing number of congenital cerebral vasculopathies have been associated with haemorrhagic stroke including MOPDII, PHACES and Alagille syndromes. Moyamoya (discussed above) carries increasing risk of haemorrhagic stroke with age that may be predictable by neuroimaging.

Acquired arteriopathies also cause haemorrhagic stroke in children. Infectious arteriopathies including mycotic aneurysms secondary to bacterial endocarditis and HIV vasculopathy may be particularly high risk for haemorrhagic stroke. Intracranial arterial dissection also carries a risk of paediatric SAH (Fullerton et al. 2001): other arteriopathies typically causing AIS but risking haemorrhagic stroke include sickle-cell vasculopathy, postradiation vasculopathy as well as primary and secondary CNS vasculitides. Hypertension has been associated with 5–10% of childhood haemorrhagic stroke but recent studies suggest it is rarely a primary causative factor (Lo et al. 2008). Traumatic haemorrhagic stroke can occur in any compartment although most commonly are epidural or subdural and may appear as haemorrhagic contusions or smaller foci. Recent minor trauma may be associated with aneurysmal haemorrhage in children (Singhal et al. 2013) while unexplained haemorrhagic stroke in young infants should raise consideration of non-accidental trauma. One shaken baby syndrome study found subdural bleeds predominated (94%) but SAH (16%) and ICH (8%) also occurred (Morad et al. 2002). Haemorrhagic stroke can complicate dural arteriovenous fistulas (DAVF) which can be spontaneous or post-traumatic (Neumaier-Probst 2009): haemorrhaging into brain neoplasms accounts for 2–15% of patients (Lo et al. 2008) while iatrogenic haemorrhagic stroke may occur with neurosurgical procedures or intravascular interventions. CSVT infarcts often feature haemorrhagic transformation and can mimic primary haemorrhagic stroke (deVeber et al. 2001) while AIS transformation is also

common (Beslow et al. 2011; Schechter et al. 2012) and needs to be differentiated from primary haemorrhagic stroke.

Haemorrhagic diathesis as the primary cause for haemorrhagic stroke occurs more commonly in children than adults (Roach and Riela 1995). Such haematological factors occur in up to 30% of patients (Livingston and Brown 1986; Lanthier et al. 2000; Blom et al. 2003; Meyer-Heim and Bolshhauser 2003; Kumar et al. 2009) with one study reporting 32% including thrombocytopenia, coagulation factor deficiencies or sickle-cell disease (Fig. 15.8) (Al Jarallah et al. 2000). Other haemorrhagic diatheses include genetic factor deficiencies such as hemophilia, haematological malignancies and their treatment, as well as hepatic failure. Thrombocytopenia can be secondary to infectious, immune or oncological disease and screening for medication, accidental ingestion and illicit drug use should include consideration of intoxication with anticoagulants, antiplatelet agents, sympathomimetic drugs, cocaine and amphetamine (Forman et al. 1989; Levine et al. 1990). Children with haemorrhagic stroke require immediate laboratory hemostatic evaluations including complete blood count, prothrombin and partial hromboplastin times, as well as international normalised ratio.

**TREATMENT IN HAEMORRHAGIC STROKE**

The fundamental principles of acute brain injury management outlined above apply to the child with haemorrhagic stroke. Immediate consultation of a paediatric neurosurgeon is essential as neurosurgical intervention is required in 60–80% of patients (Livingston and Brown 1986; Blom et al. 2003; Meyer-Heim and Bolshhauser 2003; de Ribaupierre et al. 2008; Kumar et al. 2009): procedures include hematoma evacuations though clear evidence-based indications or even accurate predictive tools do not exist for children. Placement of intraventricular drains and intracranial pressure monitoring devices is often indicated to maintain cerebral perfusion while additional surgical procedures may include removal or embolisation of AVMs, clipping or coiling of aneurysms, tumour removal and VP shunts for posthaemorrhagic hydrocephalus.

Medical management of childhood HA focuses on supportive neuroprotective care as outlined above. Acute seizures are common and may exacerbate intracranial hypertension or occur subclinically, suggesting a role for EEG monitoring (Beslow et al. 2013). Treatment or underlying conditions includes antibiotics for endocarditis, replacement of deficient factors (e.g. factor VIII in hemophilia), reversal of antithrombotic medications (e.g. vitamin K, protamine, platelet transfusion) and immunomodulatory therapy for inflammatory conditions (e.g. ITP). Recombinant factor VIIa (rFVIIa) within 4 hours appeared to improve haemorrhage and neurological outcomes in adults but carried high thrombotic complications, while applications in children are not defined.

**OUTCOMES IN HAEMORRHAGIC STROKE**

When compared to childhood ischaemic stroke long-term outcomes are better for haemorrhagic stroke but early mortality is higher (Lo et al. 2013): a summary of the outcomes from the largest studies to date is found in Table 15.2. Across all studies mortality rates ranged from 6–54% and epilepsy in 0–17% to overall ‘good’ outcome in 50–75%. A long-term outcome study of 56 children including detailed neuropsychological testing reported 65% survival with 50% having favourable outcomes (Blom et al. 2003) while hemiparesis persisted in 31% though typically not severe, with 17% having epilepsy. Additional adverse outcomes include visual deficits, language disorders and ataxia after posterior fossa haemorrhagic stroke, with hydrocephalus requiring shunting after intraventricular haemorrhage. Nearly half of children will require some form of rehabilitation (Meyer-Heim and Bolshhauser 2003): a paediatric imaging ICH score of 2 or more based on larger bleed size predicts severe outcome or death with sensitivity and specificity of 90% and 68% (Beslow et al. 2010; Lo et al. 2013; Beslow et al. 2014). Other accurate outcome predictors for childhood haemorrhagic stroke remain to be determined, with factors associated with poor outcome including delayed diagnosis, impaired consciousness at presentation, posterior fossa location (Higgins et al. 1991; Kumar et al. 2009) as well as aetiology and associated diagnoses (Lo et al. 2013). Mortality appears highest with acute posterior fossa bleeds (Livingston and Brown 1986) while risk of epilepsy may be associated with need for acute intervention (Beslow et al. 2013).

Recurrence of paediatric haemorrhagic stroke is common, requiring treatment of at risk lesions and careful long-term surveillance. One population-based study suggested 5-year cumulative recurrence rates of 10%, most within 6 months (Fullerton et al. 2007a) while another longer-term study found recurrence in 21% over 10 years (Blom et al. 2003). AVM recurrence rates are comparable to adults, ~2% per year (Fullerton et al. 2005), however, in contrast to many adults paediatric decisions must consider a risk duration lasting many decades for persistent lesions. Additional risk reduction strategies such as activity restriction and avoidance of contact sports are not well studied.

**SPECIFIC VASCULAR DISEASES CAUSING CHILDHOOD HAEMORRHAGIC STROKE**

**ARTERIOVENOUS MALFORMATIONS**

Vascular malformations are developmental anomalies with preserved connections between normal vessels. Malformations can be divided into four histological types: arteriovenous malformations (AVMs), cavernous malformations, venous angiomata and capillary telangiectasias, with the last two not causing haemorrhagic stroke, with cavernomas discussed below. True
CAVERNOUS MALFORMATIONS

Cavernous malformations are dense collections of thin, dilated, vascular channels without intervening brain parenchyma which change over time, accruing microbleeds, thrombosis and calcification. Studies of childhood cavernous malformations are limited (Acciarri et al. 2009; Bhardwaj et al. 2009) though recent large case series appear to support previous reports (Gross et al. 2013), while pathogenesis is increasingly understood through the elucidation of multiple genetic causes. Dominantly inherited familial cavernous malformations syndromes typically include multiple cerebral and retinal lesions with an accompanying higher risk of haemorrhaging (Sirvente et al. 2009): children treated with cranial irradiation are also at increased risk.

Clinical presentations in children are approximately evenly distributed between seizures, focal deficits or symptomatic haemorrhage (Lee et al. 2008). On average, paediatric cavernous malformations are larger, bleed more and have associated vascular anomalies compared to adults. Annualised risk of haemorrhaging with cavernous malformations is less than AVM and aneurysm, estimated at <0.25% annually (Del Curling et al. 1991) while bleed size is also typically small, with life-threatening haemorrhage being rare. The exception are brainstem cavernous malformations where pontine locations predominate and higher morbidities from haemorrhaging may influence management (Bhardwaj et al. 2009). Modern MRI with highly sensitive sequences for detecting microbleeds has increased cavernous malformations diagnosis (see Fig. 15.10): lesions are usually well demarcated, spherical, heterogeneous ‘popcorn’ lesion with mixed T1 and T2 intensities and evidence of blood (Mottolese et al. 2001). Angiography is usually normal aside from associated vascular malformations.

Unruptured lesions in non-eloquent locations may be managed expectantly, with surgical resection usually indicated for children with epilepsy, deficits or critically located lesions (Roach Riela 1995; Punt 2004) but the role of radiosurgery appearing limited (Mottolese et al. 2001). In a recent large series of 181 children with lobar cavernous malformations surgery in 83 was associated with older age and larger symptomatic lesions (Gross et al. 2013) with none of the 98% completed resected patients having recurrence over nearly 5 years and complication rate of 5%. Another series of 42 children undergoing cavernous malformations surgical resection reported 69% with favourable outcome and low complication rates of 7% associated with critically located lesions (Acciarri et al. 2009). Cavernous malformations surgery for epilepsy is often curative (Consales et al. 2009; Gross et al. 2013) while brainstem cavernous malformations surgery in children is likely to be influenced by location, size, approximation to the pial surface, child age and history of radiation (Bhardwaj et al. 2009).

ANEURYSMS

Aneurysms are focal enlargements of arteries secondary to compromised wall integrity. All three arterial wall layers – intima, media, adventitia – are involved. Pseudoaneurysms are enlargements involving fewer than three layers. Less than 5% of brain aneurysms become symptomatic in childhood. Across the largest case-series of childhood haemorrhagic stroke, aneurysms represent 2–34% of patients (see Table 15.2). Population-based data suggests childhood SAH is usually due to aneurysms, representing >10% of paediatric haemorrhagic stroke (Jordan et al. 2009). Paediatric aneurysms usually present with SAH, often with extension into parenchyma, intraventricular and extra-axial spaces (Lasjaunias et al. 2005), with headache and encephalopathy the leading...
clinical manifestations (Jordan et al. 2009). Large lesions may feature progressive focal deficits; in children there is a male predominance, the inverse of adults (Ostergaard 1991). Children, particularly infants, are more likely to harbour giant aneurysms (>10cm), found in up to 50% of children with aneurysms (Kasahara et al. 1996). Posterior circulation location is more common in children, found in 20–27% (Khoo and Levy 1999); on average, infants typically have larger aneurysms of major intracranial vessels while older children have smaller lesions favouring the internal carotid bifurcation (Khoo and Levy 1999; Jordan et al. 2009).

Aneurysms in children are more heterogeneous than in adults. Saccular aneurysms are relatively common and may reflect congenital conditions causing arterial wall weakness and aneurysms with presentations early in life (Khoo and Levy 1999). Pathophysiology is not well understood but a growing list of both congenital and acquired vascular diseases are associated with childhood cerebral aneurysms (Table 15.4). Genetic aetiologies are increasingly defined through research initiatives like the Familial Intracranial Aneurysms Study (Broderick et al. 2009): examples include connective tissue disorders like COL4A1, Ehlers-Danlos syndrome and polycystic kidney disease, with such inherited aneurysms appearing to carry higher risks of early and recurrent haemorrhage. Multiple aneurysms occur in Majewski osteodysplastic primordial dwarfism (MOPD-II) causing fatal SAH during childhood in most. Aneurysms and SAH occur in childhood forms of fibromuscular dysplasia (Kirton et al. 2013), while arterial dissections are a common cause of childhood pseudoaneurysms (Lasjaunias et al. 2005; Tan et al. 2009). Trauma-induced arterial injury may result in aneurysm formation while infectious cerebral emboli in bacterial endocarditis results in local arteritis, compromising wall integrity and leading to mycotic aneurysm formation over days to months that must be monitored (Brust et al. 1990). Other infectious arteriopathies, particularly HIV, may result in aneurysm formation in children.

CT/CTA can usually confirm both SAH and an aneurysmal source (Fig. 15.7) while MRI may add information including evidence of older bleeds and parenchymal injury. MRA has limited resolution for small lesions but non-invasive vascular imaging can diagnose complications such as vasospasm. Conventional angiography is the criterion standard to diagnose, characterise, and plan management of aneurysms in children and can also optimise diagnosis of arteriopathies while detecting additional lesions in at risk patients.

Immediate measures to reduce early recurrent haemorrhage include analgesia, sedation and seizure control. Vasospasm is a leading cause of post-SAH morbidity in adults, however, the now preferred term ‘delayed cerebral ischemia’ implies multiple mechanisms beyond vasospasm potentially mediating this important, treatable complication of SAH (Budohoski et al. 2014). Historical ‘triple H’ therapy (hypervolemia, hypertension and hemodilution) (Komotar et al. 2007) has not been studied in children where first principles of neuroprotection describe above may be more important. Nimodipine, a calcium channel blocker, remains the only approved medical treatment for post-SAH vasospasm in adults though mechanisms of beneficial effects are controversial (Budohoski et al. 2014) and there are no paediatric studies. Additional measures targeting post-SAH ischemia including immunomodulatory agents, magnesium, vasodilators, antiplatelet therapies and angioplasty are unproven and untested in children. Posthaemorrhagic hydrocephalus is associated with poor outcome in adult SAH though paediatric principles of hydrocephalus management are likely to apply.

Instances of early haemorrhaging re-occurring may be more common in children (Wojtacha et al. 2001). Early curative intervention is therefore ideal but not always possible with treatment options including direct surgical clipping and interventional procedures. Coiling of aneurysms with insertion of small metal pieces resulting in thrombosis and obliteration is increasingly reported in children: a series of 23 children with heterogeneous aneurysms treated endovascularly reported a high angiographic cure rate and good medium term outcome in >95% (Saraf et al. 2012). A recent more than 20-year follow-up of over 100 children with aneurysms found surprisingly high excess long-term mortality attributable to aneurysms, suggesting long-term follow-up is essential (Koroknay-Pal et al. 2012).

VEIN OF GALEN MALFORMATIONS

Vein of Galen malformations (VGAM) form early in embryogenesis with abnormal feeding by choroidal arteries and do not connect to the deep venous system, with lesions most often presenting early in infancy with high-output heart failure secondary to intracranial shunting and cranial bruit. Macrocephaly occurs secondary to venous hypertension and hydrocephalus: brain injury often results from progressive, diffuse cerebral infarction, sometimes called the ‘melting brain’, the pathophysiology of which is incompletely understood. Antenatal ultrasound diagnosis in ~30% is associated with worse outcome (Rodesch et al. 1994; Alvarez et al. 2007) with CT or MRI showing a large dilated vascular channel in the region of the Vein of Galen. MRI is most sensitive to parenchymal injury with MRA, while MRV characterises vascular anatomy: only conventional angiography can establish the number and origin of feeding arteries and venous drainage.

VGAM management is enormously challenging. A score combining neurological, cardiac and systemic involvement with lesion characteristics helps select children for emergent intervention, delayed surgery or palliative care (Alvarez et al. 2007; Geibprasert et al. 2010). Stable neonates are often followed for 4–6 months before intervening; those with refractory heart failure, hydrocephalus or neurological deterioration are treated earlier. Embolisation procedures typically involve injection of material into feeding arteries to reduce shunting and restore hemodynamic stability. A series of 317 VGAM children dominates the published experience (Lasjaunias et al. 2006; Alvarez et al. 2007). Case series from other leading institutions (Lasjaunias et al. 1996; Fullerton et al. 2003; Lasjaunias et al. 2006; Heuer et al. 2010; Li et al. 2011; Berenstein et al. 2012) total
only a small fraction of the Lasjaunias series, although findings are generally consistent. Embolisation was reported in 74% with 21% managed conservatively (5% lost to follow-up) while mortality in those requiring neonatal intervention was 52%. These results drove the development of the prognostic scale that now supports allocation of many such children for palliative management. Among treated survivors fewer than 10% had severe disability, most of these having incomplete obliteration (Alvarez et al. 2007) while most children stable enough to wait for delayed surgery had normal neurological outcomes (76%). CSF shunting for hydrocephalus is generally unsuccessful and even potentially harmful: children with VGAM require a multidisciplinary team of specialists and comprehensive chronic care.

In summary, we are in an era of rapid discovery in the field of paediatric stroke. Many current approaches to the clinical care of infants and children with ischaemic stroke are based on logical extension from adult stroke and other forms of paediatric thrombosis. Each child should be approached with knowledge of the current guidelines and an individualised appreciation of the stroke syndrome of the child: guidelines will undoubtedly change as stronger levels of evidence become available in future studies. The optimal care of infants and children with stroke requires a team approach ideally in a centre with paediatric stroke expertise, paying attention to the child and family.

Epilepsy is neither a disease nor a syndrome, but rather a symptom with multiple causes, genetic or lesional, representing a very significant part of neurology that may present in a variety of conditions and circumstances. It is not possible to describe all manifestations in this chapter, and the reader is referred to publications by Arzimanoglou et al. (2004, 2016), Bureau et al. (2012), Engel and Pedley (2007) and Duchowny et al. (2013). Clinical epileptic seizures are the most characteristic but not sole manifestation of electrographic activation as interictal abnormalities are also an important part of its semiology. This applies to electroencephalogram (EEG) manifestations as well as to clinical disturbances, especially neurological, cognitive and behavioural ones that may be present interictally.

**TERMINOLOGY AND DEFINITIONS**

Epileptic seizures are transient clinical events that result from abnormal and excessive activity of synchronised, more or less extensive populations of cerebral neurons. This abnormal activity results in paroxysmal disorganisation of one or several brain functions, manifested by positive, excitatory phenomena (motor, sensory, psychic) or negative phenomena (such as loss of awareness, of muscle tone or of language), or by a mixture of the two. The clinical events that constitute epileptic seizures can be extremely diverse, and no single manifestation is essential. A detailed description of the ictal event is the cornerstone of accurate diagnosis.

The EEG events that underlie the seizure constitute the epileptic discharge, which in some cases may remain without clinical expression or have only subtle clinical consequences, referred to as ‘subclinical seizures’ (Gastaut 1973). The seizure discharge and/or clinical seizure may remain localised or be expressed bilaterally and synchronously over most of the cortical surface – the so-called generalised seizure. In this chapter, the term ‘seizure’ is used in its etymological sense (from ‘to seize’) and applied to both epileptic and nonepileptic events (Stephenson 1990), although it is more often reserved for seizures caused by an epileptic mechanism.

Epileptic seizures may result from intercurrent events such as fever, hypoglycaemia or acute central nervous system (CNS) infections (occasional seizures), or may recur spontaneously without a known precipitant (unprovoked epileptic seizures that, when repeated, constitute epilepsy). The dividing line between isolated (or occasionally provoked) and unprovoked epileptic seizures is not always evident. In fact, isolated (occasional) seizures can have a recognisable cause, or may be unprovoked. However, factors that either precipitate the attack or contribute to arresting it must exist. Many precipitating factors such as intermittent photic stimulation, certain sounds or lack of sleep, are well-recognised but many more are unknown, imperfectly described or only suspected. Stress, psychological factors and fatigue are likely to be responsible for precipitating a sizeable proportion of epileptic seizures, but their mechanisms of action are largely unexplored. The term ‘occasional seizure’ is ambiguous. It may imply that a paroxysmal epileptic event may only occur once under given circumstances (thus, by definition, not considered as epilepsy). However, ‘occasional’ may also mean that an event (in this case a seizure) can recur from time to time, under the same circumstances.

Some confusion is caused by the interchangeable use of the terms ‘provoked’ and ‘triggered’. Provoking factors include fever, head injury, excessive alcohol intake, withdrawal from alcohol or drugs, hypoglycaemia, electrolyte disturbance, brain infection, ischaemic stroke, intracranial haemorrhage and pro-convulsive drugs (Pohlmann-Eden et al. 2006). Seizures following psychological stress or sleep deprivation are not considered ‘acute symptomatic’ but rather ‘triggered’ by these factors in susceptible individuals. Reflex seizures are also considered to be triggered by a given stimulus (stroboscopic lights, reading, etc.). Most seizures are likely to be multifactorial in origin.

Epilepsy should be considered as a more enduring condition, or a group of conditions, in which epileptic seizures occur repeatedly without a detectable cause (Gastaut 1973) due to structural brain damage or an intrinsic functional propensity. For epidemiological purposes, the term epilepsy was defined as at least two seizures separated in time. In clinical practice, it refers to a lasting, ‘chronic’ condition and may be
more than the repetition of seizures (Aicardi 1997). Subclinical epileptic activity, especially if prolonged, is likely to disorganise many brain functions and causes transient or lasting cognitive and behavioural disturbances (Tassinari et al. 1992; Arzimanoglou et al. 2005).

In 2014, the International League Against Epilepsy (ILAE) accepted the recommendations of a task force altering the practical definition of epilepsy in special circumstances that do not meet the criteria of two unprovoked seizures (Fisher et al. 2014). The task force proposed that epilepsy be considered a brain disease defined by any of the following conditions:

1. At least two unprovoked (or reflex) seizures occurring more than 24 hours apart;
2. One unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years;
3. Sufficient elements present allowing the diagnosis of an epilepsy syndrome.

Convulsions are episodes of involuntary muscle contractions that are either sustained (tonic) or brief (clonic). In principle, convulsions may be either epileptic or nonepileptic in nature. However, the term is traditionally used to designate epileptic seizures, including occasional epileptic seizures such as febrile convulsions, because they are almost exclusively marked by motor phenomena, and because the term has come to convey the idea of benignity. Nevertheless, the clinician must still remember that most infantile convulsions, including febrile seizures, are indeed epileptic seizures.

### MECHANISMS OF EPILEPTIC SEIZURES

The epileptic discharge, which is the basic electrophysiological feature of epileptic seizures, typically consists of rhythmic and high-amplitude oscillations of electrical potential that can usually be recorded on the scalp EEG but may, in some cases, remain undetectable even on the cortical surface, depending on their depth, the volume of brain involved, its geometry and the manner of propagation (Bancaud and Talairach 1975). It is direct evidence of the abnormal, excessive neuronal activity postulated by Hughlings Jackson as the origin of epilepsy. Both the scalp and cortical epileptic discharge are related to the abnormal excitability of individual neurons and the excessive synchronisation of a large cellular population. As shown schematically in Figure 16.1, EEG spikes correspond to the summation of field potentials that are themselves the direct consequence of intracellular events. The most remarkable of these, in seizures of focal origin, is an enormous increase in the size of membrane depolarisation induced by excitatory postsynaptic potentials and the paroxysmal depolarisation shift. This corresponds to a spike on the interictal EEG record, at a threshold level of affected neurons that is followed by a prolonged increased after-polarisation. This hyperpolarisation disappears during a seizure allowing repetitive bursting to go unchecked. This in turn recruits neighbouring neurons that discharge synchronously.

Different mechanisms may be operative in generalised seizures, but all convulsive seizures involve sustained membrane depolarisation. The mechanism of nonconvulsive seizures such as absences, on the other hand, involves a succession of excitatory and inhibitory potentials (Snead 1995). The EEG slow-wave discharge reflects gamma-aminobutyric acid (GABA)-mediated increased inhibition, which, together with enhanced excitation, leads to a state of epileptic hypersynchrony. Low-threshold calcium currents in reticular thalamic pacemaker neurons are likely to be responsible for the hypersynchronous spike–wave discharges of absence epilepsy. Gloor and Fariello (1988) postulated that primary generalised epilepsy is characterised by a diffusely hyper-excitatory cortex, so that an epileptic discharge can be triggered by excitation of the thalamic reticular system induced by the thalamocortical input, and thus both cortical and subcortical structures are necessary for its genesis.

Detailed studies of the mechanisms responsible for the generation of epileptic discharges is beyond the scope of this book (for reviews see Jones 2006; Hirsch et al. 2006a; Najm et al. 2006b).
The enhanced neural excitability observed in epilepsy may result from a genetically determined imbalance of excitatory and inhibitory neurotransmitters, from changes in cortical circuitry, or from the irritability of a localised lesion. In this regard, the possible influence of abnormally discharging neurons on the rest of the brain has attracted considerable attention. Focal subclinical stimulation of neuronal groups becomes increasingly effective with properly repeated stimulations and eventually may result in generalised seizures (Moshé and Ludvig 1988). The relevance of this ‘kindling’ phenomenon for human epilepsy, however, is still undetermined, although it may be a factor in the emergence of secondary foci (Morrell 1989).

Decreased inhibitory mechanisms are thought to play an important role in epilepsy, and the main cortical inhibitory neurotransmitter, GABA, has been studied extensively. The GABA hypothesis has been at the origin of major therapeutic efforts and of the development of important antiepileptic drugs.

Current research is also directed toward excitatory neurotransmitters such as glutamate and aspartate, an excess of which could account for the local or generalised enhanced cortical excitability (Najm et al. 2006b). Changes in the receptors of both excitatory (glutamate and aspartate) and inhibitory (GABA) neurotransmitters probably modulate cortical excitability, and their differential rates of maturation may explain the changing susceptibility to epilepsy at various ages (Moshé 1987; Johnston 1996; Holmes 1997).

Whatever the mechanisms involved, brain maturation plays a critical role in the susceptibility to seizures and in their clinical expression. The morphological, electrophysiological and biochemical bases of brain maturation in relation to seizures are being actively explored (Jensen 1999; Ben-Ari 2006; Dulac et al. 2013).

### AETIOLOGY OF THE EPILEPSIES

Occasional epileptic seizures, which are almost always generalised, can be provoked by a host of intercurrent events (Table 16.1) including fever, hypoglycaemia, metabolic imbalance or acute diseases (Fig. 16.2).

Provoking factors can result from acute conditions, such as structural brain damage from trauma, metabolic disturbances or infections which occur in children without any predisposition to seizures. More commonly, however, a special predisposition to seizures, that is likely to be genetic in origin and often age-dependent, renders the individual susceptible to specific stimuli, of which the most common example is febrile seizures. However, both factors may operate concurrently. For example, structural lesions precipitate seizures more frequently in patients with a family history of epilepsy than in the general population, and the same may apply to other causes, for example, acute meningitis.

Epilepsy (as a chronic disorder) can also be due exclusively to genetic factors or chronic brain damage (congenital or acquired), or to various combinations (Berkovic et al. 1987; Hani et al. 2015).

The epilepsies are usually divided into idiopathic, symptomatic and cryptogenic cases. Idiopathic epilepsies are those with no detectable brain lesion or abnormality; cryptogenic epilepsies result from brain abnormalities or acquired damage; cryptogenic epilepsies have no demonstrable organic cause. The frequency of this last category has decreased as refinements to the methods of investigation are made. The ILAE Commission on Classification and Terminology published, in 2017, a proposal for a revised terminology ‘genetic, structural–metabolic, and unknown representing modified concepts to replace idiopathic, symptomatic and cryptogenic’ (Scheiffer et al. 2017). The pros and cons modifications and evolution of the terminologies used are discussed below.

Genetic factors are of paramount importance in the epilepsies unassociated with neurological abnormalities (idiopathic epilepsies) but may also influence epilepsies associated with demonstrable brain damage (Ottman 1989, 2005), focal cortical dysplasias being a recent example (Leventer et al. 2014).

The role and mode of inheritance vary with the type of epilepsy, and known genetic data will be indicated for each epilepsy syndrome (Table 16.2a summarises identified genes for epilepsy per gene and Table 16.2b identified genes per
Table 16.1 Main causes of occasional epileptic seizures

Fever due to extracranial infections (febrile convulsions)
Intracranial infections
  Bacterial
  Meningitis, brain abscess, empyema
  Septic venous thrombosis
  Viral
  Viral meningitis, encephalitis
  Fungal or parasitic
Parainfectious encephalopathies
  Reye syndrome
  Other acute encephalopathies of obscure origin
  Haemorrhagic shock
Metabolic disturbances
  Hypocalcaemia and hypomagnesaemia
  Hypoglycaemia
  Hyponatraemia
    Inappropriate secretion of antidiuretic hormone
    Water intoxication
    Inadequate rehydration
  Hypernatraemia
    Consequence of vascular collapse due to dehydration
    Consequence of rapid correction of sodium levels
Inborn errors of metabolism (especially during episodes of decompensation)
Intoxications
  Endogenous
    Uraemia, renal dialysis
    Hepatic encephalopathy
    Diabetic ketoacidosis
    Hypertensive encephalopathy
    Renal disease
      Acute nephritis (may be paucisymptomatic)
      Haemolytic–uraemic syndrome
  Head trauma
    Early epileptic seizures
    Extradural/subdural haematoma
    Brain contusion
  Acute cerebral hypoxia
    Cardiac arrest
    Drowning
    Acute vascular collapse
  Cerebrovascular accidents
    Arterial occlusion (thrombosis or embolism)
    Venous thrombosis
    Haemorrhage from vascular malformations
  Burns encephalopathy

epilepsy syndrome). Mono-factorial origin has been demonstrated in some genetic syndromes, and rapid progress is being made in the molecular genetic basis of childhood epilepsy (for reviews and evolution of concepts see Battaglia and Guerrini 2005; Duron et al. 2005; Gardiner 2005; Heron et al. 2007; Hani et al. 2015). Only a small proportion of cases (1–2%) demonstrate single-locus traits such as tuberous sclerosis or metabolic errors. Epilepsy syndromes with a monogenic dominant transmission, described below, include benign neonatal convulsions (Leppert et al. 1989), benign infantile seizures (Vigevo et al. 1992; Echenne et al. 1994), and familial frontal (Scheffer et al. 1995a), familial mesial temporal lobe and familial lateral temporal lobe (Berkovic et al. 1996; Andermann and Kobayashi 2005) epilepsy syndromes.

The role of genetic factors is not limited to these relatively rare cases. A number of genes are operative in the genesis of multigenic epilepsy. Complex inheritance is much more common (Turnbull et al. 2005) even though dominant inheritance has been suggested for epilepsies with 3Hz spike–wave activity and possibly some forms of photosensitive epilepsy (Doose and Waltz 1993). Doose and Baier (1987) suggested that certain EEG traits (e.g. photosensitivity or spontaneous spike–wave paroxysms) could be inherited independently and that the combination of such EEG traits (and probably other factors) might account for the inherited propensity to various forms of epilepsy. Complex inheritance (multifactorial inheritance) even accounts for some syndromes once thought to be dominant, for example, in juvenile myoclonic epilepsy, for which a dominant gene had been identified (Greenberg et al. 1988), several other genes now appear to be implicated.

The current view is that many epilepsy genes are susceptibility rather than unconditional genes, whose conjugated action and additional environmental factors augment the probability of clinical epilepsy, thus accounting for the observation that siblings or parents of affected persons may be normal or present with a different epilepsy syndrome. A detailed presentation of current knowledge on the genetics of the epilepsies is beyond the scope of this book (for reviews see Pandolfo 2013; Hani et al. 2015; McTague et al. 2016; ILAE Consortium on Complex Epilepsies 2016; Striano and Zara 2017; and refer to specific sections per syndrome for more focussed references).

Brain injury is a major aetiologic factor in focal or generalised epilepsies associated with clinical evidence of neuro-developmental defects. Selected causes include cortical malformations, tuberous sclerosis complex or Sturge–Weber syndrome-related lesions, brain tumours, trauma, hippocampal sclerosis and vascular abnormalities. The main aetiologic factors of brain injury associated with epilepsy are shown in Table 16.3.

The term symptomatic (or ‘structural’, see Berg et al. 2010; Scheffer et al. 2016) is used for lesions that produce clinical or gross radiological signs, cognitive impairment and/or definite neuroimaging abnormalities. Microscopic lesions, not detectable during life, also play a considerable, albeit often imprecise, role in the genesis of the epilepsies (so-called cryptogenic epilepsy). Modern neuroimaging techniques reveal that many

Modified from Arzimanoglou et al. (2004), Guerrini (2006). (Courtesy Professor G Lesca, University Hospitals of Lyon, France.)

ICCA, infantile convulsions and choreoathetosis; ADPEAF, autosomal dominant partial epilepsy with auditory features.

Epilepsy is also common in several chromosomal disorders (see Chapter 5), including Angelman and Down syndromes, trisomy 12p, fragile X syndrome, ring chromosomes 14 and 20, the del 1p36 syndrome (Battaglia and Guerrini 2005), and can be associated with inborn errors of metabolism (Wolf et al. 2005; Pearl 2013; Campistol and Plecko 2015) (Chapter 9).

### PATHOLOGY

Epileptic seizures (and epilepsy) occur in patients with many pathological processes including brain malformations, tumours, acquired traumatic or vascular lesions (Blümcke et al. 2015). An important issue is whether lesions found in patients with epileptic seizures are the cause or the consequences of the epileptic activity. Whether lesions remain stable or are...
worsened by recurrent seizures is also unknown. Prognosis and therapeutic attitudes often depend critically on answers to these questions. The respective roles of the original lesion and of lesions resulting from the epileptic activity itself are still debated (Fuerst et al. 2003; Armstrong 2005; Bernasconi et al. 2005). Some investigators minimise the role of seizures (Lado et al. 2002), while others suggest that both experimental and clinical evidence favour the importance of epilepsy not only on structural brain damage but also on the propensity to seizure repetition and cognitive and behavioural development (Sutula 2004).

Experimental evidence reveals possible neuronal damage induced by prolonged/repeated seizures (Meldrum 1983; Holmes 2002), although its significance, especially in infants, remains controversial (Lado et al. 2002). Clinical experience indicates that, at least under certain circumstances, progression of clinical disturbances and lesion development can occur (Sutula et al. 2003). This is a critical issue for treatment and prognosis, and more robust evidence is clearly needed, but recent evidence strongly supports a detrimental role for epileptic processes.

Two major types of pathological abnormalities occur in patients with focal epilepsy: developmental cortical malformations, and acquired lesions, the commonest being hippocampal (or mesial temporal) here.

Hippocampal sclerosis is characterised by marked neuronal loss in the CA1 sector of the hippocampus, with a lesser degree of cell loss in the CA3/CA4 sectors and a relative sparing of the CA2 region (Fig. 16.3a, b). Recent data suggest that the pattern of cell loss in the hippocampus is distinct from hippocampal sclerosis associated with other neocortical temporal lobe pathologies (so-called dual pathology cases), showing a trend toward more diffuse and homogeneous neuronal loss in all hippocampal sectors (Diehl et al. 2002). The term ‘mesial temporal sclerosis’ is often used synonymously but in fact designates more extensive involvement of the internal temporal lobe. Over the past decades, there have been various attempts to classify specific patterns of hippocampal neuronal cell loss and correlate subtypes with postsurgical outcome.

In 2013, the ILAE published an international consensus classification of hippocampal sclerosis (Blümcke et al. 2013). HS-ILAE Type 1 refers always to severe neuronal cell loss and gliosis predominantly in CA1 and CA4 regions, compared to CA1 predominant neuronal cell loss and gliosis (HS-ILAE Type 2), or CA4 predominant neuronal cell loss and gliosis (HS-ILAE Type 3). Surgical hippocampus specimens obtained from patients with temporal lobe epilepsy (TLE) may also show normal content of neurons with reactive gliosis only (no-HS). According to this report (Blümcke et al. 2013) HS-ILAE Type 1 is more often associated with a history of initial precipitating injuries before age 5 years, with early seizure onset, and favourable postsurgical seizure control. CA1 predominant HS-ILAE Type 2 and CA4 predominant HS-ILAE Type 3 have been studied less systematically so far, but some reports point to less favourable outcome, and to differences regarding epilepsy history, including age of seizure onset.

There is resulting gliosis and atrophy and, in patients with epilepsies dating back to infancy or early childhood, especially those that follow prolonged febrile seizures (Sagar and Oxbury 1987; Sutula et al. 1989; Mathern et al. 1996), sprouting of the mossy fibres is prominent and results in new synaptic contacts being established (for a review, see Najm et al. 2006a).

Consequences of prolonged convulsive seizures (convulsive status epilepticus, hemiconvulsions–hemiplegia–epilepsy syndrome)
Whether hippocampal sclerosis is a cause or a consequence of repetitive or prolonged epileptic seizures is still debated (Bruton 1988; Liu et al. 1995; de Lanerolle and Lee 2005); evidence exists in favour of the latter hypothesis (Meldrum 1978). Excessive release of excitatory amino acids (glutamate) at the synapses has been shown to produce excitotoxic hippocampal damage in experimental conditions. Nerve cell death due to excessive activation (burst firing) probably results because of increase in intracellular calcium entry through N-methyl-D-aspartate (NMDA) receptors and some AMPA receptors, when the capacity of calcium-buffering proteins in postsynaptic cells is limited. This is the case in the CA1 and CA3 sectors of the hippocampus.

Even in the absence of microscopic lesions, there is evidence that seizures in infancy create lasting hyperexcitability of neuronal assemblies and favour the occurrence of later seizures (Baram 2003).

Abnormalities of cortical development (Table 16.4; also refer to Chapter 3) are recognised as a major cause of both epilepsies and developmental disabilities (Raymond et al. 1995; Guerrini et al. 1996; Arzimanoglou et al. 2004; Guerrini and Filippi 2005). Until the advent of high-resolution neuroimaging, these abnormalities were the domain of the pathologists, but they can now be detected more reliably with high-resolution magnetic resonance imaging (MRI). Some are genetically determined, while for others a genetic origin is only hypothesised (Guerrini and Carrozzo 2001; Dobyns and Kuzniecky 2006).

New data from MRI studies and the discovery of specific genetic mutations underlying some of these abnormalities have led to the development of various classifications based on morphological, anatomical or genetic characteristics (Sarnat and Flores-Sarnat 2004; Palmini et al. 2004; Barkovich et al. 2005). All have some practical value for the clinician, but the complexity of the issues makes it impossible for any one classification scheme to cover all aspects (clinical, radiological, aetiological and treatment). Furthermore, all classifications need to be regularly updated as much remains to be discovered in this rapidly expanding field (for reviews see Vigevano et al. 2003; Arzimanoglou et al. 2004; Sisodiya 2004; Blümcke et al. 2011, 2015).

Diffuse abnormalities of cortical development are usually the cause of severe and early-onset epilepsy, intellectual disability and intractability. However, some abnormalities, such as bilateral periventricular heterotopias, may be asymptomatic or associated with a relatively mild epilepsy phenotype. Focal cortical developmental anomalies are usually revealed by epilepsy, whether or not they are associated with cognitive problems. They represent one of the most frequent causes of non-idiopathic (structural) focal epilepsies. Following the recent development of high-resolution magnetic resonance neuroimaging, many ‘cryptogenic focal epilepsies’ are now recognised as being ‘symptomatic’ of cortical maldevelopment. Since the original description by Taylor et al. (1971), the term focal cortical dysplasia (FCD) is used to refer to a wide range of alterations of the cortical mantle.

Several classification schemes have been introduced. A proposal by Barkovich et al. (2005) was based more on genotype than phenotype. However, the genotype–phenotype relationship is incompletely understood for many abnormalities. A simplified classification referring to easily recognised neuropathological characteristics (Tassi et al. 2002) was based upon the identification of three subgroups: (1) architectural dysplasia characterised by abnormal cortical lamination and ectopic neurons in white matter; (2) cytarchitectural dysplasia characterised by giant neurofilament-enriched neurons in addition to altered cortical lamination; and (3) Taylor-type cortical dysplasia with giant dysmorphic neurons and

The rare association between FCD Types IIa and IIb and hippocampal sclerosis, tumours or vascular malformations should not be classified as FCD Type III variant.

balloon cells associated with cortical laminar disruption. Patients with architectural dysplasia have lower seizure frequencies than those with cytoarchitectural and Taylor-type dysplasia, and the epileptogenic zone is mainly in the temporal lobe. Surgical resection, when feasible, controls seizures in a substantial proportion of cases (Palmini et al. 1991; Chassoux et al. 2000; Tassi et al. 2002; Francione et al. 2003; Russo et al. 2003; Lawson et al. 2005; Tassi et al. 2010). In the series reported by Tassi et al. (2002), patients with Taylor-type dysplasia had the best outcome, with 75% seizure-freedom (Engel class Ia), despite the epileptogenic zone being mainly extratemporal. Seizure semiology depended on the location of the lesion, and patients with both Type I and Type II dysplasias both present high seizure frequencies (Tassi et al. 2010).

The subsequent introduction of the Palmini et al. (2004) classification of cortical dysplasias was widely used. In this schema, FCDs were histopathologically subdivided into Types I and II. FCD Type IA referred to architectural disturbances of cortical lamination, and FCD Type IB included cytoarchitectural abnormalities, including hypertrophic (not dysmorphic) pyramidal neurons outside layer 5. Dysmorphic neurons were considered the histopathologic hallmark of FCD Type IIA. Microscopic identification of dysmorphic neurons and eosinophilic balloon cells defined FCD Type IIB.

In 2011, an ad hoc ILAE Task Force reviewed available literature on clinical presentation, imaging findings, and histopathological features of distinct clinico-pathologic FCD variants (Fig. 16.4) and proposed a refined classification system (Blümcke et al. 2011). Accordingly, FCD Type I refers to isolated lesions, which present either as radial (FCD Type Ia) or tangential (FCD Type Ib) dyslamination of the neocortex, microscopically identified in one or multiple lobes. FCD Type II is an isolated lesion characterised by cortical...
Because epileptic seizures are a symptom of multiple disorders, a single classification code is not possible. Criteria need also to be pre-established when classifying epilepsies, which also correspond to a great variety of diseases. Several classification systems can be utilised at different levels (e.g. aetiological, topographic, neurophysiological, etc.). Clinical classifications have received special attention for communicative, diagnostic and prognostic purposes (for a critical review regarding mechanisms and causes. It is applicable to infants, young children as only objective phenomena are listed. In patients with drug-resistant focal seizures MRI investigations should be repeated, if possible using higher resolution scanners, because in a significant proportion of patients the brain appears morphologically normal on routine scanning (MRI was unrevealing in 34% of the patients reported by Tassi et al. 2002). Information on the suspected localisation, based on careful analysis of clinical semiology and video-EEG data, has to be provided to the neuroradiologist, who preferably should review the MRI in close collaboration with the epilepsy team at multidisciplinary sessions.

### CLASSIFICATION ISSUES

The ILAE has devised two classification schemes: one for epileptic seizures only, the other for epilepsies and epilepsy syndromes. Both evolved with time on the basis of acquired new knowledge, usually also respecting evolution of practices. (Table 16.5). This classification requires acceptance of concepts that are not universally accepted, especially with respect to generalised seizures. Separating seizures as generalised or focal is often challenging, as the concept of seizures involving homogeneously the entire cortex is untenable (see Hirsch et al. 2006a), and differentiation of secondarily generalised seizures of focal origin from generalised seizures is not always possible in clinical practice. However, seizure onset classification is important practically because treatment may not be the same and only focal seizures are amenable to surgical resective treatment.

In 1999, a conceptually different system for seizure classification was proposed (Lüders et al. 1999) (Table 16.6) based entirely on clinical description of the ictal events (phenomenology), and provided a systematic list for the clinical analysis of the seizures, thus avoiding any assumptions regarding mechanisms and causes. It is applicable to infants and young children as only objective phenomena are listed. Following publication this proposal influenced the official ILAE classifications but was not widely accepted by the epilepsy community. It is mainly used by teams practicing epilepsy surgery due to the need for detailed clinical observation and description of clinical events.

The 2006 ILAE report (Engel 2006) admitted the criticisms based on the artificial dichotomy of focal (partial) versus generalised origin of epileptic seizures but also recognised the practical value of distinguishing epileptic seizures that appear to begin in a region of one hemisphere, from those beginning in both hemispheres apparently simultaneously. Given

**UNCLASSIFIED SEIZURES**

Modified from the Commission on Classification (1981) of the International League Against Epilepsy.

### Table 16.6  The ‘Lüders’ classification of epileptic seizures

| Aura (consists exclusively of subjective symptoms) |
| Somatomotor |
| Auditory (includes complex hallucinations and illusions that affect other senses) |
| Olfactory |
| Visual (includes complex multimodal hallucinations) |
| Gustatory |
| Autonomic (purely subjective autonomic sensations) |
| Psychic (includes complex hallucinations and illusions that affect other senses) |
| Abdominal aura |
| **Autonomic seizures** (only with objective autonomic dysfunction) |
| **Dialeptic seizures**b,c (alteration of consciousness, whatever electroencephalogram and mechanism) |
| **Motor seizures** |
| Simple motor (unnatural movements resembling those produced by stimulation of areas 4 or 6) |
| Myoclonic seizures |
| Epileptic spasms (may occur after infancy) |
| Tonic–clonic seizures |
| Tonic seizures |
| Clonic seizures |
| Versive seizures (contralateral or ipsilateral) |
| Complex motorb (refers to movements that simulate natural movements) |
| Hypermotorb (complex mostly proximal, often violent) |
| Automotorb (refers to mostly distal, mouth or tongue, consciousness variable) |
| Gelastic (those that cannot be included in the aforementioned categories) |
| **Special seizures** |
| Atonic (often preceded by short myoclonic seizure) |
| Hypomotorb (decreased or total absence of motor activity; only when consciousness not assessable) |
| Negative myoclonus |
| Astatic |
| Akinesis (inability to perform voluntary movement) Aphasic |
| **Paroxysmal events** (not sufficient evidence to assume epileptic nature) |

*b May be localised to left or right, axial, generalised, bilateral asymmetrical.

+c May arise from left or right hemisphere.

The term *dialectic* was proposed in replacement of both ‘typical’ and ‘atypical’ absences on the basis that the distinction is possible on the basis of EEG data and/or the presence of other seizure types, clinical expression differences being often minimal.
the prevalent usage, and the therapeutic implications of the terms ‘focal’ and ‘generalised’, it was decided to retain them, with the understanding that the former does not necessarily imply that the epileptogenic region is limited to a small circumscribed area, while the latter does not imply that the entire brain is involved in the initiation of the epileptogenic process.

Four years later, the ad hoc ILAE Commission published a ‘revised terminology’ (Berg et al. 2010) that suggested the following changes to the 1981 classification:

1. Neonatal seizures were no longer a separate entity as seizures in neonates can be classified within the proposed general scheme. Although many paroxysmal manifestations can be documented in neonates, the practicing clinician is at risk to classify most symptoms as just ‘unknown’.
2. The previous sub-classification of absence seizures was simplified and altered. Myoclonic absence seizures and eyelid myoclonia were recognised.
3. Spasms, that were not explicitly acknowledged in the 1981 classification of seizures and considered as ‘generalised’ in the 2006 revision were re-classified as ‘epileptic spasms’ and grouped as ‘unknown’ in origin.
4. The distinction between ‘complex’ and ‘simple’ was eliminated for focal seizures and a list of ‘descriptors’ according to the degree of impairment was suggested.
5. The term ‘myoclonic–atonic’ replaced ‘myoclonic–astatic’.

The authors of the present chapter strongly believe that seizure classification is necessary and useful in everyday clinical practice. However, in comparison to the first ILAE classification (1981), the differences in the two that followed (Table 16.7) are minimal and have little impact on clinical practice; particularly when one considers the lengthy workshops needed to produce them and the confusion for those not in the epilepsy field. We believe revision is only justified when new, evidence-based data becomes available.

The latest revised operational classification of seizure types was published in 2017 as an ILAE position report (Fisher et al. 2017a) and was accompanied by an instruction manual (Fisher et al. 2017b). According to the authors, the main purpose of such a revision was to recognise that some seizure types can have either a focal or generalised onset, to allow classification when the onset is unobserved, to include some missing seizure types, and to adopt more transparent names. It also acknowledged that ‘because current knowledge is insufficient to form a scientifically based classification’, the one proposed should be considered ‘operational (practical) and based on the 1981 Classification, extended in 2010’.

Changes include the following:
1. ‘Partial’ becomes ‘focal’;
2. Awareness is used as a classifier of focal seizures;
3. The terms dyscognitive, simple partial, complex partial, psychic, and secondarily generalised are eliminated;
4. New focal seizure types include automatisms, behaviour arrest, hyperkinetic, autonomic, cognitive, and emotional;
5. Atonic, clonic, epileptic spasms, myoclonic, and tonic seizures can be of either focal or generalised onset;
6. Focal to bilateral tonic–clonic seizure replaces secondarily generalised seizure;
7. New generalised seizure types are absence with eyelid myoclonia, myoclonic absence, myoclonic–atonic, myoclonic–tonic–clonic; and
8. Seizures of unknown onset may have features that can still be classified.

The ILAE Task Force recognised that the new classification does not represent a fundamental change, but allows greater flexibility and transparency in naming seizure types. We agree that the 2017 version better reflects the needs of clinicians. It allows a description of the ictal pattern in individual patients. The level of description depends upon available information on the sequence of clinical manifestations (see also Lüders proposal in Table 16.6). It is enriched with time as more details become available (better description from the family and/or the patient; home videos; video-EEG data).

## CLASSIFICATION OF EPILEPSY SYNDROMES

Progress in epileptology made it rapidly clear that, although crucial, the description of epileptic seizures was not sufficient to allow choice of investigation tools and treatment attitudes or to provide patients and families with a clear prognosis. The concept of epilepsy syndromes was introduced, defined as ‘clusters of signs and symptoms customarily occurring together’ (Commission on Classification and Terminology 1989).

The classification of 1989 (Table 16.8) was mainly based on the clinical and EEG characteristics of epilepsy syndromes (refer also to Koutroumanidis et al. 2017a; b). In addition to the descriptive elements of the clinical phenomena (seizures), it was considered that a classification of epilepsies should incorporate some information about the cause of the disorder, age at occurrence, features associated with the seizures, localisation and other aspects. However, any classification system must be understood as a compromise between the needs of the user and available knowledge. Often, a classification that is adapted to the needs of the neurosurgeon (type and localisation of an epileptogenic lesion), or to an epidemiologist (underlying aetiology or outcome) do not coincide with the goals of the basic scientist, geneticist, epileptologist, neurologist or general practitioner. In fact, no classification system can incorporate all possible issues related to such a complex and multifactorial disorder as epilepsy.

The ILAE system classified epilepsy syndromes according not only to their ictal phenomenology (clinical and EEG) but also to aetiology (idiopathic, symptomatic and cryptogenic syndromes) and mechanisms or topography (generalised, localisation-related, undetermined whether focal or generalised, and special or situation-related). The term ‘idiopathic’ includes syndromes in which epilepsy is not caused by a postnatally-acquired lesion or brain damage;

**III. Neonatal seizures**

Engel (2006) and Berg et al. (2010).
Table 16.8 The 1989 classification of epilepsies and epileptic syndromes

LOCALISATION-RELATED (FOCAL, LOCAL, PARTIAL) EPILEPSIES AND EPILEPTIC SYNDROMES

**Idiopathic (with age-related onset)**
- Benign childhood epilepsy with centro-temporal spikes (rolandic epilepsy)
- Childhood epilepsy with occipital paroxysms (Panayiotopoulos type and Gastaut type; early versus later onset with different semiology)
- Primary reading epilepsy

**Symptomatic**
- Chronic progressive epilepsia partialis continua of childhood (Kojewnikow syndrome)
- Syndromes characterised by seizures with specific modes of precipitation (include focal seizures following acquired lesions, usually involving tactile or proprioceptive stimuli; focal seizures precipitated by sudden arousal or startle epilepsy)
  - Temporal lobe epilepsies;
  - Frontal lobe epilepsies;
  - Parietal lobe epilepsies
  - Occipital lobe epilepsies

**Cryptogenic**

GENERALISED EPILEPSIES AND SYNDROMES

**Idiopathic (with age-related onset)**
- Benign neonatal convulsions (isolated or familial)
- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy (also called in the past ‘pyknolepsy’)
  - Juvenile absence epilepsy
  - Juvenile myoclonic epilepsy (impulsive petit mal)
- Epilepsy with grand mal seizures on awakening
- Other generalised epilepsies (not defined above)
  - Epilepsies with seizures precipitated by specific modes of activation

**Cryptogenic or symptomatic**
- West syndrome (infantile spasms, Blitz–Nick–Salaam Krämpfe)
- Lennox–Gastaut syndrome
- Epilepsy with myoclonic–astatic seizures
- Epilepsy with myoclonic absences

**Symptomatic**
- Early myoclonic encephalopathy
  - Early infantile epileptic encephalopathy with suppression–burst EEG
- Other symptomatic generalised epilepsies not defined above

Specific syndromes (including diseases in which seizures are a presenting or predominant feature)

EPILEPSIES AND EPILEPTIC SYNDROMES UNDETERMINED WHETHER FOCAL OR GENERALISED

**With both generalised and focal seizures**
- Neonatal seizures
- Severe myoclonic epilepsy in infancy (Dravet syndrome)
- Epilepsy with continuous spike–waves during slow-wave sleep
- Acquired epileptic aphasia (Landau–Kleffner syndrome)
- Other undetermined epilepsies not defined above

**Without unequivocal generalised or focal features**

Continued
symptomatic seizures are those in which seizures are due to the presence of a defined underlying disorder, focal or diffuse; the term cryptogenic included syndromes that are likely to be secondary to a prenatally-acquired cause but not a primary disorder. Allocation to a particular group may be difficult or impossible, and the definition of the cryptogenic group is unsatisfactory as it depends on the completeness of aetiological investigations.

In 2001, the ILAE Task Force on Classification and Terminology proposed a diagnostic scheme for people with epileptic seizures (Engel 2001). It comprised five ‘axes’ (Glossary to describe ictal events; List of recognised seizure types; List of epilepsy syndromes, accepting the fact that definitive classification is not always possible; List of diseases often associated with seizures or epilepsy; Impairment resulting from disease). This diagnostic scheme had the advantage of flexibility for use in clinical practice, a factor seriously lacking in previous classifications. However, the terms ‘generalised’, ‘idiopathic’ and ‘symptomatic’ were still included even though they no longer formed the basis for classification. Indeed, although their pathophysiological significance may be limited, the practical value of these terms is difficult to contest.

The ILAE proposal for a revised terminology (Berg et al. 2010) argued that since its first introduction in 1989 the terms idiopathic, symptomatic, and cryptogenic have et al. 2010) argued that since its first introduction in 1989 the value of these terms is difficult to contest. However, the terms ‘generalised’, ‘idiopathic’ and ‘symptomatic’ were still included even though they no longer formed the basis for classification. Indeed, although their pathophysiological significance may be limited, the practical value of these terms is difficult to contest.

1. Genetic: The concept of genetic epilepsy implies that epilepsy is best understood as the direct result of a known or presumed genetic defect(s) in which seizures are the core symptom. Knowledge of genetic contributions derive from specific molecular genetic studies that can be replicated and form the basis of diagnostic tests (e.g. SCN1A and Dravet syndrome) or appropriately designed family studies.

2. Structural/metabolic: Structural or metabolic conditions or disease can substantially increase the risk of developing epilepsy. These include acquired disorders such as stroke, trauma, and infection but may also be genetic in origin (e.g. tuberous sclerosis, malformations of cortical development); however, as we currently understand it, there is a separate disorder interposed between the genetic defect and the epilepsy.

3. Unknown cause: Unknown implies that the nature of the underlying cause is unknown; it may have a fundamental genetic defect at its core or be a consequence of a separate, as yet unrecognised, disorder.

The 2010 ILAE proposal also redefined the concept of ‘electroclinical’ syndrome versus disease and introduced novel concepts such as ‘constellations’ on the basis of ‘specific lesions or other causes’ (see Berg et al. 2010).

Although we agree that recent knowledge allows a more precise definition of underlying causes in a small number of the epilepsies, we are not of the opinion that a radical change in terminology will reduce uncertainty for aetiologies (‘known or presumed’ genetic defects) and may increase confusion for non-specialists in epilepsy.

Delineating epilepsy syndromes should permit more precise diagnosis and prognosis than simply classifying seizure types. Epilepsy syndromes are heterogeneous as the link between the components of a particular syndrome may be topographical, aetiological or not understood. More importantly, their specificity is variable. Some syndromes, for example, rolandic epilepsy, are well defined, whereas others such as grand mal seizures on awakening are linked as a common seizure type. Because the concept of a syndrome is entirely pragmatic and because agreement on the definition is often difficult, only well-defined and generally accepted syndromes are of value (Aicardi 1994; Duchowny and Harvey 1996; Watanabe 1996; Arzimanoglou et al. 2004). Increasing the number of poorly documented subgroups or fitting atypical cases into generally accepted syndromes are two dangers that can defeat the value of the epilepsy syndrome which is to assist in diagnosis, prognosis and management. As a result, a variable proportion of cases of childhood epilepsy are better left unclassified.

In 2016, the ILAE Commission for Classification and Terminology published a special report on new concepts related to the classification of the epilepsies for discussion and debate (Scheffer et al. 2016). The ILAE position paper, published a year later (Scheffer et al. 2017), recognised that ‘as a critical tool for the practicing clinician, epilepsy classification must be relevant and dynamic to changes in thinking, yet robust and
translatable to all areas of the globe. Its primary purpose is for diagnosing patients, but it is also critical for epilepsy research, development of antiepileptic therapies, and communication around the world’. The 2017 ILAE position paper recognised three diagnostic levels, starting with seizure types as defined by their onset characteristics. (also see Fisher et al. 2017a), the next step being diagnosis of epilepsy type. In relation to the data available a patient can be classified as presenting with: focal epilepsy; generalised epilepsy; combined generalised and focal epilepsy; or an unknown type of epilepsy. The third level is that of epilepsy syndrome, if specific syndromic diagnosis is possible.

Aetiology was broken into six subgroups (Structural; Genetic; Infectious; Metabolic; Immune; Unknown), selected because of their potential therapeutic consequences. These categories are non-exclusive as the aetiology may fall into two or more categories (e.g. a structural lesion, result of a genetically determined disorder). Comorbidities should also to be considered.

The new classification also incorporated aetiology in each stage, emphasising the need to consider aetiology at each step of diagnosis, as it often carries significant treatment implications. The framework (Fig. 16.5) elegantly illustrates this multi-level classification, designed to cater to classifying epilepsy in different clinical environments (see also Scheffer et al. 2017).

Current classifications do not account for non-critical manifestations of epilepsy, especially intellectual or psychiatric manifestations. This shortcoming is highly important as epileptic encephalopathy implies that the epileptic activity itself, irrespective of its cause, is responsible for neuropsychiatric manifestations and deterioration. Subclinical epilepsy is purely neurophysiological and generally manifested only by paroxysmal EEG abnormalities. Although a pattern of epileptic encephalopathies is mostly observed in some syndromes such as West syndrome, Lennox–Gastaut syndrome, Dravet syndrome and Electrical Status Epilepticus during Sleep (ESES) occurring in infants and young children, the deleterious role of non-critical manifestations could easily apply to other forms of generalised or focal epilepsy in adults as well as children.

Publication of ‘new’ classifications of epileptic seizures and/or epilepsies undoubtedly reflect evolution of our knowledge in a highly complex field. However, unless strong evidence-based data is utilised to revise existing terminologies, frequent ‘official’ changes in nomenclature increase confusion and produce an opposite effect: general neurologists still refer to ‘epilepsy’ as one entity, perpetuate suboptimal use of diagnostic tools and prescribe antiepileptic drugs (AEDs) rather randomly.
EPILEPTIC SEIZURES AND EPILEPSY SYNDROMES BY AGE AT ONSET

Age at onset is an important determinant of the prognosis for epileptic disorders and a useful parameter for syndrome diagnosis. This section covers epilepsy syndromes in infancy, early and late childhood and adolescence. Despite broad overlaps, such a division is useful in clinical practice (Table 16.9) for general orientation in diagnosis on the basis of the predominant type of seizures, the choice of the most appropriate investigations and treatment attitudes, and for prognosis (Arzimanoglou et al. 2004, 2016; Duchowny et al. 2013). Because of their specificities reflex epilepsies will be covered in a different section.

In general,

- **the neonatal period** extends from birth to approximately age 3 months in contrast to the conventional interval of the first 4 weeks. During this period, seizures are caused predominantly by structural pathology which carries a poor prognosis. Febrile seizures do not occur during the first 4 months of life; thus, intracranial infection should be diligently searched for in neonates having seizures associated with fever.

- **Infancy and early childhood** (3 months to 4 years) is characterised by either occasional seizures (particularly febrile seizures) or epileptic encephalopathies. Focal epilepsies related to structural lesions may also present with seizures usually occurring during the first 2 years of life.

- **Later childhood and adolescence** is marked either by the onset of idiopathic epilepsies, both focal and generalised of genetic origin or by increased seizure frequency of focal non-idiopathic (structural) epilepsies. Occasional seizures are rare.

SEIZURES AND SYNDROMES OF THE NEONATAL PERIOD

Seizures during the first 28 days of life are a major problem of neonatal is challenging despite video-EEG analysis that has reduced over-diagnosis of epileptic seizures or their delayed diagnosis and treatment (Arzimanoglou and Aicardi 2001).

NEONATAL SEIZURES

Clinical Features of Neonatal Seizures

The main types of neonatal seizures are shown in Table 16.10. Not all behavioural phenomena classically attributed to neonatal seizures are regularly associated with rhythmic EEG discharges (Mizrahi and Kellaway 1987; Scher and Painter 1990; Mizrahi and Pressler 2015), as seen in older patients. These include clonic seizures, which are always focal with a fixed or shifting location (migratory seizures), and multifocal seizures, which often demonstrate asynchrony between foci that discharge at different rhythms, either simultaneously or in succession. Generalised tonic–clonic seizures are exceptional in this age group; only familial neonatal convulsions are associated with EEG patterns that are also observed at older ages (Hirsch et al. 1993; Ronen et al. 1993). Myoclonic seizures are unusual. Tonic seizures and subtle or ‘minimal’ seizures that include oral or ocular movements, grimacing, eye opening, blinking or staring, pedalling or boxing movements, and, rarely, isolated apnoea (Watanabe et al. 1982a; Donati et al. 1995) are most common.

A large group of behavioural phenomena, often regarded as seizures on a clinical basis, are not regularly associated with EEG discharges. These include most tonic (generalised or partial) and ‘subtle’ seizures. Scher et al. (1993a) were able to demonstrate paroxysmal EEG correlates in only 17% of subtle seizures. Such phenomena are often elicited by stimulation; their severity varies with intensity of stimulation, and they may demonstrate temporal or spatial summation (Mizrahi and Kellaway 1987). These patterns may represent ‘release’ phenomena related to disinhibition of brainstem structures after cortical damage.

The absence of an EEG discharge on the neonatal scalp does not confirm the nonepileptic nature of an event (Volpe 1989; Lombroso 1996) as epileptic seizures without EEG correlates are known to exist. EEG seizure discharges without clinical seizures are also common in neonates (Clancy et al. 1988; Scher and Painter 1990). This is most often noted following repeated seizures treated with anticonvulsants and less frequently, in untreated infants. Brief discharges lasting less than 10 seconds (‘brief intermittent rhythmic discharges’ or BIRDs) (Scher et al. 1993a, b) are frequent in the newborn EEG and are unassociated with clinical seizure activity. As a result, the definition of neonatal seizures remains imprecise and consequently their incidence is poorly known. Figures quoted vary from 0.15% to 1.4% (Arzimanoglou et al. 2004).

Both term and preterm infants may be affected. Seizures in preterm infants have a more limited expression and subclinical EEG discharges are especially common (Scher et al. 1993a, b; Janáčková et al. 2016).

Neonatal seizures rarely occur as isolated events. Most frequently brief seizures occur repeatedly over a period of a few hours or days (Clancy and Legido 1987; Scher et al. 1993b; Bye and Flanagan 1995) and tend to subside, even without treatment after 24–96 hours. The mean duration of individual seizures is 14.2 minutes for term infants and 3.1 minutes for preterm infants (Scher et al. 1993b), but this difference reflects the frequency of status epilepticus in term infants and its rarity in preterm newborn infants.

Ictal EEG discharges may consist of either focal rhythmic spikes or sharp wave forms at variable frequencies (from alpha to delta) or sharp wave discharges (Tharp 1981; Holmes 1985; Lombroso 1996) in both term and preterm infants (Radvanyi-Bouvet et al. 1985; Legido et al. 1988).
Neonatal seizures should be distinguished from tremors and jitteriness which, although extremely common, are periodic movements. They occur at a rhythm of 5–6 per second, can be suppressed by restraint or repositioning (Kramer and Harel 1994; Fernández-Alvarez and Aicardi 2001) and have a favourable outcome. Seizures should also be differentiated from benign neonatal sleep myoclonus (Chapter 21); and vegetative phenomena such as nonepileptic apnoea. It is especially challenging to diagnose atypical seizures with suggestive clinical manifestations that are unassociated with EEG paroxysms as epileptic in origin. The problem is often unresolved, making a decision on treatment difficult (Hellström-Westas 2015).

Clinical recognition of nonepileptic phenomena in neonates is often possible. Important diagnostic clues include the ability to elicit abnormal phenomena by stimulation, whether tactile or otherwise; the demonstration that spatial or temporal summation of stimuli is effective; and the ability to prevent or interrupt abnormal events by restraint. More importantly, the clinician must consider the neurological context within which the paroxysmal phenomena are observed (Arzimanoglou and Aicardi 2001).

### Aetiology of Neonatal Seizures

The main causes of neonatal seizures are listed in Table 16.11. Many seizures associated with intracranial haemorrhage or inborn errors of metabolism are probably not epileptic; the same applies to hypoxic–ischaemic encephalopathy (HIE), despite being a common cause of neonatal seizures (Levene and Trounce 1986; Vasudevan and Levene 2013). Many infants with HIE have already been injured in utero, as shown by the frequency of prenatal placental damage (Burke and Tannenberg 1995; Scher 2003). Perinatal events may therefore not be significant. Seizures after HIE typically occur within the first 24–48 hours of life, and are regularly associated with other symptoms including behavioural suppression or coma (Chapter 1). The EEG in severe cases is typically severely attenuated or discontinuous (‘tracé paroxystique’).

Localised arterial infarction is an important cause of localised, fixed clonic seizures (Levy et al. 1985). Scher et al. (1993a) noted infarctions in 58% of their cases of EEG-confirmed neonatal seizures.

Infections are mainly of viral origin. However, the frequency of meningitis and encephalitis is sufficiently high to justify lumbar puncture whenever there is no other obvious cause.

Hypocalcaemia and hypoglycaemia (Cornblath and Schwartz 1991) are much less common but treatable conditions. Late hypocalcaemia due to high phosphorus load in artificial milk feeds is now rarely seen, and currently observed cases are often associated with cardiac disease and have a guarded prognosis (Lynch and Rust 1994). Early hypocalcaemia is usually associated with other problems, so other causes for the seizures should be sought in affected patients. De Vivo et al. (1991) described a defect of glucose transport across the blood–brain barrier caused by the genetic absence of the GLUT1 protein causing severe hypoglycorrhachia accompanied by isolated seizures without hypoglycaemia. Onset usually occurs toward the end of the first month of life but neonatal and late onset can occur (see also Chapters 9 and 16). Rare metabolic causes include pyridoxine dependency (see also Chapters 9 and 27), spongiform encephalopathy with low activity of Na/K pumps (Renkawek et al. 1992), pyridoxal-dependent seizures and familial folinic acid-responsive seizures (Hyland et al. 1995; Baxter 2002; Wolf et al. 2005; Campistol and Plecko 2015). Cases of neonatal seizures resistant to pyridoxine but responsive to pyridoxal phosphate have been reported (Wang et al. 2005).
Epileptic seizures related to hereditary metabolic disorders are usually associated with widespread neurological dysfunction. A key diagnostic feature is the early appearance of symptoms, following a symptom-free period of a few hours or days, particularly if otherwise unexplained (no antenatal or prenatal history). The diversity of causes calls for rigorous analysis of symptoms and of biological samples in the interest of rapid diagnosis and the most appropriate treatment (Livet et al. 2005; Campistol and Plecko 2015). Seizure types and EEG patterns are rarely specific for any particular metabolic disorder (Wolf et al. 2005).

### Table 16.10 Features of the main types of neonatal seizures

### Table 16.11 Main causes of neonatal seizures

**Hypoxic–ischaemic encephalopathy**
(may produce both clearly epileptic seizures and seizures probably nonepileptic in nature)

**Intracranial haemorrhage**
Subarachnoid haemorrhage (clonic seizures in term infants 1–5 days of age)
Intraventricular haemorrhage (mainly tonic seizures and episodes of apnoea without EEG correlates, occasionally typical EEG discharges)
Intracerebral haematoma (fixed localised clonic seizures)

**Intracranial infections**
Bacterial meningitis and/or abscess
Viral meningoencephalitis

**Cerebral malformations**
Myoclonic and focal tonic seizures, infantile epileptic spasms, others

**Metabolic causes**
Hypocalcaemia (clonic, multifocal seizures)
Hypoglycaemia
Hyponatraemia
Inborn errors of amino acids or organic acids and NH₃ metabolism (often atypical, mostly unassociated with EEG discharges)
Molybdenum cofactor deficiency
Bilirubin encephalopathy (atypical, no EEG discharges)
Pyridoxine dependency
Biotinidase deficiency
Carbohydrate-deficient glycoprotein syndrome

**Toxic or withdrawal seizures** (probably not true epileptic seizures in most cases)

**Familial neonatal convulsions** (clonic localised, shifting seizures with EEG correlates)

‘Benign’ neonatal seizures of unknown origin (‘fifth-day fits’)
Clonic and apnoic seizures with typical EEG correlates
Seizures in infants born to mothers addicted to narcotics or barbiturates are typically nonepileptic in origin but EEGs have only rarely been recorded in such cases. Their prognosis appears to be favourable (Doberczak et al. 1988).

Seizures due to cerebral malformations include infantile spasms and myoclonic patterns. Neonatal convulsions without detectable cause are not uncommon (Painter et al. 1986; Aicardi 1991).

The aetiologic profile and neurodevelopmental outcome of seizures in term newborn infants was studied by Telgul et al. (2006). Eighty-nine term infants with clinical neonatal seizures were evaluated in the newborn period and at 12–18 months. Aetiology was defined in 77 infants. Global cerebral hypoxia–ischaemia, focal cerebral hypoxia–ischaemia, and intracranial haemorrhage were most common. Neonatal mortality was 7%, and 28% of survivors had poor long-term outcome. Association between seizure aetiology and poor outcome was strong, with cerebral dysgenesis and global hypoxia–ischaemia associated with the poorest outcome. A normal neonatal period/early infancy neurological examination was associated with uniformly favourable outcomes at 12–18 months; neuroradiological abnormalities lacked specificity. A normal or mildly abnormal neonatal EEG had a favourable outcome, particularly if neonatal neuroimaging was normal. A moderate or severely abnormal EEG and multifocal and diffuse cortical or primary deep grey matter lesions carried a poorer prognosis. Mortality associated with neonatal seizures has declined in the current era of neonatal intensive care, although long-term neurodevelopmental morbidity remains unchanged. Seizure aetiology and background EEG patterns are important prognostic factors.

Neuroimaging is very helpful to identify the underlying aetiology. Cranial ultrasound is more suitable for identifying severe and centrally located lesions during the acute phase; calcifications can also be identified by ultrasound and are typically unrecognised on MRI. More detailed information will subsequently be obtained with MRI, using thin (2mm) slices and sequences suitable for imaging neonates. MRI is especially useful in revealing migrational disorders. Magnetic resonance spectroscopy may be used to identify metabolic disorders before the results of metabolic investigations are available (Weeke et al. 2015; Campistol and Plecko 2015).

SYNDROMES OF THE NEONATAL AND EARLY INFANTILE PERIOD

Only a few well-defined syndromes are currently recognised in newborn infants.

Benign Familial Neonatal Seizures (BFNS)

Benign familial neonatal seizures (BFNS) are dominantly inherited. The most frequently implicated gene is located on chromosome 20q (Leppert et al. 1989; Malafosse et al. 1994) and codes for the KCNQ2 potassium channel (Singh et al. 1998), but rare cases are linked to chromosome 8 on a gene for KCNQ3 (Ryan et al. 1991; Charlier et al. 1998). In other cases, no linkage to either locus has been found (Plecko 1994).

Seizure onset occurs within 2–15 days of birth, recur for a few days, then cease. Later relapses occur in 14% of cases (for a review see Plouin and Neubauer 2012). Seizures are generalised (Hirsch et al. 1993; Ronen et al. 1993), although focal seizures have been reported (Aso and Watanabe 1992; Bye 1994). The phenotype is variable with some members of affected families presenting with febrile convulsions or generalised epilepsies (Berkovic et al. 1994). Rare cases of apparent recessively inherited neonatal seizures have been reported (Schiffmann et al. 1991). Diagnosis rests on a history of similar events in relatives, consistent with an autosomal dominant transmission. A mutation of the SCN2A sodium channel subunit has been found in a subtype in which seizure onset may be either neonatal or infantile (see below). The phenotypic, functional and mutational variations in BFNC are reviewed in a study of 17 families with KCNQ2 mutations (Singh et al. 2003).

The natural course of the seizures is self-limited, as seizures cease within a few days or weeks. In two members of one family, the phenotype extended beyond neonatal seizures and included rolandic seizures, while a subset of families experienced seizure in infancy. One patient with BFNS that evolved to rolandic epilepsy was reported by Coppola et al. (2003). Ten to 15% of patients have febrile or afebrile seizures later in life (Ronen et al. 1993) while showing normal psychomotor development. There are no published guidelines for treating benign familial neonatal convulsions. Formerly no treatment was offered (Plouin and Anderson 2005). Phenobarbitone, sodium valproate or phenytoin are the classic drugs of choice and are administered over a period of 3–6 months. Data on long-term more recent AEDs, such as levetiracetam and topiramate are not yet available (Ikonomidou 2015).

Benign Familial Infantile Convulsions (BFIC)

A slightly later seizure onset was observed in several families and named benign familial infantile convulsions (BFIC).

Their presentation is characterised by focal seizures, with or without secondary generalisation, occurring mostly in clusters, and with onset between ages 3–9 months. Patients typically have normal psychomotor development at seizure onset and a favourable outcome (Vigevano et al. 1992; Chahine and Mikati 2006). The condition is genetically heterogeneous with loci identified on chromosomes 19q12–13.1 and 16p12–q12, allelic to infantile convulsions and choreoathetosis. Mutations were subsequently identified in the gene encoding the voltage-gated sodium channel a2 subunit (SCN2A) on chromosome 2q24 (Heron et al. 2002) in two families affected by neonatal and infantile seizures (benign familial neonatal–infantile convulsions) and confirmed in six other families investigated by the same group (Berkovic et al. 2004).
The relevance of chromosome 16 locus in BFIC was confirmed in a recent study of 16 families (Striano et al. 2006).

**Benign non-familial neonatal convulsions** (Plouin and Neubauer 2012), also known as ‘fifth day seizures’, consist of repeated seizures mainly clonic or apnoeic in type with onset between 3 and 7 days of age. The interictal neurological state and EEG are normal, although the latter may show peaked theta rhythm (so-called théta pointu alternant) (Plouin 1994). Neonatal seizures of late onset (after 3 days) without known cause often have a favourable outcome (Lombroso 1996).

**KCNQ2 Encephalopathy**

KCNQ2 encephalopathy is a recently described entity, characterised by drug-resistant seizures of neonatal onset and severe psychomotor impairment (Weckhuysen et al. 2012, 2013). Age at onset is nearly identical to BFNS, (first week of life), and the seizure pattern is also similar – a prominent tonic component with or without associated clonic jerking of the face or limbs. Motor manifestations are often associated with autonomic features such as apnoea and desaturation (Serino et al. 2013). Further evolution is distinct from BFNS as seizure frequency increases dramatically, sometimes up to 10 per hour. All affected children have a severely abnormal interictal EEG pattern, either burst suppression or multifocal epileptic activity. Treatment is usually ineffective at symptom onset. While many children achieve seizure-freedom by the first or second year of life, their psychomotor development remains profoundly impaired. A recent report (Numis et al. 2014) described three cases with dramatic seizure control following the introduction of oral carbamazepine but psychomotor development was still impaired (for a discussion on mechanisms probably involved, refer to the review by Cilio and Oldham 2015).

**Epileptic Encephalopathy Associated with CDKL5 Mutations**

Epileptic encephalopathy associated with CDKL5 mutations, first described in 2003 (Kalscheuer et al. 2003), is another well-delineated entity with the majority of the patients having onset of seizures within the first 3 months of life (Bahi-Buisson et al. 2008). A three-phase course is reported starting with frequent, albeit brief seizures, hypotonia and poor eye contact. Even with proper seizure management, the second phase progresses to epileptic spasms, with or without hypersrrhythmia that evolves into a severe epilepsy with multiple seizure types, including myoclonic and tonic. A distinctive seizure pattern, described as ‘hypermotor-tonic-spasms’ may appear during the first or the second stage (Klein et al. 2011). Because the syndrome is more frequently seen in girls accompanied by deceleration of head growth and hand stereotypes, a Rett-variant has been proposed. However, this hypothesis is not supported by a recent excellent review (Feht et al. 2013) based on a large international cohort including over 80 children (77 females and nine males).

**Syndrome of Focal Neonatal Convulsions and Stroke**

The syndrome of focal neonatal convulsions and stroke is less well defined. However, this diagnosis should be considered by the occurrence in the 2nd to 7th day of age of repeated focal clonic seizures that remain localised to the same restricted part of the body. The diagnosis is confirmed by neuroimaging revealing the presence of infarction involving mostly the middle cerebral artery territory. The overall prognosis is favourable but hemiplegia persists in about half the cases. Some patients develop later focal or unilateral ESES and present with learning difficulties.

Severe neonatal or infantile epilepsies with suppression-burst pattern (early infantile epileptic encephalopathy with suppression–bursts or Ohtahara syndrome and early neonatal myoclonic encephalopathy) are discussed in the Seizures and Syndromes of Infancy and Early Childhood section.

Prenatal seizures have been demonstrated by ultrasonography (Landy et al. 1989; Du Plessis et al. 1993). They may occur with pyridoxine dependency and with some brain malformations (Du Plessis et al. 1993).

**Prognosis in Neonatal Seizures**

The prognosis in neonatal seizures is mainly determined by their cause (Volpe 1989; Lombroso 1996; Tegkul et al. 2006). The possible role of the seizures themselves in generating or increasing brain damage remains controversial (Volpe 1989; Lombroso 1996; Scher 2003). Although some aggravating effect of seizures is likely, the occurrence of seizures of long duration without sequelae, such as those of hypocalcaemia or of familial seizures, suggests that the role of paroxysmal activity (Lombroso 1996) is less important than its causes.

The poorest outcome occurs in patients with seizures due to brain dysplasias (an often surgically treatable aetiology particularly when identified early), followed by hypoxic–ischaemic encephalopathy and neonatal infections. These disorders carry a high mortality and have a high incidence of later epilepsy, intellectual disability and cerebral palsy (Holden et al. 1982; Watanabe et al. 1982b; Lombroso 1983b, 1996). In contrast, the prognosis for some metabolic seizures (late hypocalcaemia) and seizures of unknown cause with onset after the second day of life is largely favourable (Arzimanoglou and Aicardi 2001). In a series of patients with electroencephalographically confirmed seizures, the mortality was 32.5% and sequelae were found in 55.5% of survivors (Legido et al. 1988). Late epilepsy occurs in 10–26% of patients but may be as high as 81% in patients with large brain malformation.

The prognostic value of the interictal EEG for neurodevelopment has been repeatedly emphasised (Lombroso 1983b; Scher and Beggarly 1989). Long-term prognosis was also studied in a prospective population-based study of 88 participants (Ronen et al. 2007). Prognosis was better for term than preterm infants (P<0.003). The authors reported for term infants: 28 (45%) normal, 10 (16%) deaths and 24 (39%) with impairments; in comparison, preterm infants...
showed: three (12%) normal, 11 (42%) deaths and 12 (46%) with impairments. Of survivors, 17 (27%) developed epilepsy, 16 (25%) had cerebral palsy, 13 (20%) had intellectual disability and 17 (27%) had learning disorders. Variables associated with poor prognosis were Sarnat stage III or equivalent severe encephalopathy, cerebral dysgenesis, complicated intraventricular haemorrhage, infections in preterm infants, abnormal neonatal EEGs, and the need for multiple drugs to treat neonatal seizures. Pure clonic seizures without facial involvement in term infants were associated with a favourable outcome, whereas generalised myoclonic seizures in preterm infants were associated with high mortality.

Treatment of Neonatal Seizures

Symptomatic treatment is imperative in addition to treatment of the cause of seizures. This includes maintaining a clear airway and vital signs (cardiac rate, blood pressure, etc.) and administering specific therapy (e.g. late hypocalcaemia, hypomagnesaemia and some cases of hypoglycaemia). Pyridoxine and pyridoxal phosphate should be administered. A single dose of 100mg of pyridoxine for all neonates is standard; excessive doses should be avoided as hypotonia and apnoea may result (Kroll 1985).

As a direct result of lack of controlled trials in neonates, antiepileptic drug treatment still commonly relies on phenobarbitone or phenytoin, but these are only 50% effective (Booth and Evans 2004; Pressler and Mangum 2013). Large loading doses are usually recommended (phenytoin, a single intravenous dose of 20mg/kg, not to be repeated – further doses can be administered while monitoring serum levels; phenobarbitone, 20–25mg/kg/day – some authors use doses as high as 30–120mg/kg/day in 10mg/kg boluses every 30 minutes), provided ventilatory support is available (Crawford et al. 1988). However, anticonvulsant agents may have deleterious effects on the neonatal brain (Mikati et al. 1994) and their efficacy is not established. Painter et al. (1999) found similar efficacy between phenobarbitone and phenytoin. More importantly, seizure frequency decreased if a decreasing trend had occurred previously, and the drugs failed to prevent subsequent seizures, to delay seizure recurrence or attenuate the severity. Furthermore, antiepileptic agents may eliminate clinical seizure expression without modifying the ictal EEG.

Benzodiazepines, especially lorazepam, is often a first-line or single therapy (Lombroso 1983b; Deshmukh et al. 1986; Hakeem and Wallace 1990). A retrospective non-randomised study (Castro Conde et al. 2005) demonstrated complete electrical control with midazolam in 13 phenobarbitone and phenytoin non-responders and encountered no adverse reactions.

We have found that the use of benzodiazepines as first-line agents often obviates the need for additional therapies. Lidocaine and paraldehyde administration are rarely utilised. Maintenance treatment should be carefully monitored as most AEDs are slowly metabolised in the neonatal period creating a risk of accumulation. In fact, prolonged treatment of neonatal seizures is probably not warranted except for major structural brain abnormalities, as neonatal seizures have a strong tendency to be short-lasting (Hellström-Westas et al. 1995).

The treatment of neonatal seizures remains challenging (Sankar and Painter 2005; Ikonomidou 2015). The two most commonly used medications, phenobarbitone and phenytoin were introduced as anticonvulsants in 1912 and 1938 for adult seizures; they were only secondarily employed in infants and children. Little is known about their effects on cellular and network excitability or early brain development. The choice of phenobarbitone or phenytoin (currently formulated as fosphenytoin) largely rests on their availability in parenteral dosage forms for preterm infants and the relative comfort level of treating physicians (Sankar and Painter 2005). Data are scarce concerning newer AEDs.

A Cochrane review of randomised controlled trials (Booth and Evans 2004) revealed little evidence to support the use of any of current anticonvulsants in the neonatal period. A similar conclusion was confirmed in a more recent systematic review of existing literature (Slaughter et al. 2013). The 2007 Cochrane review (Evans et al. 2007), focusing more specifically on perinatal asphyxia-related seizures, also underscored that anticonvulsant therapy to term infants in the immediate period following perinatal asphyxia cannot be recommended for routine clinical practice, other than in the treatment of prolonged or frequent clinical seizures.

There remains a body of opinion that seizures should be treated because of the concern that seizures in themselves may be harmful, although this is only supported by relatively low-grade evidence. Development of safe and effective treatment strategies relies on future studies of high quality (randomised controlled trials with methodology that assures validity) and of sufficient size to have the power to detect clinically important reductions in mortality and severe neurodevelopmental disability in addition to any short-term reduction in seizure burden (see also Pressler and Mangum 2013).

As for emerging therapies for neonatal seizures, preclinical data suggested that the loop-diuretic bumetanide could be an effective treatment for neonatal seizures. However, the NEMO study (Pressler et al. 2015), evaluating bumetanide as an add-on to phenobarbital, did not confirm this hypothesis in newborn infants with hypoxic–ischaemic encephalopathy. They also found that bumetanide might increase the risk of hearing loss, highlighting the risks associated with the off-label use of drugs in newborn infants before safety assessment in controlled trials.

There are encouraging developments, both in terms of the use of newer AEDs (Ikonomidou 2015; Arzimanoglou et al. 2016c) and hypothermia (Low et al. 2012; Srinivasakumar et al. 2013) to improve antiepileptic efficacy as well as novel measures to prevent neurotoxicity. Lithium and melatonin are promising agents (Ikonomidou 2015).

In 2011, with the contribution of the ILAE, the World Health Organization (2011) published Guidelines on Neonatal Seizures, an evidence-based document which provides diagnostic and management recommendations which can be used in different health care settings.
Almost all forms of epilepsy may begin in this age range (Eltze 2015), including focal epilepsies (to be discussed in the Seizures and Syndromes of Late Childhood and Adolescence section), rare forms of idiopathic epilepsies such as myoclonic epilepsy of infancy and, particularly, the so-called epileptic encephalopathies (West syndrome, Dravet syndrome, Lennox–Gastaut syndrome). Epilepsies with predominantly myoclonic–astatic seizures may also begin at this age range (Arzimanoglou and Resnick 2011).

In infants and young children under 2–3 years, behavioural problems predominate even more than seizures, and deterioration, whether cognitive or behavioural or both, may occur. The term ‘epileptic encephalopathy’ is often used to characterise this phenomenon, presuming that the epilepsy itself contributes significantly to global deterioration.

Finally, this period is remarkable because of the high susceptibility of the CNS to several extrinsic changes, particularly fever, leading to frequent occurrence of occasional seizures. Although febrile seizures, because of their transient nature, are not a form of epilepsy in the classic sense of the term, they are included at the end of this section as they pose a number of important related diagnostic and therapeutic issues.

### EPILEPTIC ENCEPHALOPATHIES IN INFANCY AND EARLY CHILDHOOD

Although the term ‘epileptic encephalopathy’ is not always precisely defined, it is often understood as signifying that the epilepsy causes cognitive and behavioural disturbance. This can accompany many types of epilepsy including seizures that are genetically determined, due to a brain lesion or subclinical with EEG changes. The concept of epileptic encephalopathy might also be extended to patients with epilepsy whose underlying condition does not completely explain the developmental and/or behavioural deterioration.

The cause of epileptic encephalopathy is largely unknown and it is often unclear whether a single mechanism accounts for the encephalopathy in all cases or if there are different mechanisms with different types or syndromes of epilepsy. In several conditions (e.g. in Dravet syndrome) a combined ‘developmental’ and ‘epileptic’ component contributes to the clinical presentation. However, it is possible that a single mechanism may underlie different syndromes. The major importance of the concept is the implication – often confirmed by clinical experience – that interruption of the epileptic process whether by drugs or by surgery improves global cognitive outcome. In this chapter, the term is used only for the major encephalopathic disorders, including West syndrome and related entities, Lennox–Gastaut syndrome, Dravet syndrome, Landau–Kleffner syndrome and ESES. A more recently described rare disorder (Coppola 1995), called malignant migrating partial seizures in infancy (MMPSI) is also discussed in the present section.

### Infantile Epileptic Spasms (including West Syndrome)

The classic syndrome, known as Infantile Spasms or West syndrome, has three major components: infantile epileptic spasms, interictal EEG tracing of hypsarrhythmia that accompanies the seizures in a typical or modified form, and the presence of cognitive and behavioural regression (Lux and Osborne 2004; Guzzetta et al. 2007). One of the elements of the triad may be absent (commonly the hypsarrhythmia), and additional features such as focal seizures, marked asymmetries and focal neurological signs may be associated (Arzimanoglou et al. 2004; Dulac and Tuchhorn 2005; Guzzetta et al. 2007).

The incidence of West syndrome is estimated at 3–4.5 per 10 000 live births. The term West syndrome should probably be reserved only for cases presenting both epileptic infantile spasms, a chaotic interictal EEG pattern (see below) and signs of developmental regression (that at onset can be limited to a loss of some acquired skills).

West syndrome virtually always begins during the first year of life, with a peak frequency between 4 and 10 months of age; more rarely epileptic spasms begin shortly after birth. Epileptic spasms can also occur outside the infantile period and may account for epileptic falls or head drops (Egli et al. 1985; Ikono et al. 1985; Auvin et al. 2010).

Infantile epileptic spasms are the characteristic and often sole type of seizures in West syndrome but may be preceded, accompanied or followed by other types of seizures. The spasms are sudden, usually bilateral, tonic contractions of the muscles of the neck, trunk and extremities that may be flexor or extensor. The intense abrupt contraction lasts less than 2 seconds but may be followed by a less intense contraction with or without behavioural arrest lasting about 10 seconds. The spasms are sometimes isolated but characteristically occur in a series up to more than 100 individual jerks, 5–30 seconds apart. The repetitive character of the spasms is an important diagnostic clue, especially as the individual spasms may have a very limited expression such as slight head nodding, elevation of the eyeballs or shrugging of the shoulders, which are all too often discounted as colic, Moro reflex or other benign phenomena.

Clinical variants, especially unilateral spasms, are relatively common (Shewmon 1994; Gaily et al. 1995). Asymmetrical and even unilateral spasms may occur and are usually associated with contralateral EEG activity, suggesting a cortical generator for infantile spasms (Donat and Wright 1991a, c; Gaily et al. 1995), and with damage to the same side. Abnormal cortical development is one of the most frequently encountered causes of asymmetrical infantile spasms (Metsähonkala et al. 2015).

Early identification of the responsible focal lesion is of major importance when deciding the most appropriate therapeutic strategy as focal dysplastic lesions are often surgically amenable. Other types of seizures may precede or accompany the spasms.
The ictal EEG features of epileptic spasms usually consist of a generalised high-amplitude slow wave coinciding with the clinical event, often with superimposed fast activity (Vigevano et al. 2001). The latter may appear in isolation (Donat and Wright 1991c; Shewmon 1994). Other patterns have been reported but appear to be rare.

Hypsarrhythmia (Fig. 16.6) is the most characteristic interictal EEG pattern associated with West syndrome. It is characterised by a chaotic succession of very high-amplitude slow waves interspersed at random with multifocal asynchronous spikes and sharp waves. During slow sleep, bursts of polyspikes separated by stretches of poorly active tracings are typically present (Vigevano et al. 2001; Dulac and Tuxhorn 2005). Because hypsarrhythmia may induce cognitive and behavioural dysfunction, certain authors (Dalla Bernardina et al. 2007) suggest that it cannot be considered stricto sensu an ‘interictal’ pattern, the entire electroclinical picture representing a continuous ictal status modified by the recurrence of more or less easily detectable ictal events.

Modified hypsarrhythmia, with preservation of some background rhythms, localising features or synchronous spike–wave activity occurs in up to 40–70% of cases. Unilateral hypsarrhythmia is rare, usually associated with unilateral spasms (Gaily et al. 1995). Several other EEG patterns can be associated with infantile spasms, and only 60% of patients were reported to have true or modified hypsarrhythmia (Dalla Bernardina and Watanabe 1994). Some infants may have nonparoxysmal EEG for a brief period at onset of the disorder or late in the course, despite persistence of the clinical spasms.

Focal EEG features may be present together with the hypsarrhythmia as foci of spikes or as localised slow waves especially during sleep. They are of value as they indicate the likelihood of a cortical lesion, thus favouring a structural cause.

Developmental deficits are present before the onset of the spasms in 68–85% of cases (Riikonen 1982). Such figures are minimal estimates as mild degrees of cognitive delay are difficult to identify at an early age. In infants who were previously well, a definite behavioural regression is observed (Guzzetta et al. 2002), the infants losing interest in their surroundings sometimes to the point of appearing blind and deaf, or simply limited to loss of previously acquired skills, usually obvious to the parents. Deterioration may seem to be the first manifestation of the syndrome when the spasms are delayed or escape recognition, and West syndrome should be considered in any infant who regresses developmentally during the first year of life. Development usually improves when the seizures subside although resumption of cognitive functioning may lag for several weeks after cessation of seizures.

Autistic features are common at the onset of West syndrome and may persist as a sequela in a high proportion of patients (Riikonen and Amnell 1981). Guzzetta et al. (1993) have clearly separated the manifestations of the acute phase, comprising mainly disturbances of awareness and communication, from the cognitive sequelae.

The diagnosis of infantile epileptic spasms should be straightforward if the repetitive character of the spasms and the associated phenomena are given due attention. However, only 12% of primary care physicians made the correct diagnosis in one series (Bellman et al. 1983), whereas 15% made a diagnosis of colic. Benign myoclonus of infancy is an axial shudder that may closely mimic infantile spasms but the EEG is normal (Lombroso and Fejerman 1977; Pachatz et al. 1999). This nonepileptic phenomenon seems related to tics or ‘gratification phenomena’. Other forms of epilepsy, especially myoclonic epilepsies (either idiopathic or of an unknown cause), are also erroneously diagnosed as infantile spasms, although their prognosis is more favourable. Early-onset Lennox–Gastaut syndrome may be difficult to differentiate as
Part VII Paroxysmal Disorders

seizures can occur in clusters in both syndromes (Donat and Wright 1991a).

Prognosis of infantile spasms depends primarily on aetiology. For this reason, a detailed diagnostic workup, with priorities decided on the basis of the overall clinical and EEG picture, should be considered an absolute priority at onset and entrusted to a child neurology team specialised in epilepsy.

An important distinction is made between symmetrical and cryptogenic spasms. Cryptogenic cases are variably defined as those for which no cause can be identified or those that, in addition, showed normal development before the onset of seizures (Lombroso 1983a). The term cryptogenic does not exclude the presence of a lesion, thus blurring the distinction between the two categories. With the latter definition, cryptogenic spasms account for only 10–15% of cases, but these are much more likely than symmetrical (structural/metabolic) cases to run a favourable course.

Some investigators (Vigevano et al. 1993; Dulac and Tuxhorn 2005) described an idiopathic group of infantile spasms with a good prognosis and peculiar clinical and EEG features. However, Haga et al. (1995) and Watanabe et al. (2001) were unable to differentiate aetiological groups on the sole basis of clinical or EEG (ictal or inter-ictal) features. Structural causes are most commonly due to brain malformations and neurocutaneous syndromes (mainly tuberous sclerosis) (Vigevano et al. 1994a; Arzimanoglou et al. 2004; Dulac and Tuxhorn 2005). Gross malformations include lissencephaly, pachygryria, diffuse subcortical heterotopias and agenesis of the corpus callosum, especially Aicardi syndrome (see Chapter 1). Tuberous sclerosis accounts for 10–20% of cases. Focal cortical dysplasia (Chugani et al. 1990, 1996; Robain and Vinters 1994; Chugani and Conti 1996) may be the single most important cause of infantile spasms. Chronic congenital and acquired lesions account for the majority of remaining symptomatic cases (Cowan and Hudson 1991). Metabolic diseases are uncommonly causative. Infantile spasms are also observed in chromosomal disorders (see Chapter 5) associated with epilepsy ( Battaglia and Guerrini 2005).

West syndrome is usually sporadic, except when due to metabolic disorders. Genetically determined forms are uncommon. X-linked cases are mainly due to mutations in the ARX gene (Suri 2005) and may be associated with other abnormalities, some of which are congenital. Other cases due to mutations at chromosome Xp11p11–Xpter (Claes et al. 1997) and in the CDL5 gene (Weaving et al. 2004; Bahi-Buisson et al. 2008) have been reported. Spasms are also a feature of the PEHO syndrome (peripheral oedema, hypsarhythmia and optic atrophy) (Chapter 10). From a pathological standpoint, most autopsied cases of infantile spasms are related to prenatal factors. Meencke and Gerhard (1985) found no detectable pathology in only 11% of 107 cases. Most cases are related to diffuse lesions, but unilateral lesions, in particular cystic encephalomalacia in the middle artery territory (porencephalic cysts) (Palm et al. 1988), may be responsible for infantile spasms with a more favourable prognosis (Alvarez et al. 1987; Cusmai et al. 1988).

Treatment of West syndrome is often unsatisfactory and the response highly related to the underlying aetiology. Most conventional AEDs are ineffective. So far, only corticosteroids or adrenocorticotropic hormone (ACTH) and vigabatrin are recognised as effective (see Hancock et al. 2013) and the American Academy of Neurology Practice parameters (Mackay et al. 2004). According to a Cochrane analysis (Hancock et al. 2013), there are few well-designed randomised controlled trials of treatment for infantile spasms, and the number of patients enrolled has been small. In the majority, methodology has been poor. Hormonal treatment resolves spasms in more infants than vigabatrin, but this may or may not translate into better long-term outcomes. High dosage is recommended if prednisolone or vigabatrin is used. Vigabatrin is considered the treatment of choice in patients with tuberous sclerosis complex. Resolution of EEG features may be important, but this has not been proven. Other agents, for example, topiramate, lamotrigine, valproate, pyridoxine and zonisamide, and non-pharmacological methods have been found useful by some authors (for reviews see Dulac and Tuxhorn 2005; Hancock et al. 2013).

All reports conclude on the need for well-designed, prospective studies with larger numbers of participants and a long follow-up. However, the authors of the present chapter believe that 174 years from the first description of the syndrome by James West and 57 years after the first prescription of ACTH to children with epileptic spasms, lack of controlled studies may be due to various reasons. This includes the use of studies utilising methodologies applied to other syndromes that are not applicable to epileptic spasms. The lack of a suitable animal experimental model of infantile spasms is also limiting. Lastly, the high risk of permanent cognitive impairment from an encephalopathic disorder is problematic for a placebo-controlled trial. We suggest that future studies should be limited to specific aetiologies, as, for example, early surgery versus ACTH or vigabatrin in infants with dysplasias, tuberous sclerosis, metabolic diseases, and so on.

Hormonal Treatment and Vigabatrin Treatment

ACTH and corticosteroids are both in widespread clinical use. The spectrum of ACTH therapy is extremely variable. ACTH doses vary from 10 to 40 units of natural hormone or 0.1–0.5mg/kg as tetracosactide. Corticosteroids including prednisolone at 2–10mg/kg, hydrocortisone at 5–20mg/kg/day and dexamethasone at 0.3–0.5mg/kg/day are used alone or in various combinations with ACTH. Only a few controlled studies and even fewer comparative studies have been performed (Glaze et al. 1988; Mackay et al. 2004).

One controlled comparative study of tetracosactide versus prednisolone found ACTH to be more effective in a small number of patients, producing remission in 13 of 15 infants compared to four of 14 receiving prednisolone (Baram et al. 1996). In contrast, the large controlled United Kingdom Infantile Spasms Study (UKISS; Lux et al. 2005) did not demonstrate any superiority of one agent over the other. High-dose ACTH (150IU/kg/day) was not found more effective than low-dose
ACTH (20IU/kg/day) in another study (Hrachovy et al. 1994), and two low-dose regimes of tetracosactide showed no difference between the lower and higher dosages (Kondo et al. 2005). Various other protocols are currently available. Heiskala et al. (1996) proposed individualising progressive ACTH therapy, starting with a dose of 3IU/kg/day and progressively increasing to a maximum of 12IU/kg/day if no response is obtained. The clinical impression is that some cases may respond selectively to either agent.

Corticosteroids obviate the need for injection and shorten hospitalisation, and many clinicians continue their use for this reason. However, ACTH might be preferred if its superiority were confirmed in more convincing, larger studies. The mode of action of both agents is unknown. Duration of treatment is no less variable, from 3 to 4 weeks to several months. Our own practice is to use hormonal treatment for short periods of the order of 4–6 weeks.

ACTH or steroid therapy controls spasms in 50–70% of cases but normalise or improve the EEG in a slightly lower proportion. Relapses occur in 20–35% of patients. The long-term neurodevelopmental benefit of therapy is less striking (Riikonen 1996; Gaily et al. 1999; Goh et al. 2005), with normal cognitive development in about 25–30% and only mild impairment in an additional 10–15%. The outcome is better in cryptogenic cases where the proportions are respectively 50% and 25%. Seizures persist in approximately half the patients. They commonly present with the characteristics of the Lennox–Gastaut syndrome, but focal seizures are also observed.

Side effects of ACTH or corticosteroids are common and are often severe if higher doses are administered for longer terms. These include hypertension, infections and metabolic disturbances. Brain shrinkage may also be observed (Konishi et al. 1992). Neuroimaging assessment of patients is therefore best performed before starting treatment.

Vigabatrin has been shown to be efficacious in several studies (for reviews see Arzimanoglou et al. 2004; Dulac and Tuxhorn 2005; Hancock et al. 2013). Doses of 100–150mg/day control spasms in approximately 50–60% of cases usually in less than a week. Its effect on EEG abnormalities is slower than for corticosteroids. In a comparative study with hormonal treatment as first-line therapy (Vigevano and Cilio 1997), vigabatrin was more effective than ACTH for infantile spasms due to cerebral malformations or tuberous sclerosis, whereas ACTH proved more effective in perinatal hypoxic–ischaemic injury patients. The efficacy of the two drugs was similar in cases of unknown cause. Disappearance of interictal ischaemic injury patients. The efficacy of the two drugs was similar in cases of unknown cause. Disappearance of interictal EEG abnormalities occurred sooner in patients randomised to ACTH than in those who received vigabatrin as initial therapy.

In the multicentre randomised controlled UKISS trial (O’Callaghan et al. 2004; Lux et al. 2005; Riikonen 2005), proportions with no spasms on days 13 and 14 were: 40 (73%) of 55 infants assigned hormonal treatments (prednisolone 21/30, tetracosactide 19/25) and 28 (54%) of 52 infants assigned vigabatrin (difference 19%, 95% confidence intervals 1–36%, P=0.043). Two infants allocated to tetracosactide and one allocated to vigabatrin received prednisolone. Adverse events were reported in 30 (55%) of 55 infants on hormonal treatments and 28 (54%) of 52 infants on vigabatrin. When the same groups of patients were assessed at 12–14 months of age (Lux et al. 2005), the absence of spasms at final clinical assessment was similar in each treatment group (hormone 41/55 [75%] versus vigabatrin 39/51 [76%]).

Neurodevelopment was also evaluated in this follow-up study, using the Vineland Adaptive Behaviour Scales (VABS). Mean scores did not differ significantly [hormone 78.6 (standard deviation 16.8) versus vigabatrin 77.5 (standard deviation 12.7)]; except for infants with no identified underlying aetiology, in whom the mean VABS score was higher in those allocated to hormone treatment than in those allocated to vigabatrin.

Vigabatrin seems highly effective in epileptic spasms due to tuberous sclerosis (Chiron et al. 1990, 1997) and is currently the drug of choice in such cases, whereas hormonal treatment is still advised by some (Riikonen 2005) in cryptogenic cases. Interpretation of differences is challenging, and the initial use of vigabatrin is still preferred by the present authors because of its rapid action (efficacy on seizures can be evaluated in less than a week in many cases) and the high tolerance. Suggested dose is 100–150mg/kg/day. In cases where vigabatrin remains without effect after a few days, trial steroid treatment is the next choice (Arzimanoglou et al. 2004).

The most worrying side effect of vigabatrin is constriction of the visual field, which occurs in up to 30–50% of adult patients and may not regress. Its frequency has varied considerably among series. Vanhalato et al. (2002) found that 17 (18.5%) of 91 children exposed to the agent had restriction of the temporal field. There was a positive correlation between field loss and both duration and dose of treatment. The shortest duration of vigabatrin treatment associated with visual field constriction was 15 months, and the lowest total dose 914g. Hammoudi et al. (2005) found that contrast sensitivity and visual acuity were reduced in a series of 28 children.

A Finish study reported visual field defects in a cohort of 35 school-age children who had never received the drug in infancy and were treated for infantile spasms (Riikonen et al. 2015). Typical vigabatrin-attributed visual field defects (VFDs) were found in 11 of 32 (34%) children: in one of 11 children (9%) who received vigabatrin for less than 1 year, in three of ten children (30%) who received vigabatrin for 12–24 months, and in seven of 11 children (63%) who received vigabatrin treatment for longer than 2 years (group 3). VFDs were mild in five and severe in six children. Patients with tuberous sclerosis were at higher risk of VFDs (six out of 10 children).

The severity of the defect is usually mild, and it seems unlikely that short-term treatment (less than 6 months) will produce a severe defect, so we believe the balance of risks in a severe condition like infantile spasms still favours the use of the drug as a first choice treatment.

OTHER ANTIPEPTIC AGENTS

Recurrences of epileptic spasms are not rare with either hormonal or vigabatrin therapy, and the optimal duration
of treatment remains undefined. Other forms of treatment include the benzodiazepines, especially nitrazepam. These are sometimes effective against clinical spasms (Chamberlain 1996) but their effect on the EEG abnormalities is limited. One comparative study found no difference between nitrazepam and hormonal treatment (Dreifuss et al. 1986) but most authors regard this treatment as less effective.

Sodium valproate in high doses (100–200mg/kg/day) has produced good results according to some investigators (Siemes et al. 1988; Prats et al. 1991; Ohtsuka et al. 1994), with control of the spasms in 40–65% of cases. Zonisamide may also prove to be an interesting choice, according to a rather large experience of Japanese colleagues (Tsuji et al. 2007).

In 2015, the ILAE published the results of an international survey on global treatment practices to control infantile seizures (Wilmshurst et al. 2015a). Epileptic spasms are managed with ACTH at most centres (42%) versus vigabatrin (22%), or prednisone (14%). In contrast, 88% of respondents from Oceania use oral prednisone (odds ratio 28.362, confidence intervals 8.466–95.010; P<0.001). Respondents noted that their management was aetiology driven; for example, there is evidence to support the first-line use of vigabatrin for patients with tuberous sclerosis complex who develop epileptic spasms. Others noted a role for the ketogenic diet and sulthiame. Duration of treatment practices varied from 3 months to 2 years, but these conflicting responses are likely to be related to confusion over the need to respond to the seizure type management itself (the epileptic spasms) versus an underlying disease process are likely to evolve further, especially to Lennox–Gastaut syndrome.

The prognosis of infantile spasms with ACTH/steroids or vigabatrin treatment depends on aetiology, with better results in cryptogenic (or idiopathic) cases with a normal development before spasm onset. The occurrence of prior seizures, neurological signs and major MRI abnormalities predicted a poor outcome. The eventual effect of treatment choices on global developmental outcome has not been properly assessed due to the heterogeneous basis of West syndrome.

**SURGICAL RESECTION**

Surgical resection of localised brain areas of cortical dysplasia responsible for the spasms has been performed (Chugani et al. 1990; Shields et al. 1992; Chugani and Pinard 1994; Jonas et al. 2005; Kang et al. 2006) and may be indicated as early treatment in selected cases, particularly when a clearly identifiable dysplastic lesion is detectable by MRI or with hemimegalencephaly. Clinicians should be particularly attentive for asymmetrical spasms, focal neurological signs or lateralised EEG abnormalities (which might require expertise given the chaotic EEG presentation early in the course of the disorder).

Defining abnormal cortex is often possible by MRI but positron emission tomography (PET; Chugani et al. 1996), or single photon emission computed tomography (SPECT; Miyazaki et al. 1994) are often complementary. However, transient PET abnormalities, especially during the period of active hysparrhythmia may occur (Watanabe et al. 1994), and when functional imaging abnormalities are found, repetition of the MRI and careful re-analyses of video-EEG findings should be performed looking for convergent features. Identification of, and possible preventive treatment for infants with neonatal difficulties at risk of developing infantile spasms have been attempted (Okumura and Watanabe 2001).

Multistage surgery may also need to be considered as the full anatomical extent of the underlying lesion may not be appreciated in the first 2 years of life. This is especially true for cortical malformations which may not be imaged fully on MRI due to immature myelination. However, the greater potential for neural reorganisation after surgical lesioning in early life argues more strongly for earlier and more complete one-stage ablation, especially if the seizure-onset zone is documented to involve eloquent cortical regions.

**Syndromes Closely Related to Infantile Spasms**

**EARLY MYOCLOTON ENXEPHALOPATHY (EME) AND OHTAHARA SYNDROME OR EARLY INFANTILE EPILEPTIC ENCEPHALOPATHY**

Syndromes closely related to infantile spasms include neonatal myoclonic encephalopathy, first described by Aicardi and Goutières (1978) as *early myoclonic encephalopathy* (EME) and Ohtahara syndrome or early infantile epileptic encephalopathy (EIEE), originally described by Ohtahara et al. (1976) (Table 16.12). In the 2005 edition of *Epileptic Syndromes in Infancy, Childhood and Adolescence* (John Libbey Eurotext editions), the two authors together discussed the common and specific features of the two entities, also discussing the possibility that they belong to a spectrum of disorders (Aicardi and Ohtahara 2005). Another entity, described by Gobbi and colleagues, is the *syndrome of periodic spasms* (Gobbi et al. 1987) is clinically characterised by repetitive lateralised spasms often following a focal seizure, can be observed at any age and is almost always due to brain malformations or extensive brain damage.

**Neonatal (or early) myoclonic encephalopathy** (EME) is an extremely severe condition of very early onset, characterised by partial or fragmentary erratic myoclonus from birth, marked hypotonia, and often the late occurrence of repetitive tonic spasms. The EEG consistently shows a suppression-burst pattern, characterised by a succession of bursts of paroxysmal activity interspersed with episodes of flat or low-amplitude tracing. The course is severe, neurological development remains absent or rudimentary, and death supervenes in about half the cases, most often in the first year of life (Aicardi and Ohtahara 2005). Non-ketotic hyperglycaemia is a major cause.

**Early infantile epileptic encephalopathy** (EIEE), also known as *Ohtahara syndrome* (Aicardi and Ohtahara 2005), is characterised by a very early onset, frequent tonic spasms, and a suppression-burst EEG pattern. It is closely related to infantile spasms, of which it may be regarded as a neonatal form. It usually does not include myoclonus and is compatible with survival with neurological and cognitive sequelae.
All three syndromes are of lesional or metabolic origin and share a poor prognosis. Although EIEE is thought to be mostly due to brain malformations and EME to metabolic disorders, there are many exceptions and migration disorders have been shown to cause myoclonic encephalopathy (Du Plessis et al. 1993). Moreover, cases of glycine encephalopathy may present with severe neonatal encephalopathy but without myoclonic phenomena, suggesting that there is no strict relationship between aetiology and clinical features (Aicardi and Ohtahara 2005). Thus, the separation between EIEE and neonatal myoclonic encephalopathy may be artificial (Lombroso 1990), and EIEE may be an early form of infantile spasms. As underscored in a recently published comparative table and comment (Mizrahi and Milh 2012), whether the two entities represent two aspects of a continuum of one disorder remains an open question, awaiting prospective study from an electroclinical perspective with well-studied pathology and genetic screening.

Known genetic causes of early-onset epileptic encephalopathies with burst suppression include brain malformations (e.g. polymicrogyria and lissencephaly), inborn errors of metabolism (e.g. pyridoxine- and other vitamin-dependent epilepsies, mitochondrial disorders, and amino acidopathies), and other genetic aetiologies (e.g. pathogenic variants in ARX, KCNQ2, SCN2A, SIK1, SLC25A22, STXBPI). Genotype–phenotype correlations in 33 patients with a referral diagnosis of Ohtahara syndrome or early myoclonic encephalopathy without malformations of cortical development were investigated by exome sequencing (Olson et al. 2017). In 17 of 28 (61%) patients with confirmed early burst suppression, the authors identified variants predicted to be pathogenic including KCNQ2 (n=10), STXBPI (n=2), SCN2A (n=2), PNPO (n=1), PIGA (n=1) and SEPSECS (n=1). In three of five (60%) patients without confirmed early burst suppression, they identified variants predicted to be pathogenic in STXBPI (n=2) and SCN2A (n=1). The patient with the homozygous PNPO variant had a low cerebrospinal fluid pyridoxal-5-phosphate level. Otherwise, no early laboratory or clinical features distinguished the cases associated with pathogenic variants in specific genes from each other or from those with no prior genetic cause identified.

Dentato–olivary dysplasia (Harding and Boyd 1991) is a rare cause of neonatal tonic seizures and possibly infantile spasms. The prognosis is very poor and the diagnosis is possible only at autopsy. One familial case is known (Harding and Copp 1997).

**Lennox–Gastaut and Related Syndromes**

The Lennox–Gastaut syndrome (LGS) includes patients with epilepsy starting mainly between ages 1 and 7 years who present with tonic, atonic, and myoclonic seizures resulting in multiple falls and atypical absences, and whose interictal EEGs contain bilateral, though not necessarily symmetrical, slow (≤2.5Hz) spike–wave activity. The limits of LGS are variably understood by different investigators who use diverse criteria for its definition and for its separation from related syndromes such as the myoclonic epilepsies (for a discussion on the nosology of the syndrome, see Aicardi and Levy Gomes 1988, 1989; Arzimanoglou et al. 2004, 2009).

Most investigators now accept the definition proposed by Beaumanoir and colleagues (Beaumanoir and Dravet 1992; Beaumanoir and Blume 2005), that is, of a syndrome of multiple seizure types with interictal slow spike–waves, spikes and bursts of 10–20Hz spikes during sleep, most often associated with intellectual disability.

The seizures of LGS include ‘core’ seizures (myoatonic and tonic, atypical absences and episodes of nonconvulsive status epilepticus) that are variably associated with less characteristic seizures such as tonic, clonic, focal or unilateral seizures. **Tonic seizures**, considered by most authors as a marker of the syndrome, are encountered in 55–92% of cases. Clinically, they are marked by body stiffening involving axial and proximal limb muscles, with extension more commonly than flexion of the trunk, lower limbs and arms. They may be limited to the trunk and neck, with opening of the eyes and, frequently,
apnoea. They sometimes consist only of eye opening with mild 'stretching' movements. Their duration does not exceed 30 seconds and is often no more than 10 seconds. Even in such cases, the contraction is clearly tonic, resulting in sustained clinical and electromyographic muscle activity (Aicardi and Levy Gomes 1988; Arzimanoglou et al. 2009). The ictal EEG shows generalised fast frequencies (≥10Hz) of increasing or high amplitude (Beaumanoir and Dravet 1992; Arzimanoglou et al. 2004; Beaumanoir and Blume 2005), sometimes followed by a few spike–wave complexes. Similar brief duration discharges without clinical manifestations are recorded during slow sleep. Tonic seizures are often nocturnal but their manifestations in sleep may be so mild that they are unnoticed (Beaumanoir and Blume 2005; Arzimanoglou et al. 2009).

**Atonic seizures** occur in 26–56% of LGS patients. They consist of abrupt muscle relaxation and are a common cause of falls in such children, although tonic and myoclonic seizures also produce falls. Atonic seizures represent a major practical problem as they often cause injuries and are not easily prevented by wearing a helmet. The mechanisms of falls are often unclear when no polygraphic recording is available, making the noncommittal term of astatic seizure preferred. Most atonic seizures are associated with loss of consciousness, and it is not clear whether they are purely atonic or are associated with tonic phenomena. Most have the same EEG concomitants as tonic seizures. Thus, they seem to differ from pure atonic seizures associated with bursts of spike–wave activity as observed in the myoclonic–astatic epilepsies (Oguni et al. 1993, 1996, 2001a).

**True myoclonic seizures** occur in up to 28% of cases and are also associated with falls. The type of seizure observed depends on the age at onset of LGS. In cases of early onset, tonic seizures predominate, whereas myoclonic jerks and absences are more frequent in late-onset cases (Chevrie and Aicardi 1972, 1996).

**Atypical absences** are present in 17–60% of patients. Although their onset and termination may be more progressive than in typical absences (see below), they are marked by the same interruption of awareness and responsiveness with only mild motor components (stiffness, hypotonia, simple automatismis) and their recognition depends on the clinical context and the EEG concomitants. These are sometimes ictal slow spike–waves that are difficult to distinguish from interictal spike–waves, but more often consist of fast discharges similar to those associated with tonic seizures.

**Episodes of nonconvulsive status epilepticus** are frequent (Dravet et al. 1986; Beaumanoir et al. 1988) and may last several days or even weeks. They may be responsible for alternating good and bad periods with considerable changes in reaction time and cognitive activity. The most common type is characterised by the alternation of tonic seizures with episodes of confused behaviour, often with erratic myoclonic activity of the face and upper limbs that last from hours to weeks (Arzimanoglou et al. 2009).

The interictal EEG in LGS reveals a diffuse slow spike–wave pattern with slow blunted spikes followed by irregular 1–2Hz slow waves of variable amplitude, usually on a slow, irregular background. The discharges may be asymmetrical and are often subclinical. They show little or no response to hyperventilation or photic stimulation but activate during drowsiness and sleep (Aicardi and Levy Gomes 1988). Runs of 10–20Hz rhythms lasting several seconds occur during non-rapid eye movement (REM) sleep that are likely to represent subclinical or minimal tonic seizures (Fig. 16.7a, b). At the same stage, slow spike–wave complexes are frequently replaced by polyspike–wave complexes. Multifocal discharges may also occur.

Intellectual disability is present before onset of seizures in 20–60% of cases (Arzimanoglou et al. 2006, 2009), as aetiology plays a major role. The proportion of patients with intellectual impairment increases with the passing of time, rising to 90% 5 years after onset (Chevrie and Aicardi 1972). Children having experienced infantile spasms at onset who later develop LGS syndrome also have intellectual disability. Clear loss of skills is observed in some patients. Psychotic symptoms are often present.

**The aetiology of LGS** is heterogeneous. Brain lesions play an important role, whereas genetic factors are regarded as less important. Up to two-thirds of cases may result from a demonstrable brain abnormality or occur in patients with previous developmental delay, and these are termed symptomatic. A significant proportion of LGS cases follow infantile epileptic spasms, with a gradual transition, and are due to the same brain insults that produced the spasms. Brain malformations, however, are less common in LGS, and LGS has been only exceptionally recorded in the course of Aicardi syndrome and of lissencephaly. Focal or multifocal abnormalities of cortical development are frequent, and cases of band heterotopia and of bilateral perisylvian syndromes are on record (see Chapters 1 and 3). Tuberous sclerosis and less common neurocutaneous disorders, such as linear nevus sebaceous syndrome and hypomelanosis of Ito (personal cases), may also be responsible (see Chapter 4). Acquired destructive lesions are less common. Metabolic diseases are exceptional, although LGS due to Leigh encephalomyelopathy has been recorded (Matsuishi et al. 1985). Rare cases of LGS secondary to brain tumours are reported (Honda et al. 1985).

A proportion of cases have no obvious recognised cause and are considered cryptogenic. The occurrence of LGS in patients with unilateral lesions has led to attempts at distinguishing true LGS from bilateral secondary synchrony (Gastaut and Zifkin 1988). In fact, cases of secondary bilateral synchrony fulfil criteria for diagnosing LGS, and their recognition raises the possibility of surgery. PET studies reveal several metabolic patterns (focal, multifocal or diffuse) that correspond to different mechanisms (Chugani et al. 1987; Iinuma et al. 1987; Theodore et al. 1987). Their practical significance is still unclear as the criteria for the diagnosis of LGS was variable within this series.

The diagnosis of LGS is not difficult if strict criteria are applied and the progressive course of the disorder, at least in its initial phases, is considered. Differentiating LGS from other syndromes associated with falls may be challenging, particularly in the early stages or if tonic seizures have not occurred (Arzimanoglou et al. 2009). Rare cases of atypical benign
epilepsy of children, also called Aicardi-Chevrie syndrome (Aicardi and Levy Gomes 1992) or pseudo-Lennox syndrome (Hahn 2000), in which repeated falls and diffuse paroxysmal EEG activity during sleep may mimic LGS and are a source of clinical confusion. Such cases may run a relatively benign course and should be differentiated.

The prognosis of LGS is poor (Arzimanoglou 2003, 2009). Approximately 80% of patients continue to have seizures and, due to seizures or cognitive deterioration, very few patients live independent lives. Outcome is especially poor for patients with brain damage, early seizure onset or antecedents including infantile spasms, or the presence of intellectual disability.
before the seizure onset. Less than 10% of patients have a normal intellectual level. It is difficult to distinguish these cases from those with less favourable outcome, although a later age at onset, a positive response to hyperventilation and a higher incidence of 3Hz spike–wave complexes carry more positive prognostic value. Cases with these features have been termed ‘intermediate petit mal’ but the separation of this subgroup is debatable as the diagnostic criteria are similar to LGS. In typical cases the clinical pattern changes with age and overall seizure frequency usually diminishes between ages 15 and 20 years. Atypical absences and drop attacks may become rare but other seizure types, including tonic seizures in sleep, often persist. Tonic seizures during sleep are probably underreported for older patients by their parents (Beaumanoir and Blume 2005; Arzimanoglou et al. 2009).

The treatment of LGS is often unsatisfactory, even in experienced hands. This is directly related to the various aetiologies underlying the syndrome and the presence of multiple types of seizures that respond differently to the AEDs prescribed. The most recent Cochrane review (Hancock and Cross 2013) listed only nine randomised controlled trials and concluded that it was not possible to proceed to meta-analysis as the trials studied different populations, utilised different therapies and measured different outcomes. From our point of view another criticism is that patients are enrolled in the studies too late in the course of the disorder, when intellectual disability and multiple seizure types are already established. The lack of biomarkers is an important reason that a confident diagnosis cannot be established early in the course of the disorder. Thus, the trials only provide selective information on the control of a given seizure type, without addressing the overall evolution of the syndrome.

As a result, treatment is based on clinical experience or uncontrolled studies. Among conventional AEDs, combinations of sodium valproate and a benzodiazepine are most beneficial, but all medications may be worth trying in individual patients. Lamotrigine is reported to be efficacious (Motte et al. 1997) especially against atomic seizures. In our experience, an association of lamotrigine and sodium valproate is probably the best treatment combination currently available and should be tried early. Titration of lamotrigine should be done slowly to diminish the risk of an allergic reaction. Topiramate (Sachdeo et al. 1999) and rufinamide (Glauser et al. 2008; Otsuka et al. 2014; Arzimanoglou 2016) were also shown to be effective in randomised controlled or open trials.

Carbamazepine is deemed satisfactory by some clinicians for focal and tonic seizures but may have no effect or even aggravate other seizure types, such as myoclonic seizures or atypical absences. Because of its lack of interactions with other AEDs, vigabatrin has been used with some measure of success, particularly in LGS patients combining focal seizures with the core seizures of the syndrome. Felbamate, particularly when used in accordance with existing recommendations and close monitoring, should also be considered despite possible toxicity (Pellock et al. 2006; Heyman et al. 2014; Shi et al. 2014).

Interestingly, combinations of drugs are often required as individual drugs may have a specific activity against only certain types of seizures. A working knowledge of AED interactions (see Zaccara and Perucca 2015) is required, and children should be treated by child neurologists who specialise in epilepsy.

Surgery is an option, particularly in lesional cases such as cortical dysplasias, following the usual presurgical evaluation processes to be performed within comprehensive epilepsy programmes. Callosotomy is often effective for seizures associated with falls that cause craniofacial trauma (Jackson et al. 2015).

Because of the high rate of drug failure, other treatments may be worth trying even late in the course of the disorder. The ketogenic diet has favourable short-term effects despite unpalatability and side effects (Kossoff and Shields 2014). Vagus nerve stimulation may also be an alternative (Oroz et al. 2014; Kossoff and Shields 2014). Corticosteroids are used to stabilise very active epilepsy or status epilepticus. Intravenous immunoglobulins have been advocated but have not been properly tested. Thyrotropin-releasing hormone (Matsumoto et al. 1987) has been used, mainly in Japan.

A consensus approach reviewed issues associated with the diagnosis and treatment of LGS (Arzimanoglou et al. 2009). The limitations and difficulties of clinical trials were emphasised and a comprehensive approach for the treatment of this syndrome was proposed. Irrational polytherapy, combining three to four and sometimes more AEDs should be avoided.

**Dravet Syndrome**

The syndrome was initially described by Dr Charlotte Dravet as **severe myoclonic epilepsy of infants** (Dravet 1978, 1982). Although it does often feature myoclonic phenomena, only uncommonly are these the first manifestation of the syndrome. As suggested by clinical observations (Veggiotti et al. 2001), progress in molecular genetics has confirmed that Dravet syndrome is part of a continuum of severe epilepsies of infancy that may or may not feature additional generalised tonic–clonic seizures, focal seizures, atypical absences and myoclonias (Arzimanoglou 2009). Dravet syndrome can be considered as the most severe end of the spectrum of epilepsy syndromes classified as ‘generalised epilepsy with febrile seizures (GEFS+)’ (see below). Although the recognition of Dravet syndrome has increased in the last decade, it remains a rare disorder (incidence estimated less than one per 20000 to 40000; prevalence in the United States lower than 10 000 cases). It is classified as ORPHA 33069 (Orphanet classification).

Dravet syndrome is caused by new mutations in the sodium channel gene **SCN1A** in over 70–80% of cases (Claes et al. 2001). No mutations of the **SCN1A** gene are present in the remaining 20%. Two familial cases of **GABRG2** mutations have been reported.

Symptom onset usually occurs between ages 4 and 10 months and is characterised by clonic seizures, that are often unilateral and prolonged and precipitated by fever in 75% of cases. Seizures recur several times, at short intervals (usually less than 2 months). Initial development is normal but other seizure types appear during the second or third year including
focal seizures, atypical absences, myoclonic jerks and nonconvulsive status. At the same time, cognitive slowing becomes evident and pyramidal tract signs and ataxia often supervene.

Interictal EEG recordings are generally normal during the first months of the disorder despite frequent seizures. After the second year of life, the EEG does not show slow spike–wave complexes but rather bursts of fast spike–wave complexes, often associated with multifocal spikes. Photosensitivity occurs in 25% of patients, and self-precipitation of seizures is common. The long-term outcome is poor. Seizures persist mainly as tonic–clonic and myoclonic seizures tend to disappear. Intellectual disability of variable degree is constant (Ogini et al. 2001b; Dravet et al. 2012). A severe gait apraxia develops in a substantial proportion of affected patients, and a parkinsonian syndrome has been described in some adults with Dravet syndrome.

The number of reported associated mutations of SCN1A now exceeds 330 (Lossin 2009), most frequently truncating mutations, but also splice site, deletion and missense mutations. Zuberi et al. (2011) retrospectively evaluated clinical and genetic data from 273 individuals with SCN1A mutations identified in their laboratory and reviewed data from 546 published cases. They found that compared to missense mutations, truncating mutations were associated with an earlier mean onset of prolonged seizures, myoclonic seizures, and atypical absence seizures. Intra-familial clinical variability in epilepsy phenotype was reported as well as severity of epilepsy in the several familial cases showing the same missense mutations or even the same truncating mutations, for example proband with Dravet syndrome core phenotype, sibling with Dravet syndrome borderline phenotype or parent with febrile seizures or even no symptoms (for a summary, refer to Dravet et al. 2012), suggesting the presence of other modifying factors such as genes or environmental influences, and also somatic or germline mosaicsisms.

In a large cohort of Dravet syndrome patients, germline mosaicism was established in 7% of parent pairs (Depienne et al. 2006, 2010). The same gene also occurs in other epilepsy syndromes including epilepsy with myoclonic–astatic seizures and some GEFS+ families (Ebach et al. 2005). Harkin et al. (2007) reviewed 90 cases of ‘epileptic encephalopathy’ with SCN1A mutations: 52 had typical Dravet syndrome; 25 had atypical forms; six had cryptogenic generalised epilepsy, four had cryptogenic focal epilepsy, two had myoclonic–astatic epilepsy and one had LGS, broadening the range of expression of the gene.

Berkovic et al. (2006) identified SCN1A mutations in 11 of 14 patients with alleged vaccine encephalopathy. Clinical–molecular correlation showed mutations in eight cases with phenotypes of Dravet syndrome, in three of four cases with borderline Dravet syndrome, but not in two cases with LGS. While these findings require replication, they provide an important alternative explanation that these disorders of early childhood are not caused by vaccinations.

Generalised or unilateral clonic seizures, often precipitated by mild fever or even by hot baths, are the prominent or even the sole seizure type in some patients. Brief seizures may not be obvious and may not always include myoclonic seizures. These have been described incorrectly as variants of severe myoclonic epilepsy (Ogino et al. 1989; Watanabe et al. 1989), epilepsy with hemi-grand mal and high-amplitude EEG slow waves (Dooze 1992) or idiopathic epilepsy of infancy (Ebach et al. 2005). Such forms have been grouped (Ogini et al. 2001a; Fukuma et al. 2004) as ‘borderline cases’ of severe myoclonic epilepsy. The course of such cases appears similar to the typical form, although less severe.

The identification of mutations in other genes in the remaining 20–30% of SCN1A-negative Dravet syndrome patients has failed to locate other genes except for a GABRG2 gene mutation and a SCN1B mutation found in single patients. The recent identification of protocadherin 19 (PCDH19) mutations in SCN1A-negative Dravet syndrome patients could account for 5% of all Dravet syndrome patients, because their clinical pictures shared with those of the Dravet borderline phenotype (Depienne et al. 2010). In another study, seven (37%) of 19 patients with SCN1A-negative Dravet syndrome were found to have PCDH19 mutations (Marini et al. 2010). Further studies to investigate the molecular and cellular basis of epileptogenesis in Dravet syndrome have been performed in animal models of severe myoclonic epilepsy of infancy, and SCN1A knock-out and knock-in mouse models were developed.

The identification of genes associated with Dravet syndrome and related syndromes hints at their complexity. Early identification of SCN1A mutations is useful to support an early diagnosis of Dravet syndrome, facilitate counselling, and avoid AEDs with adverse effects. However, the defining characteristics of seizure type and EEG patterns initially identified by Dravet remain fundamental to diagnosis (Arzimanoglou 2009).

Therapy for Dravet syndrome is disappointing, although occasional cases with a satisfactory outcome with high-dose sodium valproate are reported. Our practice is to initiate treatment with sodium valproate rapidly in association with a benzodiazepine, with a preference for clobazam. If seizures persist we strongly recommend the introduction of stiripentol in countries where it is available. Stiripentol (Chiron 2007) was granted orphan drug status in the European Union for the treatment of Dravet syndrome, following a study where it was used in combination with sodium valproate and clobazam (Chiron et al. 2000). The interactions of stiripentol with many other drugs need to be carefully considered. Although complete control is rarely reached, this association reduces both the frequency and the duration of convulsive episodes in most of the cases.

Among the most recent AEDs, several open-label studies showed that topiramate may lead to relatively good control of convulsive and focal seizures. Levetiracetam and zonisamide are alternative options. Ethosuximide can prove useful when myoclonic seizures are very frequent. Bromides are also useful

This chapter has been written by Dr. J. Dravet.
Part VII Paroxysmal Disorders

With acceptable results in older patients, often in combination with sodium valproate. The respective place of ketogenic diet and vagus nerve stimulation (VNS) are unknown, but are alternative options. Trials with cannabidiol or fenfluramine are ongoing. Similar to LGS drug choices should be made by experienced paediatric epileptologists.

Malignant Migrating Partial Seizures in Infancy

Malignant migrating partial seizures in infancy (MMPSI) is a rare and easily overlooked disorder (Coppola et al. 1995; Coppola 2013). Early diagnosis is based on seizure onset in the first 6 months of life, multiple types of seizures occurring independently and even simultaneously migrating between cortical areas in one or both hemispheres. Clinical diagnosis also depends on the functional features of the involved cortex, absence of a significant family history, and lack of an established aetiology.

At onset, the paroxysmal events may be misinterpreted as nonepileptic phenomena because of the combination of autonomic manifestations (apnoea, flushing) and focal motor events. Rapidly (from 3 weeks to 10 months of age) a ‘stormy phase’ is observed, as seizures become very frequent and polymorphous, occurring in clusters of 5–30 several times a day or near-continuous for days or weeks. Seizure semiology mostly includes lateral head and eye deviation, eyelid twitches, unilateral or bilateral clonic or tonic limb movement, apnoea, facial flushing, chewing movements, mastication, and secondary tonic–clonic generalisation (Coppola et al. 1995).

Focal ictal EEG discharges typically migrate, beginning in one cortical area and either remaining localised or expanding to contiguous regions; other seizures develop independently in different areas of the same or opposite cerebral hemisphere (Caraballo et al. 2008; Coppola 2013).

Seizures in MMPSI are highly drug resistant. In his last review, Coppola discussed the use of bromides (60–80mg/kg/day) and stiripentol, clobazam and levetiracetam (Coppola 2013). The ketogenic diet and VNS therapy yielded poor results.

The long-term outcome of psychomotor development and cognitive function in MMPSI remains poor. Between clusters of seizures, patients remain floppy, drooling, drowsy, and unable to drink or swallow. Limited recovery is observed after clusters, usually consisting of visual tracking without reaching for objects. Major axial hypotonia, pyramidal and extrapyramidal signs with athetotic movements develop progressively.

The potential role of a gene mutation coding for some ion channels is gaining clinical acceptance. The initial mutational scanning of KCNQ2, KCNQ3, SCN1A, SCN2A, CLCN2 and MECP2 genes did not disclose any mutations. However, almost half of sporadic MMPSI cases show mutations in KCN7, resulting in a gain-of-function of this non-conducting potassium channel that is involved in developmental signalling pathways (Barcia et al. 2012). A small number of other children have mutations in the SCN1A gene; one patient presented with an inherited homozygous deletion disrupting the PLCB1 gene (for reviews see Coppola 2013; Striano et al. 2013). A mutation in the TBC1D24 gene, an ARF6-interacting protein, was identified in two affected siblings but was not confirmed in others. Similar discordances are observed in reports discussing the role of a novel homozygous mutation in the SLC25A2 gene (Poduri et al. 2013; Striano et al. 2013).

Epilepsies and Syndromes of Infancy and Early Childhood with Predominantly Myoclonic Seizures

Epilepsies that consist mainly of true myoclonic seizures—that is, seizures marked clinically by very brief shock-like muscle contractions and, electrically, by fast spike–wave or polyspike–wave complexes—occur mostly in infancy and early childhood (Aicardi 1996; Guerrini and Aicardi 2003; Arzimanoglou et al. 2004). These epilepsies may sometimes be confused with the LGS because of the frequent repetition of brief episodes associated with multiple falls, the presence of spike–wave discharges in both groups, and the frequent association of intellectual disability or regression associated with the seizures. However, the clinical and EEG manifestations of the myoclonic epilepsies clearly differ from those of LGS, and the outlook for control of seizures and cognitive development may not be the same.

Myoclonic seizures consist of sudden, lightning-like muscle contractions that may involve the whole body (massive myoclonic seizures) or be limited to the upper limbs, face or eyelids. The jerks are usually symmetrical but may be unilateral or localised to small muscle groups. The ictal EEG shows polyspike–wave paroxysms. Ictal electromyography demonstrates an extremely brief muscle contraction followed by a period of inactivity lasting 100–350ms. When this period is relatively long, muscle resolution may become clinically evident, resulting in a myotonic seizure (Oguni et al. 1994, 1997). Occasionally, only the tonic phase is detectable, the so-called negative myoclonus (Guerrini and Aicardi 2003). Clinically, atonia of variable intensity and duration often follows the myoclonic jerk. When generalised and long enough, it results in falls (drop attacks), and the differentiation of tonic from myoclonic seizures may therefore be clinically impossible. Myoclonic–astatic epilepsy should therefore be considered as a variant of myoclonic epilepsy in which the tonic component is particularly obvious.

The nosology of the myoclonic epilepsies remains unclear. The ILAE International Classification identifies three major groups within this age group: severe myoclonic epilepsy or Dravet syndrome of earlier onset, myoclonic epilepsy of infancy, and epilepsy with myoclonic–astatic seizures (first described by Doose 1992). A number of cases of myoclonic epilepsies in infancy and early childhood remain unclassified,
Myoclonic (Benign) Epilepsy of Infancy

Myoclonic epilepsy of infancy (MEI) was first described by Dravet and Bureau in 1981. The syndrome is characterised by brief myoclonic seizures, spontaneous or provoked by noise or contact, starting between the ages of 4 months and 3 years in otherwise neurodevelopmentally typical children, predominately in boys (Dravet et al. 1992, 2005). Myoclonic seizures are the single presenting seizure type, with the exception of rare simple febrile convulsions. The interictal EEG, including sleep organisation, is normal, and spontaneous spike–wave discharges are rare. Myoclonias are associated with EEG discharges, in the form of fast generalised spike–wave or polyspike–waves greater than 3Hz and of similar duration as the myoclonias.

The course of the epilepsy is benign with a good response to monotherapy with sodium valproate and, when indicated, the association of ethosuximide or a benzodiazepine. Levetiracetam is another possible first option. The active phase of the syndrome is limited to a few months, but in the absence of evidence-based guidelines expert clinicians continue AED treatment for 2–3 years. Global cognitive outcome is less favourable than initially believed (Guerrini et al. 2012; de Bellescize et al. 2015) as mild learning or behavioural difficulties and neurodevelopmental delay may occur.

It is still not clear whether the term ‘benign myoclonic epilepsy’ should be limited to cases exclusively with myoclonic seizures. Aicardi and Levy Gomes (1989) reported 19 young children, mainly boys with a high frequency of familial antecedents of seizures and infrequent tonic–clonic seizures and/or brief absences in addition to frequent myoclonic jerks and a relatively favourable outcome. Such cases suggest the existence of a spectrum of nonlesional, probably genetically determined, myoclonic epilepsies. In some infants, seizures are precipitated by sudden exteroceptive or proprioceptive stimuli. This ‘touch’ or reflex myoclonic epilepsy (Ricci et al. 1995) has an excellent prognosis and treatment may be avoided. Cases like MEI may also occur in older children, and the syndrome is likely to be an early expression of an idiopathic generalised epilepsy, the infantile equivalent of juvenile myoclonic epilepsy.

The genetics of MEI are unknown. Cases are rare and no familial cases of MEI have been described. Arzimanoglou et al. (1996) described a family in which the proband had epilepsy with myoclonic–astatic seizures and his younger brother experienced typical MEI with excellent outcome.

Myoclonic–Astatic Epilepsy (Doose Syndrome)

Myoclonic–astic epilepsy (probably more appropriately epilepsy with predominantly myoclonic–astic or atonic seizures) is perhaps better regarded as a category of generalised nonlesional myoclonic epilepsies rather than a discrete syndrome (Guerrini and Aicardi 2003; Arzimanoglou et al. 2004; Guerrini et al. 2005). The term ‘myoclonic–astic’ was first used by Doose et al. (1970) in a manuscript on ‘centrencephalic myoclonic–astic petit mal’ and further developed in by Doose and Baier (1987) in a paper entitled ‘Genetic factors in epilepsies with primarily generalised minor seizures’. It was initially defined as a form of genetically determined, nonlesional generalised epilepsy, and probably included cases that are now termed severe or benign myoclonic epilepsy as well as cases fulfilling the current concept of myoclonic–astic epilepsy (Guerrini and Aicardi 2003).

Onset is later than for Dravet syndrome, usually between 1 and 5 years of age, and it occurs more often in boys. It is characterised clinically by the predominance of purely myoclonic and/or myoatonic seizures (Fig. 16.8a, b); the seizures may result in falls or produce only a series of head drops and/or sagging at the knees when brief. Other seizure types are often associated, including generalised tonic–clonic seizures, atypical absences and episodes of nonconvulsive status epilepticus. Tonic seizures are unusual but are relatively frequent in some series (Kaminska et al. 1999; Oguni et al. 2001a). The latter authors found them to be present in up to two-thirds of their cases, a finding probably reflecting the nosological uncertainties mentioned above. Astatic seizures (drop attacks) may have different mechanisms (myoclonic, atonic or tonic) that are indistinguishable without polygraphic recording. Tonic seizures may be more frequent in children with an unfavourable outcome, but also occur in almost 30% of cases with a favourable outcome (Kaminska et al. 1999). Differentiating MAE from LGS may be difficult during the early stages of the disorder.

The EEG shows fast (≥3Hz) generalised spike–wave or poly-spike–wave discharges of short duration (usually less than 4–5 seconds). Doose emphasised the presence of bi-parietal theta rhythms.

Genetic factors play an important role and several children with MAE belong to large generalised epilepsy with febrile seizures plus (GEFS+) families with missense mutations of the SCN1A gene. AED-resistant cases should be screened for GLUT-1 deficiency (Mullen et al. 2011).

Remission within a few years with normal cognition occurs in almost 60% of cases (Oguni et al. 2001a; Guerrini et al. 2005). However, at onset, falls are often difficult to control and result in serious injury. In our experience the initial presentation is often ‘stormy’, with repeated drop attacks. However, a severe onset does not necessarily predict a poor outcome. Other patients run an unfavourable course with frequent seizures and learning difficulties (20%) or intellectual disability (20%) but outcome is unpredictable at symptom onset.
Figure 16.8  (a) Atonic seizure. EEG discharge starts with brief burst of fast rhythm, followed by a few spike–wave complexes and by slow waves. EMG trace shows disappearance of normal tonic activity during EEG discharge in posterior cervical muscles (CERV.C.R), sternomastoid (STCM.R) and deltoid (DELT.R) on right side. (Courtesy Dr J Roger, Centre Saint Paul, Marseille; reproduced from 3rd edition.) (b) Atonic seizure. Awakening EEG (150µV/cm) in a 4-year-old girl with atypical rolandic epilepsy demonstrating an atonic seizure after a polyspike. Head drop coincides with the slow wave that follows (8th second) at the moment of muscle atonia. (Courtesy Dept of Paediatric Clinical Epileptology, Sleep Disorders and Functional Neurology, University Hospitals of Lyon, France.)
The effectiveness of AEDs is variable. Sodium valproate is considered a first-line agent and if needed, according to our experience, a combination of sodium valproate and lamotrigine. Ethosuximide, for myoclonic seizures and absences, or benzodiazepines, particularly clobazam, can be effective. Finally, topiramate and levetiracetam or sulthiame are important alternatives. The ketogenic diet is also an effective alternative to medication (Caraballo et al. 2006). Rufinamide and perampanel are under evaluation. Carbamazepine, vigabatrin, oxcarbazepine and gabapentin should be avoided (Arzimanoglou et al. 2004; Guerrini et al. 2005).

FOCAL EPILEPSIES OF INFANCY AND EARLY CHILDHOOD

Focal epilepsies, particularly structural, may begin at any age. Most are discussed in the Seizures and Syndromes of Late Childhood and Adolescence section.

A large proportion of seizures in the first 2 years of life cannot be categorised into a recognised epilepsy syndrome (Korff and Nordli 2006). Most are probably focal disorders although their clinical manifestations may not be localising. Their features include head and eye version or focal tonic contraction, but seizures with generalised vasomotor phenomena or diffuse tonic changes may have a focal origin, as shown on the EEG (Duchowny 1987; Rathgeb et al. 1998; Watanabe et al. 2005). Evaluation of the state of consciousness is obviously very difficult in this age range (Acharya et al. 1997).

Focal seizures are often due to gross brain damage (Chevrie and Aicardi 1977, 1979; Cavazzuti et al. 1984). Duchowny (1987, 1992) reported 14 infants with complex partial seizures due to gross brain damage whose main ictal features were head version and body stiffening, very much like most cases of focal seizures of infancy. Generalised seizures, which are rare in this age group, may have a better outlook in the absence of gross brain pathology (Chevrie and Aicardi 1978). The development of high-definition neuroimaging techniques has facilitated the early detection in infants of small lesions (cortical dysplasias, dysembryoplastic neuroepithelial tumours, gangliogliomas and tuberous sclerosis-related lesions) at the origin of focal seizures, which are often surgically treatable despite young age of the patients. Treatment of lesonal epilepsies is discussed in a later section, as more data are available on epilepsies of late childhood and adolescence. However, it is important to underscore here that focal epilepsy in infancy may be due to identifiable small lesions, as this may influence treatment choices. Whether early surgery might modify overall cognitive outcome is currently under evaluation but as far as seizure outcome is concerned all teams with experience in epilepsy surgery favour early resection whenever feasible (Arzimanoglou et al. 2016c).

Other specific syndromes of focal seizures in infancy have been described. The rare syndrome of partial migratory seizures in infancy with malignant outcome (Coppola et al. 1995; Coppola 2013) or MMPSI was discussed in the section on Malignant Migrating Partial Seizures in Infancy (MMPSI). The syndrome is characterised by very frequent focal seizures of multiple origin and neurological deterioration leading rapidly to death. Although this syndrome has been described as a progressive condition, similar features may be obtained with fixed or progressive encephalopathies with several causes (Ishii et al. 2002).

Self-Limited (Previously Called ‘Benign’) Epilepsy Syndromes of Infancy

Recognition of benign epilepsy syndromes in infants is important, as their prognosis is much better than other types of seizures in this age range. Their frequency is not known and may be variable depending on ethnic origin.

Watanabe et al. (1987) described nine infants with complex focal seizures with a favourable course as benign complex partial epilepsy of infancy. They later described a second group of seven children who developed secondarily generalised seizures with focal onset (Watanabe 1996). More recently, Okumura et al. (2006) reviewed 33 cases and grouped them all as benign partial epilepsy in infancy. Seizures began before age 6 months in 26 cases and were infrequent (average of seven seizures). Seizures occurred in clusters and could be focal with altered consciousness, secondary generalisation or both. Seizures stopped before the age of 18 months in all cases, although a few infants experienced later febrile seizures. Seventeen infants had a family history of seizures. Several syndromes with similar characteristics are reported (see Vigevano and Bureau 2005; Chahine and Mikati 2006; de Bellescize et al. 2015).

Vigevano et al. (1992, 1994b) first described the syndrome of familial benign partial seizures of infants. This syndrome is dominantly inherited and has its onset after the neonatal period. The interictal EEG is usually normal. A few infants demonstrate small-amplitude spikes during sleep suggesting a specific syndrome (Coppola et al. 1995, 2006). Diagnosis rests on a history of similar events in relatives, consistent with an autosomal dominant transmission. In an as yet undefined proportion of cases, choreo-athetotic movements supervene in the same patients several months or years after disappearance of the convulsions (Szepetowski et al. 1997; Swoboda et al. 2000) and respond well to carbamazepine.

Focal infantile convulsions are linked to several chromosomal loci including 19q and 16 but no genes are yet characterised (see Table 16.2). The subgroup of patients with movement disorder are consistently linked to centromeric chromosome 16 (Striano et al. 2006). Berkovic et al. (2004) observed an intermediate form between neonatal and infantile seizures, termed infantile–neonatal convulsions due to a mutation in the gene encoding the voltage-gated sodium channel a2 subunit (SCN2A) on chromosome 2q24 (Heron et al. 2002). Caraballo et al. (2003) studied 64 cases of infantile seizures and found no clinical differences between genetic and apparent non-genetic infantile convulsions. It is unknown...
whether the clinically similar benign syndromes of infantile seizures belong to the same or different entities.

Benign seizures are also recognised in Asian patients and recently in European infants in association with benign diarrhoeal disease (Lee et al. 1993; Komori et al. 1995; Imai et al. 1999).

A syndrome of benign infantile focal epilepsy with midline spike and waves during sleep was first described by Bureau and Maton (1998). Seizures occurred in wakefulness or sleep, with onset characterised by a combination of staring, psychomotor arrest, arm stiffening and loss of consciousness; cyanosis, particularly of the face, was a constant feature in all affected patients. Seizure duration ranged from 1 to 5 minutes. The waking EEG consistently showed no abnormalities, but diphasic spikes of low or medium voltage followed by a bell-shaped slow wave of higher voltage were recorded in sleep. Morphologically, these transients are readily discernible from physiological sleep vertex spikes. Seizures usually cease before age 4 years and treatment is rarely necessary (Capovilla et al. 2006).

### FEBRILE CONVULSIONS

Febrile convulsions are epileptic seizures precipitated by fever that are not due to an intracranial infection or other definable CNS cause and are not preceded by afebrile seizures. Febrile convulsions are the single most common problem in paediatric neurology, with a total incidence of 2–5% in children under age 5 years in Western countries and up to 8% in Japan. Excellent reviews of the topic are available (Nelson and Ellenberg 1981; Wallace 1988; Baram and Shinnar 2002).

#### Aetiology of febrile convulsions

Genetic factors are important in the causation of febrile convulsions, and there is a high incidence of a family history of febrile convulsions varying between 17% and 31% in first-degree relatives. Most studies suggest a polygenic mode of transmission (Rich et al. 1987). An autosomal dominant pattern, however, may be at play in probands with three or more episodes and in some families with multiple affected members and a tendency to long-lasting seizures (see also discussion below on GEFS+).

The genes responsible for febrile convulsions are probably distinct from those causing afebrile seizures (see Table 16.2). Only a small proportion of children with febrile convulsions have a first-degree relative with epilepsy (Berg et al. 1992). Febrile seizures may precede some forms of epilepsy such as childhood absence epilepsy, rolandic epilepsy and LGS.

Rarely, early-onset febrile seizures are associated with de novo PRRT2 mutations which encode the proline-rich transmembrane protein 2 gene. Febrile seizure episodes are best characterised as benign familial infantile epilepsy (BFIE) with febrile seizure onset typically beginning at about 6 months of age. As the seizures in BFIE may consist of simple febrile episodes (Schieffer et al. 2012) they are often difficult to distinguish from febrile seizures due to other aetiologies.

The fever associated with febrile seizures is usually high (>38.5°C) and has the same causes as other fevers in this age group, including immunisations (Millichap and Millichap 2006). One exception may be exanthema subitum, which is associated with a higher incidence of seizures, varying between 8% and 13% (Asano et al. 1994). Gastroenteritis, on the other hand, is a relatively rare cause for the degree of temperature (Berg et al. 1995). Seizures usually occur early in the course of a fever and are actually the first symptom in 25–42% of cases. An earlier onset is noted in girls (Wallace 1988).

Prenatal and perinatal factors do not play an important role in causation (Nelson and Ellenberg 1990), even though they may adversely influence the prognosis with regard to later afebrile seizures. Some delay in passing early milestones may be slightly more frequent than in the general population (Wallace 1988). The only predictors of febrile convulsions are a fever >40.5°C and a family history of febrile seizures (Bethune et al. 1993; Berg et al. 1995).

The incidence of seizures after diphtheria-pertussis-tetanus vaccination has decreased with the abandonment of whole-cell vaccines in favour of acellular vaccines which are less reactogenic. Febrile seizures that occur within 48 hours of immunisation are not clinically distinct from febrile seizures due to other causes. However, patients with Dravet syndrome are particularly vulnerable to immunisation-induced febrile seizures which are described in up to one-third of cases (Cendes and Sanker 2012). Vaccination-induced seizures in patients with Dravet syndrome do not significantly affect the subsequent clinical or cognitive evolution (Zamponi et al. 2013).

#### Clinical and EEG features of febrile convulsions

The great majority of febrile convulsions are brief, bilateral clonic or tonic–clonic seizures. Unilateral seizures occur in about 4% of patients. These are often prolonged seizures lasting 30 minutes or more (Nelson and Ellenberg 1981). Seizures lasting more than 15 minutes, unilateral seizures, and those followed by a Todd paralysis are termed complex febrile convulsions and have a higher risk (up to 50%) of being followed by epilepsy. However, most cases of epilepsy subsequent to febrile convulsions occur after brief (so-called simple) febrile convulsions, just because these are overwhelmingly frequent and despite their lower attendant risk of epilepsy (about 1%).

Febrile convulsions lasting 30 minutes or more are one type of status epilepticus and may cause sequela if untreated (Aicardi and Chevrie 1976; Viani et al. 1987; Phillips and Shanahan 1989). These include the hemiconvulsion–hemiplegia–epilepsy syndrome (Arzimanoglou and Dravet...
The role of long-lasting febrile convulsions in the genesis of focal epilepsy, especially the syndrome of mesial temporal epilepsy with hippocampal sclerosis, remains disputed. MRI studies have shown evidence of acute swelling of the hippocampus in the days following a long febrile convulsion (VanLandingham et al. 1998; Scott et al. 2003). The later development of hippocampal atrophy and sclerosis in patients with intractable temporal lobe epilepsy and a history of prolonged febrile seizures (Kuks et al. 1993; Holthausen 1994; Harvey et al. 1995; Cendes et al. 2005) are strong arguments in favour of a causal relationship in many cases. Thus, vigorous treatment of febrile status is imperative, as shown by the persistence of sequelae in areas where emergency treatment is not available and febrile seizures are allowed to go untreated for hours.

Compared to children with simple febrile seizures, febrile status epilepticus is associated with younger age, lower temperature, longer duration of recognised temperature before the seizure, female sex, structural temporal lobe abnormality and first-degree family members with a history of febrile seizures (Hesdorffer et al. 2013). These diverse features suggest that children with febrile status epilepticus are predisposed by a combination of factors.

Most cases of prolonged febrile convulsions occur during the first 18 months of life and especially before the age of 12 or 13 months. After 2 years of age, the risk of status epilepticus decreases (Aicardi and Chevrie 1983; Arzimanoglou et al. 2004). The role of developmental malformations in the aetiology of temporal lobe seizures following febrile convulsions may also be considered, either as explaining the whole sequence of the febrile seizures that are followed by unprovoked seizures or as a factor determining the localisation and severity of the febrile convulsions. The latter would then constitute a ‘second hit’ in the full sequence leading to hippocampal sclerosis.

EEG tracings recorded within a week of a febrile convolution are abnormally slow for a few days in approximately one-third of patients. Epileptiform discharges occur in one-third of children with febrile convulsions followed prospectively whether in the form of rolandic spike foci or bilateral spike–wave bursts (Kajitani et al. 1981; Sofijanov et al. 1992). However, the real figures may be lower because hypnagogic bursts, frequent in this age bracket, may be misdiagnosed as actual paroxysms. Such abnormalities are poorly correlated with the later occurrence of epilepsy (Sofijanov et al. 1992). In particular, they are exceptional in children below 18 months of age who are particularly at risk of recurrence of the development of febrile seizures (Viani et al. 1987), whereas they occur in up to 50% of 4-year-olds who are at much lower risk. Therefore, EEG recording is not indicated in the management of febrile convulsions.

The clinical features of febrile status epilepticus are being studied in greater detail in a large prospective multicentre prospective study examining the consequences of prolonged febrile seizures lasting at least 30 minutes in children ages 1 month to 5 years (FEBSTAT) (Shinnar et al. 2008; Hesdorffer et al. 2012). In this population, febrile status epilepticus was often the initial presentation and was continuous in 52% and behaviourally intermittent in 48%. Mean febrile seizure duration was 68 minutes (range 1–24 hours) with 24% of affected individuals experiencing seizures lasting more than 2 hours. Almost all cases (99%) were convulsive and were focal in approximately half. Somewhat disconcerting was the recognition that a third of all cases went unrecognised in emergency departments.

EEGs in the FEBSTAT cohort recorded within 72 hours of the status revealed high rates of focal slowing or background attenuation. These EEG changes were highly correlated with subsequent MRI revealing hippocampal damage (Nordli et al. 2012). This association suggests that the EEG abnormalities that appear early in the course of febrile status epilepticus may serve as markers of structural alteration.

The FEBSTAT trial and two affiliated studies further examined a cohort of 226 children with febrile status epilepticus to determine its role in the evolution of hippocampal injury (Lewis et al. 2013). All participants were studied with acute MRI and follow-up MRI at 1 year. Acute hippocampal T2 signal hyperintensity changes that were maximal in Sommer’s sector were associated with increased hippocampal volume indicative of oedema in 22 children. Follow-up MRI in 14 of the 22 children with acute changes revealed hippocampal sclerosis in ten and reduced hippocampal volume in 12. In contrast, only one of 116 children without acute changes evidenced abnormal T2 signal. Even participants with normal acute studies were prone to smaller hippocampal volumes and reduced hippocampal growth. This would suggest a subtler injury that is MRI negative (Lewis et al. 2014).

Given the association of febrile seizures and later hippocampal sclerosis, and the relationship of the SCN1A mutation to febrile seizures, Kasperaviciute et al. (2013) performed a genome-wide association study of a large cohort of individuals with mesial temporal lobe epilepsy and hippocampal sclerosis with and without a history of febrile seizures. Meta-analysis revealed a significant genetic association of mesial temporal lobe epilepsy and hippocampal sclerosis with febrile seizures at the sodium channel gene cluster on chromosome 2q24.3, within an intron of the SCN1A gene. These findings provide further understanding of a biological predisposition in this clinical setting.

Histopathological studies of temporal lobe tissue removed at epilepsy surgery reveal an unexpectedly high incidence of the HHV6B virus replication in hippocampal astrocytes (Theodore et al. 2008). This agent is commonly associated with roseola infantum but may reactivate to cause limbic encephalitis in immunologically compromised patients. As HHV6B viral infection could play an important role linking early viral infection, febrile status epilepticus and hippocampal sclerosis, serum has recently been screened for this agent in patients with febrile status epilepticus. The HHV6B virus was identified in one-third of specimens (Epstein et al. 2012). In contrast,
HHV7 virus occurs much less commonly (Epstein et al. 2012). No child diagnosed with herpesvirus viremia had evidence of cerebrospinal fluid (CSF) involvement.

**Differential diagnosis in febrile convulsions**

The differential diagnosis of febrile convulsions includes primarily seizures with infections of the CNS (meningitis and encephalitis). In CNS infections, there is almost always an abnormal CSF. Green et al. (1993) found that none of 115 children with convulsions associated with meningitis had occult disease. However, such cases are known to occur (Heijbel et al. 1980), so lumbar puncture is advised in children under age 18 months and especially under 6 months of age. Lumbar puncture is also indicated in children with long-lasting or otherwise atypical convulsions and in those who fail to recover full consciousness promptly.

Herpes encephalitis in infants often manifests itself initially with febrile focal seizures and may pose an important clinical problem. Puchhammer-Stöckl et al. (1993) reported on 257 patients with suspected herpes simplex virus encephalitis prospectively analysed by herpes simplex virus polymerase chain reaction (PCR). The PCR indicated herpes simplex virus encephalitis in nine serologically proven cases and in 14 additional patients. Increased PCR signals were observed together with more severe neurological symptoms ($P < 0.01$) and within the first days of acyclovir treatment ($P < 0.05$). In such cases, MRI can be of considerable value by showing signal alterations in a localised or multifocal distribution.

Differentiating acute convulsive encephalopathies from febrile seizures may be difficult if the CSF is normal. Indeed, the distinction is sometimes made only a posteriori, cases with sequelae not being regarded as febrile convulsions. However, cases of febrile convulsions with sequelae do exist and are important in assessing the prognosis of febrile seizures. Likewise, it is very difficult to separate febrile seizures from ‘true’ epileptic seizures precipitated by fever as there is a large overlap between these categories. Dravet syndrome starting with prolonged unilateral febrile seizures may be difficult to diagnose early. Repetition of long-lasting seizures within a short period (<2 months) is suggestive. Nonepileptic paroxysmal events are frequent in febrile children and include febrile syncope (‘anoxic seizures’) (Stephenson 1990); febrile delirium and rigors can also be mistaken for febrile convulsions.

**Prognosis of febrile convulsions**

The prognosis of febrile convulsions is generally extremely favourable. Approximately 60–70% of children have only one episode of febrile convulsions and most of the remaining will have two or three seizures. Only 9% of patients experience more than three episodes. Three-quarters of the recurrences take place during the year following the first seizure, and the risk of severe recurrence is quite low (Nelson and Ellenberg 1981; Annegers et al. 1990; Van Esch et al. 1996). The risk of recurrence is greater in children with seizures in the first 2 hours of fever or with a temperature below 40°C, those with a family history of febrile or afebrile seizures, children under 1 year of age and patients with two or more episodes. Complex febrile seizures are also a predictor of a higher risk of recurrence (Offringa et al. 1994; Baram and Shinnar 2002).

The risk of developing afebrile seizures is approximately 2–5%. It is lower in children with simple seizures after age 1 year but increases at a younger age. The presence of previous developmental or neurological abnormality, a family history of epilepsy, and complex febrile convulsions (Verity et al. 1993) all increase the risk of developing afebrile seizures, which reaches up to 50% when all three factors are present (Annegers et al. 1990).

The majority of epilepsies following febrile convulsions are nonlesional generalised epilepsies with tonic-clonic seizures, often with only a few seizures (Wallace 1991; Camfield et al. 1994). Such cases mainly follow brief, uncomplicated febrile convulsions (Aicardi and Chevrie 1976) and are relatively common. Afebrile seizures are mostly frequent and generally tend to disappear by age 9–10 years (Arzimanoglou et al. 2004).

Focal epilepsy may occur after long-lasting unilateral seizures (Aicardi and Chevrie 1976, 1983), although their exact frequency is unclear. Whether afebrile seizures are a direct consequence of febrile convulsions is debated, but the fact that such seizures are observed following febrile convulsions is well established.

The neurodevelopmental prognosis of febrile convulsions is excellent, except in patients who develop epilepsy, some of whom develop learning difficulties. This illustrates the tendency of complications to occur in association and is often the case with accidental prolongation of an episode of febrile convulsions. Some affected children may have had a previous subclinical brain lesion before the febrile seizure with the result that it was long-lasting and localised. This is in agreement with the relatively high incidence of abnormal pre- and perinatal history found in several studies (Chevrie and Aicardi 1975; Wallace 1988).

**Treatment of febrile convulsions**

Brief febrile convulsions do not require treatment apart from the causative febrile illness (Baram and Shinnar 2002). Simple measures such as removal of excess blankets and physical cooling are usually recommended. However, there is no evidence that antipyretic agents are effective in the prevention of febrile convulsions (Uhari et al. 1995). Hospitalisation is unnecessary for uncomplicated febrile convulsions if adequate surveillance is possible. In case of doubt, a 12-hour hospitalisation is sufficient. Long-lasting episodes should be treated vigorously (see Table 16.14 in the section on treatment of status epilepticus) to avoid the later emergence of epilepsy and its sequelae, especially for seizures before age 1 year. Parents and caregivers should be instructed on how to rapidly administer rectal diazepam (at a dose of 0.5–1mg/kg) or buccal or nasal midazolam for acute febrile episodes lasting more
than 2–3 minutes (McIntyre et al. 2005; Wait et al. 2013; Cross et al. 2013).

Continuous prophylactic treatment of recurrences is not generally advised (Consensus Developmental Panel 1980) but may be indicated when factors of high risk are present. Our own practice is to treat systematically infants below 1 year of age; treatment for patients with complex febrile seizures may be indicated, although there is no proof that it prevents the occurrence of later epilepsy (Nelson and Ellenberg 1981; Shinnar and Berg 1996). The balance of risks and advantages is generally against prophylactic therapy. The American Academy of Pediatrics Practice Parameter Committee reached a similar conclusion and stated that the potential toxicity associated with antiepileptic therapy outweighs the relatively minor risks associated with simple febrile seizures. Thus, long-term treatment is not recommended (Baumann and Duffner 2000). Phenobarbitone (30–40mg/kg/day) that reaches a blood level of around 15µg/mL is reasonably safe, although concern has been expressed about the effects of the drug on IQ levels (Farwell et al. 1990) and for this reason it has largely been abandoned. Sodium valproate reduces the recurrence rate to a similar extent (Wallace 1988), provided an underlying metabolic disorder is excluded. More recently developed AEDs, particularly levetiracetam for which PK data in very young children is available (Arzimanoglou et al. 2016b), are reasonable alternatives.

Intermittent prophylaxis with oral diazepam was reported effective provided large enough doses are used (0.5mg/kg t.i.d.) (Aurent et al. 1990; Rosman et al. 1993; Knudsen 1996). However, efficacy is limited by the early occurrence of seizures, which may be the first symptom of fever – as was the case in 25% of patients in the series reported by Wolf et al. (1977). Knudsen et al. (1996) reported on a cohort of 289 children with febrile convulsions who had been randomised in early childhood to either intermittent prophylaxis (diazepam at fever) or no prophylaxis (diazepam at seizures) and followed up 12 years later. Children with simple and complex febrile convulsions had the same benign outcome. The long-term prognosis in terms of subsequent epilepsy and neurological, motor, intellectual, cognitive and scholastic ability was not influenced by the type of treatment applied in early childhood. They concluded that it was ‘as good to interrupt as to prevent’ a febrile seizure and thought that prophylactic treatment at the time of fever should be reserved for special cases. Intermittent treatment of fever with acetaminophen alone (Bethune et al. 1993) or combined with low-dose diazepam (Uhari et al. 1995) is not effective. A larger availability of easier to administer rescue formulations, such as buccal or nasal midazolam, will further reduce the indications for the prescription of intermittent prophylaxis.

Recent recommendations for treatment of febrile seizures by the Italian League Against Epilepsy have reaffirmed these principles (Capovilla et al. 2009). Prophylactic therapy was not recommended for simple febrile seizures while rectal or buccal benzodiazepines are indicated for acute seizure termination.

Convulsive febrile status epilepticus is a medical emergency. Treatment should be offered within 2 minutes of seizure onset (or earlier) with either intravenous diazepam or lorazepam if possible (Neville et al. 2007). Home treatment with rectal diazepam or buccal midazolam are also effective in the majority of cases. More than two doses of benzodiazepines or the co-administration of barbiturates should be discouraged as there is a significant possibility of respiratory depression.

**Generalised Epilepsy with Febrile Seizures Plus**

The term ‘generalised epilepsy with febrile seizures plus’ was first used by Scheffer and Berkovic (1997) to describe ‘a genetic disorder with heterogeneous clinical phenotypes’. The description was based on the recognition that in one large Anglo-Australian extended family, febrile seizures, often of unusual duration or severity, and febrile generalised seizures of various types appeared to be transmitted as a dominant genetic trait. Simple febrile seizures constituted the most common manifestation. However, they often occurred beyond the usual upper limit of 6 years, and the term ‘febrile seizures plus’ was proposed for children with febrile seizures persisting after the age of 6 years.

About seizures, mainly generalised tonic–clonic ones, but in some cases, myoclonic seizures myoclonic–astatic seizures or even episodes of status epilepticus occurred in some pedigree members. The pattern of inheritance was autosomal dominant. Although GEFS+ is named after the occurrence of generalised tonic–clonic seizures, these are not the only type of seizures that are observed. Indeed, in some individual cases, such seizures may be absent altogether. More often they are associated with other seizure types. The very term of ‘syndrome’ may not be appropriate to designate the condition as it is not characterised by the ‘non-foothuitous association of signs and symptoms in one individual patient but by its genetic nature indicated by the familial occurrence and by the demonstration of the same genes in affected persons of GEFS+ families in some cases’ (Arzimanoglou 2007).

Other authors reported that patients within the GEFS+ spectrum may present with focal seizures like temporal lobe epilepsy (Abou-Khalil et al. 2001) that is variably associated with hippocampal sclerosis. The fact that GEFS+ is linked to mutations in genes coding for sodium channels and GABA-A receptors suggested that this ‘genetic syndrome’ belongs to the ‘channelopathies’. The mechanism for the phenotypic variability in GEFS+ families is uncertain.

A locus for the GEFS+ spectrum was mapped to chromosome 19q13, where the voltage-gated sodium channel 1 subunit gene (SCN1B) has been assigned. A second mutation in SCN1A, which encodes for the alpha-1 subunit of the same sodium channel, with linkage to chromosome 2q24–33, was found in patients with a similar clinical picture. Claes et al. (2001) found different mutations of this gene in seven children with Dravet syndrome (see Dravet Syndrome section). The GABA-A receptor gamma-2 subunit gene, GABRG2
is also involved in the pathogenesis of GEFS+, confirming locus heterogeneity for this spectrum of epilepsy phenotypes (Bananni et al. 2004; for a review see also Baulac et al. 2004). Duplication of 17q12 has also been described in families with GEFS+ (Hardies et al. 2013). Although some affected family members present with intellectual disability, seizures were the only clinical symptom in others.

Guidelines for ordering genetic screening for the SCN1A mutation have been proposed (Hirose et al. 2013). Testing is highly recommended in infants suspected of Dravet syndrome or other early-onset infantile epileptic encephalopathies, and in normal infants with recurrent febrile or afebrile, prolonged hemiconic or generalised status epilepticus. In contrast, the utility of SCN1A screening for phenotypes that are not clearly associated with GEFS+ is not recommended. As negative screening does not detect variations in introns or promoter or regulatory regions, a negative test should not exclude a pathogenic role of SCN1A or exclude the possible diagnosis of Dravet syndrome.

Febrile Infection-Related Epilepsy Syndrome (FIRES)

Febrile infection-related epilepsy syndrome (FIRES) was described in typically developing children with a catastrophic onset illness mimicking infectious encephalitis. Affected patients are typically school-age and experience a nonspecific febrile illness followed by altered cognitive status and seizures that rapidly evolve to focal status epilepticus that is refractory to AEDs and immunotherapy, and requires management in an intensive care setting (Kramer et al. 2011). FIRES has been reported under a variety of descriptive titles including devastating encephalopathy in school-age children (DESC) (Mikaeloff et al. 2006), acute encephalitis with refractory repetitive partial seizures (AERRPS) (Sakuma et al. 2010) and fever-induced epileptic encephalopathy of school-age children (Nabbout et al. 2011).

The occurrence of fever and mild CSF pleocytosis in some patients has suggested an infectious or immune-mediated aetiology but no organism or autoimmune dysregulation has been identified. Histological examination of biopsied or autopsied brain tissue has not revealed any inflammatory changes. A protracted intensive care course is the rule. Attempts to control the status epilepticus are often unsuccessful despite heroic measures with intravenous and anaesthetic anti-seizure agents. Gradually, the clinical course evolves into a state of chronic focal or multifocal epilepsy accompanied by neurocognitive and behavioural disturbance.

Howell et al. (2012) reported on the long-term follow-up of seven children with FIRES who had a median age at presentation of 10.8 years (range 6.7–14 years). All were developmentally normal and presented with fever, headache, confusion and lethargy. The onset of their epilepsy was uniformly explosive and characterised by multiple hourly seizures in all cases. Ictal semiology consisted of head version, facial twitching, hemi-clonic jerking that variably progressed to bilateral clonic jerking. Electrographic seizure onset typically localised to the temporal lobes with secondary hemispheric or bilateral spread. MRI obtained early in the course was generally unremarkable although generalised cerebral oedema was noted in one child. All six children who survived evolved to chronic epilepsy. Frequent medically refractory seizures occurred in all patients and ictal semiologies closely followed the initial presentations. Their EEGs uniformly demonstrated rhythmic or polymorphous delta activity in the frontal and temporal regions.

Seizures and Syndromes of Late Childhood and Adolescence

Several of the epilepsy syndromes of infants and young children may persist or have their onset later in life, and there is no definitive separation between age groups. They can manifest with generalised (absences, myoclonic, tonic–clonic seizures) or focal seizures. Focal non-idiopathic (structural) epilepsies having presented earlier in life with just a few, easily controlled seizures may present later with recurrence of seizures or an increase in frequency.

Most epilepsy syndromes of later childhood and adolescence are unassociated with gross brain damage, and genetic factors probably play a prominent role. As a result, affected children are usually normal both cognitively and neurologically, and prognosis is generally better than for early-onset epilepsies where brain lesions are common.

Syndromes of Late Childhood and Adolescence with Predominantly Typical Absences

The International Classification recognises two varieties of absences: typical and atypical. To avoid confusion when discussing seizure phenomenology, Lüders et al. (1999) suggested the term dialeptic seizures, underscoring the fact that a further distinction between typical and atypical absences can be made only when EEG findings or a more precise syndromic diagnosis become available. The term, although correct from a semantic point of view, was not really adopted from the epileptological community.

Typical absences are a well-defined seizure type with a characteristic EEG correlate. They are characterised clinically by the sudden suppression or marked decrease of consciousness, with abolition of awareness, responsiveness and memory function (Hirsch and Panayiotopoulos 2005). They can be simple or complex. Simple typical absences last 5–15 seconds in 90% of cases (Penry et al. 1975) and usually do not involve motor phenomena, except for possible mild jerking of eyelids and minor changes in muscle tone. The onset and termination of a typical absence are relatively abrupt: this is of value to differentiate absences from focal seizures with alteration of consciousness and minimal motor symptoms. The
same also applies to the lack of a postictal phase of impaired awareness and/or fatigue (Penry et al. 1975). In complex typical absences, more marked motor components (increased or decreased muscle tone), simple automatisms (Penry et al. 1975) and autonomic phenomena accompany the loss of consciousness and the duration of the attack is often longer. As discussed below, the degree of consciousness impairment is variable depending on the epilepsy syndrome of which the typical absences are a part (Panayiotopoulos et al. 1989).

The EEG in typical absences, whether simple or complex, shows rhythmical bursts of spike–wave complexes at a rhythm of 2.5–3.5Hz that are bilateral, synchronous and symmetrical with abrupt onset and termination (Fig. 16.9). Less rhythmical discharges may occur, especially during sleep, and some degree of asymmetry is present in 9% of cases (Loiseau et al. 2002). EEG variants are observed in some absence syndromes (Panayiotopoulos et al. 1989; Hirsch and Panayiotopoulos 2005). The interictal records are often normal, but brief bursts of irregular spike–wave complexes are seen in 30% of patients. Posterior 3Hz slow waves occur in 10–20% of children with typical absences.

Hyperventilation is highly effective in precipitating typical absences and can be performed safely in the clinic in patients who do not manifest signs of cerebrovascular disorder (to be avoided in the presence of moyamoya disease). In an untreated child, a negative test makes the diagnosis of absences unlikely. About 10–20% of children with absences respond to light stimulation which is a risk factor for ‘grand mal’ seizures. Absences should be distinguished from inattention and day-dreaming, tics, abnormal head movements and stereotypies. Distinction from focal seizures with impaired awareness may sometimes be difficult, although typical absences are usually much more frequent (the term ‘pyknolepsy’, signifying ‘dense in frequency’ was also used). The brief duration of episodes, their frequent repetition and the lack of a postictal phase are all important features, but an EEG with ictal recording is necessary for a definitive diagnosis. Differentiation from atypical absences rests on the different history, often with other seizure types besides absences and the EEG findings. Atypical absences occur mainly in LGS and some forms of polymorphic epilepsy. Absences due to frontal lobe damage result from post-traumatic atrophy or tumours (Ferrie et al. 1995).

The occurrence of typical absences as the predominant or exclusive type of seizure is the hallmark of absence epilepsy. Several syndromes of absence epilepsy are recognised. These include absence epilepsy of childhood, absence epilepsy of adolescence, absences in juvenile myoclonic epilepsy, myoclonic or clonic absences and some rarer syndromes (Panayiotopoulos 1998, 2002).

**Childhood Absence Epilepsy (CAE)**

Childhood absence epilepsy (CAE), also called pyknolepsy or (incorrectly) *petit mal*, has its onset between the ages of 3 and 8 years, although rare cases are described as early as the first year of life (Aicardi 1995; Chaix et al. 2003). It is more common in girls than in boys. The absences occur many times daily and constitute the first manifestation of epilepsy, although febrile convulsions may have occurred in infancy. Affected children are normal between episodes of the interictal EEG, is also normal although brief bursts of spike–wave complexes without clinical absence may be recorded. The absences do not include prominent clonic or atonic
phenomena but simple automatisms and complex absences are common (Loiseau and Duché 1995; Loiseau et al. 2002). The loss of awareness is marked, and the eyes open during the discharge (Panayiotopoulos 1994b, 1998). In typical cases neuroimaging is not indicated as there is no appreciable brain pathology; a family history of seizures is relatively frequent. The occurrence of several cases of absence epilepsy in the same lineage is not rare (Loiseau and Duché 1995) and polygenic inheritance appears likely.

Treatment with sodium valproate, ethosuximide or lamotrigin is usually effective (Arzimanoglou et al. 2004; Hirsch and Panayiotopoulos 2005). Glauser and colleagues have undertaken an important multicentre, randomised, double-blind trial in 453 children with newly diagnosed childhood absence epilepsy (Glauser et al. 2010). Lamotrigin, the only second-generation drug approved for the treatment of absence seizures, was included for comparison. At the final assessment after 16–20 weeks of treatment (children eligible for a final dose increase at week 16 were followed up for 4 additional weeks), valproate and ethosuximide were similarly effective, but valproate caused greater attentional dysfunction as determined by the Conners’ continuous performance test than the other drugs. Because of this association and because lamotrigin monotherapy had a lower success rate (29% free from treatment failure) than ethosuximide (53%) and valproate (58%), the authors concluded that ‘ethosuximide is the optimal initial empirical monotherapy for childhood absence epilepsy’.

When drugs have equivalent efficacy, comparative side effect profiles become paramount in making treatment decisions, which is why the results of the Glauser et al. study (2010) are likely to affect current practice. In their study, less than 15% of children randomly assigned to ethosuximide or valproate had treatment failure because of poor seizure control, but intolerable adverse effects occurred in 24% of children assigned to each of these drugs. Thus, the only reason for preferring ethosuximide to valproate is the reported greater occurrence of neuropsychological impairment with valproate. Attentional difficulties occurred at baseline with a higher frequency in the valproate cohort (42%) than in the ethosuximide (34%) or lamotrigin (30%) cohorts. Undoubtedly this very well-designed study has many merits and long-term follow-up of the cohort is ongoing. When considering the results, the reader should, however, also take into account that in children with uncontrolled seizures, drug dose should be increased according to tolerability up to a maximum dose, which was 60mg/kg per day for valproate (Arzimanoglou et al. 2010). In several European countries, the highest recommended dose of valproate is 30mg/kg per day, and it is possible that a lower ceiling dose might improve tolerability without compromising efficacy. Older children who are approaching an age consistent with juvenile absence epilepsy (see Juvenile Absence Epilepsy section) have an increased risk of generalised tonic–clonic seizures that are suppressed by valproate but not ethosuximide.

For refractory cases, the combination of two drugs may be effective. In our practice, we often administer lamotrigin with low-dose valproate. In some resistant cases, benzodiazepines (especially clobazam) may control otherwise intractable seizures. Similar results were reported with sulthiame (Gorman and Shahwan 2016). Typical absence seizures do not respond to many AEDs including carbamazepine, oxcarbazepine, vigabatrin, gabapentin and phenytoin, which in some cases may increase seizure frequency or facilitate the occurrence of myoclonias.

The outlook of CAE is favourable. However, absences can persist into adulthood in a small proportion of cases, and generalised convulsions develop in about 10–30% of patients followed into adulthood although they are infrequent and easily treatable (Loiseau et al. 1983). Wirrell et al. (1996) showed that only 65% of children presenting with CAE had remission of their epilepsy. Forty-four per cent of those without remission had developed juvenile myoclonic epilepsy (JME). At the time of diagnosis, remission is difficult to predict accurately in most patients. Development of generalised tonic–clonic or myoclonic seizures during AED treatment was ominous, predicting both lack of remission of CAE and progression to JME. Trinka et al. (2004) reported a similar experience. The educational achievements are often less than optimal. The socio-professional outlook for CAE is less favourable than that of rolandic epilepsy, and affected individuals often fare less well than their cognitive level would normally allow (Loiseau et al. 1983).

**Juvenile Absence Epilepsy (JAE)**

Juvenile absence epilepsy (JAE) occurs in patients presenting beyond the age of 9–10 years, although the borderline between childhood and juvenile types is incompletely demarcated. Absences in adolescents are usually less frequent than in children and often cluster in the hour following awakening. Loss of consciousness is less complete than in childhood absence epilepsy (Panayiotopoulos 1994b, 1998), and in some cases the absences are hardly detectable even by the patient.

Other types of seizures, especially generalised tonic–clonic seizures, occur in 90% of cases, and myoclonic seizures may also be present. In the latter cases the absences may be especially mild and often produce only subclinical discharges. The EEG of juvenile absences is either identical to childhood absence epilepsy (Panayiotopoulos 1994b, 1998), and in some cases the absences are hardly detectable even by the patient.

Typical absences also occur in juvenile myoclonic epilepsy where they may precede the appearance of other seizure types (Martinez-Juarez et al. 2006). Such cases might be a subgroup of JME and might be responsible for some cases of absences that evolve into medically resistant adult epilepsy (Panayiotopoulos 2002).

Juvenile absences, generalised tonic–clonic seizures on awakening and JME, often present as a triad of idiopathic (genetic) generalised epilepsy of adolescence. The associated tonic–clonic seizures and sometimes absences often persist into adulthood.
Treatment choices are similar to CAE. However, ethosuximide is unsuitable as a monotherapy as it may control absence seizures but not convulsions. Treatment must be prolonged particularly for female patients. Issues related to contraception and/or future pregnancy must be considered when first choosing antiepileptic drug therapy (see section AEDs and Pregnancy Related Issues).

Other Syndromes Featuring Typical Absences

The rare syndrome of epilepsy with myoclonic absences (clonic absences) is characterised by a specific seizure type, the myoclonic absences (Bureau and Tassinari 2005). Clinically, the intensity of the clonic jerking that affects the upper and often the lower limbs is distinctive. The EEG expression is non-specific with bilateral rhythmic spike–wave discharge at 3Hz similar to cases of typical absences. Rare onset occurs during the first year of life but mean age at onset is 7 years; the course is variable. Some cases develop intellectual disability and may evolve to LGS while others respond promptly to treatment and have a benign course (Manonmani and Wallace 1994; Bureau and Tassinari 2005). Some children develop tonic seizures. The classic treatment combines sodium valproate with ethosuximide or lamotrigine. Benzodiazepines may also be useful.

Other less well-defined syndromes include cases of absences preceded by generalised tonic–clonic seizures other than febrile convulsions (Dieterich et al. 1985) that generally have an unfavourable outcome, eyelid myoclonia with absences (Jeavons syndrome) which is essentially a form of myoclonic epilepsy (see Juvenile Myoclonic Epilepsy section), and perioral myoclonia with absences, which may prove drug resistant. The individualisation of some of these syndromes is unclear (Arzimanoglou et al. 2004). Very slight absences, often unrecognised even by the patient and sometimes revealed only by associated rare tonic–clonic seizures, have been termed phantom absences (Panayiotopoulos 2002).

Absences associated with brain injury are rare (Ferrie et al. 1995) but may occur with either diffuse lesions or focal damage, especially to the mediodorsal frontal lobe. A focal component (clinical and/or EEG) may be present. In most cases the association is probably coincidental.

The genetics of epilepsies featuring typical absences (see Table 16.2) are imperfectly understood. Typical CAE appears to be genetically unrelated to JME, and linkage to chromosome 6p has been excluded. Photosensitive cases seem to be genetically distinct, often with a dominant inheritance, and some may be genetically related to JME (Bianchi et al. 1995). Rare cases of absences linked to definite mutations are on record (Hirose et al. 2005; Ito et al. 2005).

SYNDROMES OF LATE CHILDHOOD AND ADOLESCENCE WITH PREDOMINANTLY GENERALISED TONIC-CLONIC SEIZURES

Generalised tonic–clonic seizures (or bilateral tonic–clonic seizures) may be generalised from the start and are often a manifestation of idiopathic (genetic) epilepsy. They may also represent the secondary generalisation of a focal seizure that is traditionally termed the ‘aura’ of the generalised attack. These two types may be difficult to separate clinically, although their aetiological significance is different (Arzimanoglou et al. 2004; Hirsch et al. 2006a).

Primary generalised tonic–clonic seizures comprise a stereotyped succession of events, beginning with a tonic contraction of the entire musculature with respiratory blockade resulting in cyanosis and loss of consciousness. After 10–30 seconds, the tonic phase gives way to clonic jerks that progressively slow and become increasingly violent. Muscular relaxation occurs after 30–60 seconds. The patient remains unconscious for variable durations. Tongue biting and urinary or, rarely, double incontinence are frequent but nonspecific as they also occur with nonepileptic seizures (Stephenson 1990).

Generalised tonic–clonic seizures are characterised by the succession of a fast (≥10Hz) rhythm of increasing amplitude that becomes fragmented during the clonic phase, evolving to single spike–wave complexes. An electrodecremental response follows the clonic phase but is rapidly replaced by slow waves that progressively decrease merges with interictal tracing. The EEG may show generalised spike–wave complexes, sometimes with a positive response to photic stimulation. Lateralising manifestations including versive movement or circling may occur in patients with typical bilateral paroxysms (Gastaut et al. 1986; Lancman et al. 1994). Although relatively straightforward to diagnose, some idiopathic generalised seizures exhibit focal features that create diagnostic problems (Ferrie 2005) and some symptomatic epilepsies (Oguni 2005).

Secondarily generalised tonic–clonic seizures present in two ways (Theodore et al. 1994). In some cases, the initial focal seizure manifests clinically with localised motor, sensory or other phenomena. In others, the seizure is generalised at onset while the ictal EEG reveals an initial, clinically silent focal discharge. When ictal records are unavailable, the presence of a stable interictal spike focus – present in 20–40% of patients with tonic–clonic seizures (Arzimanoglou et al. 2004) – provides indirect evidence for secondarily generalised seizures. Such seizures are usually the expression of a localised brain lesion but may also occur with nonlesional epilepsies.

Syndromes with secondarily generalised seizures will be discussed in detail in the section on focal epilepsies.

Atypical tonic–clonic seizures are very common in childhood: the clonic phase may be extremely brief and EEG activity is not always synchronous or symmetrical. In some children, the tonic phase is too brief to be noted. Generalised tonic–clonic seizures occur in several epilepsy syndromes and are, therefore, non-diagnostic. Indeed, when they occur in association with other seizures in the same patient, the latter are considered more characteristic. For example, in this age range, their association of typical absences suggests the diagnosis of juvenile absence epilepsy (see Juvenile Absence Epilepsy section), while the absence of myoclonic jerks suggests juvenile myoclonic epilepsy (see Juvenile Myoclonic Epilepsy section).
Epilepsy with Grand Mal Seizures on Awakening or Epilepsy with Generalized Tonic-Clonic Seizures Alone

Epilepsies with exclusively or predominantly generalised tonic–clonic seizures have also been classified according to their relationship to the sleep–waking cycle: awakening grand mal; grand mal of sleep; and diffuse (or of random distribution) grand mal (Janz 1994; Wolf 2002; Genton et al. 2005; Fernández and Salas-Puig 2007). The only relatively well-defined syndrome in this category is grand mal on awakening, considered as a form of idiopathic generalised epilepsy. However, the diagnosis of this condition is difficult as a strict relation to awakening is necessary for the diagnosis, and the number of seizures necessary for diagnosis is arbitrary. Janz (1994) stated that the diagnosis should be accepted only if 90% of seizures occur within 30 minutes of awakening, whereas Wolf (2002) requires that the clear majority of seizures must occur in the first 2 hours after awakening. Andermann and Berkovic (2001) suggest that the three syndromes of awakening grand mal, juvenile myoclonic epilepsy and juvenile absences are variants of a broader epilepsy syndrome termed primary generalised epilepsy. The term ‘epilepsy with generalised tonic–clonic seizures alone’ was the one privileged in the latest ILAE Classification (Scheffer et al. 2017).

Triggering factors include sleep deprivation, photic stimulation, and excessive alcohol intake, and counselling is therefore important. Pharmacological sensitivity is probably similar to other idiopathic generalised epilepsies (valproate, lamotrigine, topiramate or levetiracetam), but controlled studies are lacking. Duration of treatment is unknown and should be decided on an individual basis.

SYNDROMES OF LATE CHILDHOOD AND ADOLESCENCE WITH PREDOMINANTLY MYOCLONUIC SEIZURES

In some epilepsies of late childhood and adolescence, myoclonias constitute a predominant, if not exclusive, proportion of the seizures. The epilepsies characterised by marked myoclonic phenomena in this age range are, in most cases, idiopathic in origin. A strong genetic predisposition to convulsive disorders is very common (Arzimanoglou et al. 2004). A phenomenon that is more typical of older children and adolescents is a succession of myoclonic jerks often culminating in a generalised tonic–clonic seizure (clonic–tonic–clonic seizure). Myoclonic seizures in this setting differ in outlook and therapy from that observed in Lennox–Gastaut or Dravet syndrome (discussed in the Seizures and Syndromes of Infancy and Early Childhood section). Properly recognising the different types of seizures is important and involves not only detailed history but also video-EEG. The precise determination of the other seizure types that often accompany myoclonic seizures is also important, as the associated seizures are critical for making the most appropriate diagnosis and for classifying the myoclonic epilepsies.

Epilepsy syndromes with prominent myoclonus are divided into four main types:

1. Absence seizures associated with myoclonus (epilepsy with myoclonic absences and eyelid myoclonia with absences; see Other Syndromes Featuring Typical Absences section);
2. Myoclonic seizures induced by intermittent photic stimulation (see Stimulus-Sensitive or Reflex Epilepsies section);
3. Adolescent-onset ‘grand mal’ seizures as the main seizure type with associated absence seizures (i.e. juvenile myoclonic epilepsy, discussed in the Juvenile Myoclonic Epilepsy section);
4. Rhythmic distal myoclonus with onset between late childhood into adulthood; these are mostly familial, with prominent generalised jerks and tonic–clonic and focal seizures in some patients.

Duron et al. (2005) have reviewed the frequency of different seizure types in generalised epilepsy syndromes, their age dependency and the temporal profile of seizures.

Progressive myoclonic epilepsies (PME) are also treated in this section, with respect to age range at onset.

Juvenile Myoclonic Epilepsy (JME)

Juvenile myoclonic epilepsy (JME) (also referred to as myoclonic epilepsy of adolescence or Janz syndrome) is the most frequent and well-defined idiopathic generalised epilepsy syndrome. Onset occurs between 12 and 18 years (Delgado-Escueta and Enrile-Bacsal 1984; Janz 1989) but may occur outside this age range. The condition has been termed ‘myoclonic petit mal’ or ‘impulsive petit mal’, a term that is confusing as JME clearly differs from absence epilepsy. It occurs in 5–11% of adolescents with epilepsy. The myoclonic jerks typically involve the shoulders and arms, and uncommonly the lower extremities. They may be asymmetrical or even unilateral (Genten et al. 1994; Janz 1994). Consciousness is usually preserved, but the involuntary movements often result in the patient throwing whatever is held (French authors term this ‘le syndrome de la soucoupe volante’, i.e. the flying saucer syndrome).

The jerks occur mainly after awakening as single shocks or serial jerks that rarely produce myoclonic status. Ninety per cent of patients experience associated generalised tonic–clonic seizures. The latter may sometimes supervene following a series of jerks, a sequence referred to as a clonic–tonic–clonic seizure. Fifteen to 30% of patients also have absence seizures. The complex relationship between the various idiopathic (genetic) generalised epilepsies is discussed by Thomas et al. (2005).

The typical ictal EEG consists of a burst of high frequency spikes followed by one or a series of slow waves (Figs 16.10 and 16.11). Similar polyspike–wave complexes may occur interictally. Focal EEG features occur in up to 20% of cases (Panayiotoopoulos 1994a). Sleep deprivation and photic stimulation can trigger seizures.
About 80% of patients respond well to sodium valproate therapy, but treatment should be long-standing, probably indefinitely. In women with JME, future pregnancy issues should be discussed when choosing the most appropriate AED (Tomson and Battino 2005; Tomson et al. 2016) particularly for sodium valproate (Tomson et al. 2015). In resistant cases benzodiazepines are worthwhile. Lamotrigine has been used with variable effect on myoclonic jerks, including aggravation in rare cases (Crespel et al. 2005). The combination of low doses of lamotrigine and of sodium valproate may be efficacious when monotherapy is insufficient. A randomised double-blind control study showed clear efficacy
of levetiracetam for myoclonic jerks in JME (Vedru et al. 2005) and the use of this agent is now widespread. Topiramate, zonisamide and most probably perampanel are useful alternatives.

A particular profile of pharmacosensitivity of JME, similar to that of other idiopathic generalised epilepsies, has been described by Thomas et al. (2006) who stressed the potential for seizure aggravation with phenytoin, and particularly carbamazepine which could precipitate myoclonic status. Seizure prevention involves the promotion of good sleep hygiene as sleep deprivation is a reliable provoking factor.

Response to treatment is usually excellent, with complete control observed in approximately 80–90% of cases, although remission is rare. Seizure relapse after discontinuation of medication is frequent, even after many years of seizure control, but may not occur for several years (Thomas et al. 2005). Prognosis should be discussed, particularly with adolescents who are seizure-free for years. If a trial of discontinuation is initiated, advice regarding driving must be provided.

Diagnosing JME is usually easy. However, rare progressive myoclonus epilepsies, like Lafora disease and some cases of Unverricht–Lundborg disease must be ruled out, as their onset may mimic JME (see Progressive Myoclonus Epilepsies section). Subsequent worsening of the myoclonic syndrome, appearance of slow background EEG activity and cognitive deterioration all suggest the possibility of a progressive disorder (Arzimanoglou et al. 2004).

Genetic factors play an important causal role in this syndrome (see Table 16.2). Genetic studies (review in Thomas et al. 2005) report linkage to the short arm of chromosome 6 or long arm of chromosome 15. However, family studies of transmission are often contradictory. A polygenic model is considered most probable (Bate and Gardiner 1999), and might account for the ambiguous and contradictory results of linkage studies that are based on simple, Mendelian models of transmission. This polygenic model assumes a common core of genes that lower the epileptogenic threshold in the idiopathic generalised epilepsies; the specific expression of JME is thus considered a consequence of dysfunction in one or several other genes (Sander et al. 2000). Additional ion channel genes are likely to be identified in JME, and there is growing evidence that non-ion channel genes are also associated with the disease. Indeed, mutations in the EFHC gene have recently been associated with familial JME (Suzuki et al. 2004), whereas polymorphisms in BRD2 (Pal et al. 2003) and MAE (Greenberg et al. 2005) are associated with complex inheritance in JME.

**Eyelid Myoclonia with Absences (EMA)**

This disorder is characterised by the frequent occurrence of eyelid jerks with upward eye deviation that is variably associated with a brief loss of awareness (Jeavons 1982; Appleton et al. 1993; Panayiotopoulos 1998). The EEG reveals short duration polyspike–wave complexes (<6 seconds) and photosensitivity. Treatment with sodium valproate or other AEDs indicated in the idiopathic generalised epilepsies, is effective.

**PROGRESSIVE MYOCLONUS EPILEPSIES**

The progressive myoclonus epilepsies (PMEs) are a group of symptomatic generalised epilepsies caused by rare diseases that are mostly genetic in origin (Shalwan et al. 2005; Minassian et al. 2016). Mitochondrial disorders, especially the syndrome of myoclonic encephalopathy with ragged red fibres (MERRF), however, can produce a similar clinical picture (see Chapter 9).

The history of PMEs spans more than a century (Genton et al. 2016) but their nosological framework originated with the Marseille School in France. The late Jo Roger, wrote that the:

PME syndrome is characterised clinically by the association of the following:

1. A myoclonic syndrome associating generalised myoclonus and arrhythmic asynchronous and asymmetrical, partial or segmental myoclonus;
2. An epilepsy syndrome in which the seizures are of various types, the most frequent being generalised tonic–clonic seizures, myoclonic seizures and tonic seizures;
3. Progressive cognitive deterioration leading to dementia;
4. A neurological syndrome generally associating cerebellar, pyramidal and eventually extrapyramidal signs.

On the EEG, there exists a progressive deterioration of the background rhythm, a progressive alteration in the organisation of the sleep patterns and paroxysmal abnormalities … (Roger 1985).

It was already known that the term PME includes a wide spectrum of different aetiologies that were mostly unknown at that time. However, the concept served as a practical basis for electroclinical diagnoses and better delineation of the syndromes (Marseille Consensus Group 1990). The inclusion of less heterogeneous subgroups and a better understanding of the underlying pathophysiological mechanisms has resulted in ‘the Gene-Empowered era of the PMEs’ (Minassian et al. 2016).

Disorders with myoclonus and myoclonic epilepsy are given in Table 16.13. Myoclonic epilepsies with known metabolic defects are considered in Chapter 9 and Neuronal Ceroid-Lipofuscinoses (NCLs) in Chapter 10. The reader is also referred to reviews by the Marseille Consensus Group (1990), and the recently published state-of-the-art supplement edited by Minassian et al. (2016).

In the present section, we will only discuss two of the PMEs that, particularly at onset in early adolescence, may be misdiagnosed as JME. Both Unverricht–Lundborg and Lafora disease combine generalised tonic–clonic seizures or massive myoclonic jerks, localised myoclonus that may be spontaneous but is often induced by external stimuli such as touch, action or intention, and various degrees of neurological and cognitive deterioration.
Diseases in which PME is pure or in forefront of clinical picture

- Lafora disease (PME1, PME2A, PME2B)
- Unverricht–Lundborg disease
- Myoclonic epilepsy with ragged-red fibres (MERRF) (Chapter 9)
- Juvenile Gaucher disease (Type III) (Chapter 9)
- Hereditary dentatorubral–pallidoluysian degeneration
- PME with lipomas (Ekbom syndrome) (Berkovic et al. 1993)
- PME with deafness (May–White syndrome)
- PME with renal failure (Badhwar et al. 2004)

Diseases in which PME is atypical or associated with other manifestations

- Neuronal ceroid–lipofuscinosis (several types)
- Alpers poliodystrophy and related mitochondrial disorders
- Mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes (MELAS)
- Huntington chorea (myoclonic form) (Gambardella et al. 2001)
- Hallervorden–Spetz disease
- Biotin deficiency (Chapter 9)

Diseases in which PME is overshadowed by other manifestations

- Nonketotic hyperglycinæmia
- D-glyceric aciduria
- Biotin deficiency
- Krabbe disease
- Tay–Sachs disease
- Sandhoff disease
- Niemann–Pick disease
- Spinal muscular atrophy and progressive myoclonic epilepsy (Striano et al. 2004)
- Myoclonic epilepsy and acute intermittent porphyria (Vârsik et al. 2005)

- The same (or a very similar) disorder is referred to as Ramsay Hunt syndrome in some publications (Genton et al. 2005).
- These syndromes are probably related to mitochondrial disorders.

Unverricht–Lundborg Disease (Baltic Myoclonus, Ramsay Hunt Syndrome, EPM1)

Unverricht–Lundborg Disease (ULD) is the best example and the most common of the degenerative myoclonic epilepsies. It is transmitted as an autosomal recessive condition and is due to an unstable dodecamer repeat located in the promoter region of the cystatin B gene, a cysteine protease inhibitor, on chromosome 21. This mutation is associated with a deficiency of cystatin B messenger RNA in some cell types. In some cases, other mutations such as splicing errors or other point mutations resulting in loss of function of cystatin B have been reported (Lehesjoki 2003). The pathology is limited to the cerebellum with loss of Purkinje cells and occasionally of neurons in deep cerebellar nuclei and the inferior olive (Friede 1989; Koskineni et al. 1994).

Onset of the clinical manifestations occurs between the ages 6 and 16 years with tonic–clonic seizures in 50% of cases and myoclonic seizures in the other half (Koskineni et al. 1974a). The myoclonus disappears during sleep or rest and is induced by external stimuli but mainly by maintenance of posture or intended movement. Its intensity increases progressively and it may become totally incapacitating in adulthood. Epileptic seizures are seldom severe and include generalised tonic–clonic seizures, often occurring on awakening, and massive myoclonic jerks very similar to those in juvenile myoclonic epilepsy. Absences or drop attacks occur in a minority of patients.

Intelligence is relatively preserved but there is often slow mild deterioration attributed most often to phenytoin treatment. Källerman et al. (1991) reported the occurrence of ‘cascades’ of seizures and myoclonic jerks. Neurological signs including intention tremor appear after a few years; pyramidal tract signs occur in one-third of cases (Berkovic et al. 1993). Cerebellar signs are difficult to assess because of intention myoclonus.

The EEG reveals variable slowing of background activity with superimposed paroxysmal activity (Koskineni et al. 1974b). Background rhythms may remain normal for many years despite the paroxysmal abnormalities, a scenario identical to the primary generalised epilepsies. Runs of spikes appear at the vertex during REM sleep. These differences are considered to be of nosological significance by some investigators who prefer to separate a subgroup of Mediterranean myoclonus from the Baltic form that corresponds to the original description of Unverricht. It is now known that cases of Baltic myoclonus and Mediterranean myoclonus or Ramsay Hunt syndrome (Tassinari et al. 1989) represent the same disease. Both are linked to the same locus on chromosome 21 (Cochius et al. 1993), and the same mutation has been found in both Finnish and Italian cases (Parmeggiani et al. 1997). Giant somasthetic evoked potentials are recorded in all cases, indicating a cortical-type myoclonus (Shibasaki et al. 1986).

Given the absence of specific clinical or pathological markers, confirmation of ULD is based on genetic analysis. While diagnosis formerly relied on a combination of positive signs in the absence of more specific symptoms and markers of other PMEs, molecular biological techniques are now in widespread clinical use. However, given the cost of genetic diagnosis, we agree with Crespel et al. (2016) that this procedure should follow solid electroclinical evidence rather than screening for all possible genetic aetiologies in poorly assessed participants with epilepsy and myoclonus.

Treatment is oriented to preventing the intention myoclonus. Sodium valproate, primidone, clonazepam (or clobazam) and 5-hydroxytryptophan, sometimes in combination, may be effective (Obeso et al. 1989). Piracetam in very large doses has been shown to be efficacious for myoclonus, and levetiracetam may also be of benefit (Crest et al. 2004). Phenytoin...
may aggravate incapacity and is, therefore, contra-indicated. Commonly used combinations include sodium valproate with levetiracetam, topiramate or zonisamide, with the eventual addition of benzodiazepine (Crespel et al. 2016). The use of perampanel is under evaluation. Vagal nerve stimulation has limited benefit. The benefit of deep brain stimulation is unknown.

The prognosis of ULD is poor from a functional standpoint, but with modern treatment the disease is rarely life threatening. The term Ramsay Hunt syndrome should be abandoned as some investigators believe it designates a disorder identical with or similar to ULD. For other authors (Marseille Consensus Group 1990) it applies to a progressive ataxia associated with intention myoclonus, with or without epilepsy but accompanied by cerebellar signs.

A second type of recessive progressive myoclonus epilepsy with similar clinical features but without mutations in the cystatin B gene has been described in an inbred Arab family, mapping to the pericentric region of chromosome 12 (Berkovic et al. 2005).

**Lafora Disease**

Lafora disease (EPM2) (Turnbull et al. 2016) is the best-defined type of progressive myoclonus epilepsy with a detectable storage. Lafora (amyloid) bodies are found within neurons throughout the neuraxis, especially substantia nigra, dentate nucleus, reticular substance and hippocampus. They are also present in muscle, liver, and sweat gland ducts, thus permitting diagnosis by skin biopsy. Biochemically, Lafora bodies consist of a glucose polymer chemically related to glycogen in association with protein. These neurotoxic polyglucosans accumulate in the endoplasmic reticulum where they are normally cleared by the protein laforin, a dual-action phosphatase.

The disease is inherited as an autosomal recessive trait, and two different loci and genes have been found: EPM2A has been mapped to chromosome 6q24 and codes for laforin; EPM2B on chromosome 6p22 codes for a different protein, malin (Chan et al. 2003), with no substantial genotype-phenotype differences between the two. Founder effects and recurrent mutations are common, and mostly isolated to specific ethnic groups and/or geographical locations. The EPM2A and EPM2B mutations were responsible respectively for 70% and 27% of the 54 cases studied by Gomez-Abad et al. (2005), but the proportions vary with the populations studied (Franceschetti et al. 2006).

Clinical onset occurs between ages 6 and 19 years and in 80% of cases is marked by epileptic seizures, mainly myoclonic, clonic or tonic-clonic. Focal seizures with visual symptoms are reported in half the cases. Erratic, fragmentary myoclonic jerks and massive myoclonias are common and exaggerated by movement and intention. Intellectual disability is often rapidly progressive but may be absent for several years. Pyramidal, extrapyramidal and cerebellar signs appear after a variable delay.

The EEG initially reveals polyspike–wave discharges. Background rhythms then become progressively slower. Death occurs, on average, 5–6 years after onset. Axillary skin biopsy is optimal for diagnosis, although pitfalls in interpretation are known to exist (Andrade et al. 2003). Liver and muscle biopsy also reveal the polyglucosan storage.

Ganesh et al. (2002) reported on a different ‘sub-phenotype’ with childhood onset of dyslexia and other specific learning difficulties, followed by epilepsy and neurological deterioration in association with mutations in exon 1 of the EPM2A gene.

Differential diagnosis includes the idiopathic generalised epilepsies, especially the juvenile form, which may be very difficult to separate at onset. EEG slowing may be the first worrisome symptom. Other degenerative and metabolic epilepsies may also cause diagnostic uncertainty. Rarely, a negative skin, muscle or liver biopsy or a negative search for EPM genes has not excluded the diagnosis which is subsequently made only by brain biopsy (Al Otaibi et al. 2003).

There is no specific therapy, only the symptomatic treatment of epilepsy. Social support is vital (Turnbull et al. 2016) and psychological support is available from patient organisations. Counselling is useful during the early stages of the condition. Physical therapy maintains optimal muscular condition and prolongs ambulation.

**Other Myoclonic Syndromes**

These include late cases similar to benign myoclonic epilepsy of infancy but with a late onset up to 5–6 years of age (Guerrini et al. 1994a) and self-induced photomyoclonic seizures.

An autosomal dominant association of cortical tremor, myoclonus and epileptic seizures with different acronyms has been reported in many Japanese and European families. This disorder is currently termed familial adult myoclonic epilepsy. Striano et al. (2005) reviewed familial cases and concluded that they are all the same clinical entity even if genetically heterogeneous: Japanese families are linked to 8q24 and Italian families to 2p11.1–q12. A third locus may also be involved and sporadic cases with similar characteristics have also been reported.

**SYNDROMES OF LATE CHILDHOOD AND ADOLESCENCE WITH FOCAL (PARTIAL) SEIZURES**

Focal (partial) epileptic seizures are defined as seizures with onset in a neuronal population limited to one cerebral hemisphere (Fig. 16.12a–d). Focal seizures in children are not necessarily indicative of a localised brain lesion as idiopathic focal epilepsies are frequent. However, the symptomatology of non-idiopathic (structural/lesional) forms may be similar, but a careful analysis of clinical and EEG features will enable correct diagnosis (Kahane et al. 2005).
Figure 16.12  Focal temporal lobe seizure. Continued
Focal seizures of lesional origin are caused mainly by malformational lesions (including developmental tumours) and destructive lesions of pre-, peri- or postnatal origin. The extent of the causal lesion largely determines the outcome. Large lesions of prenatal origin may involve several lobes and raise formidable problems of treatment. However, even relatively small lesions may have a noxious effect on overall brain function and cause behavioural and cognitive deterioration through poorly understood mechanisms involving aberrant neural circuitry. Early resection of lesions and seizure-freedom will prevent a progressive course.

Two main categories of focal seizures were initially recognised by the ILAE (Commission on Classification and Terminology 1989) depending on the presence or absence of impairment of consciousness. Consciousness is defined operationally as awareness and responsiveness (Commission on Classification and Terminology 1981). Seizures with impairment of awareness and/or responsiveness were termed ‘complex partial seizures’; those without impaired consciousness were termed ‘simple partial seizures’. Although the concept is debatable (Gloor 1986), this scheme has been widely used even in recent publications. The ILAE classification stated that both forms can evolve into generalised seizures, and that simple partial seizures can evolve into the complex form.

Currently, the trend is to use more descriptive terms without necessarily having pathophysiological value (Lüders et al. 1993, 1999; Engel 2001; Arzimanoglou et al. 2004), because loss of consciousness is related to more widespread discharging rather than to a different origin. If propagation is restricted, the clinical expression is a simple partial seizure; if the discharge propagates from the seizure-onset zone the ‘simple’ partial seizure constitutes the aura of the ‘complex partial’ attack. More recent reports from ILAE Task Forces (Scheffer et al. 2016; Fisher et al. 2017) underscored the need for a pragmatic approach when describing and classifying focal seizures. The use of descriptors (motor versus non-motor; aware/impaired awareness/unknown awareness; motor tonic/hypermotor, etc.) should be privileged and applied individually or in combination with other features depending on the purpose.

Recognising the focal origin of a seizure by obtaining a detailed description of the ictal clinical phenomena is of paramount importance as it will orientate investigation priorities and treatment choices. The next important step is to differentiate, on the basis of clinical examination and EEG data, ‘functional’ (idiopathic) from lesional (non-idiopathic) epilepsies and correlated with neuroimaging investigations. The latter should be correlated based on a localising hypotheses from the clinical semiology. A more detailed analysis of the cortical anatomy of epileptogenesis is required for purposes of localisation and surgery.

Various seizure types are listed in Tables 16.6 and 16.7. Their clinical expression reflects the origin and propagation of the epileptic discharge.

Focal epilepsies of childhood can be conveniently divided into two groups: idiopathic focal epilepsies, in most cases genetic (for a review see Pal et al. 2016) and non-idiopathic (structural and/or genetic) types.

Self-Limited (Idiopathic, Genetic)

Focal Rolandic Epilepsy

Rolandic epilepsy (also described as benign partial epilepsy of childhood with centrotemporal spikes [BECTS]) is
the most common syndrome of idiopathic focal epilepsy in childhood and one of the best-defined, self-limited, epilepsy syndromes. Fifteen to 25% of school-age children with epilepsy are affected (Heijbel et al. 1975; Dalla Bernardina et al. 2005). The syndrome is believed to be genetic in origin but whether a dominant or multifactorial transmission is responsible is unknown, although the latter seems more likely (see Table 16.2). Recent twin studies (Vladlamundi et al. 2006) have challenged the genetic hypothesis and emphasise the importance of acquired factors. The issue is complicated because fewer than 10% of children with rolandic spikes have seizures, and the EEG abnormalities are themselves a heritable trait. Foci of characteristic rolandic sharp waves are frequently encountered in children without epilepsy and their diagnostic value, when isolated, is, therefore, limited.

Age at onset is almost always between 2 and 13 years, with rare cases recorded as early as 1 year. The typical seizures are ‘simple partial seizures’, preferably termed focal motor seizures without impaired consciousness. They are mainly motor in expression, although buccal or labial paraesthesiae are common, and preferentially involve the facial and oropharyngeal musculature, with resulting salivation and/or speech arrest. Individual seizures are brief (30–60 seconds). Sixty to 80% of seizures occur during asleep or upon awakening. Secondary generalisation occurs in 20% of patients, mainly nocturnally, while pure motor seizures tend to occur on falling asleep or awakening. Postictal transient paresis (Todd paralysis) can be observed. Most children have rare seizures, and the response to antiepileptic drugs is favourable, indicating a low epileptogenicity of the focus, which remains clinically silent in over 90% of cases (Arzimanoglou et al. 2004; Dalla Bernardina et al. 2005).

Patients with rolandic epilepsy have a normal neurological examination, and most achieve normal neurodevelopmental progress. However, language difficulties of mild to moderate severity are being increasingly recognised (Staden et al. 1998; Deonna 2000; Saint-Martin et al. 2001a; Pinton et al. 2006). In a case-control study, Weglage et al. (1997) found frequent visuomotor and spatial difficulties in children with centrotemporal spikes.

The EEG abnormality in rolandic epilepsy consists of a focal negative diphasic slow spike, of medium to high voltage, followed by a slow wave located in the centrotemporal areas with a field that may include adjacent regions superimposed on a normal background (Fig. 16.13). A more posterior predominance is often observed in younger individuals. Discharges may occur in isolation or in brief runs (Fig. 16.14). Temporary disappearance and migration of paroxysms between hemispheres is frequently observed. The electrical field is represented as a horizontal dipole (frontal positivity and maximum negativity posteriorly in the rolandic region). Activation in drowsiness and sleep is a hallmark. Localisation over the upper rolandic area is also possible but the middle area is not involved (Legarda et al. 1994). However, unusual localisations are not infrequent (Witrell et al. 1995) and the characteristic stereotyped spike morphology is more important for diagnosis than precise topography. Yet, paroxysms morphologically similar to benign focal epilepsy may also exist in epilepsies due to brain injury (Gobbi et al. 1989; Santanelli et al. 1989; Ambrosetto 1992). As reported by several authors
Part VII  Paroxysmal Disorders

(For reviews see Dalla Bernardina et al. 2005; Pal et al. 2016), the most striking finding of centrotemporal spikes is the significant increase in frequency during drowsiness and all stages of sleep. They appear only during sleep in approximately 30% of children.

The outcome of rolandic epilepsy in terms of seizures is extremely favourable. Up to 25% of children have only one seizure and most have only a few episodes the occurrence of more frequent seizures does not alter outcome. Recurrence after age 16 years is exceptional (Loiseau et al. 1988). Occasional generalised tonic–clonic seizures have been observed in a few adult patients after the resolution of rolandic epilepsy, and a few cases of status epilepticus have also been reported. Prognosis for school and social functioning is favourable (Loiseau et al. 1983).

Following the description by Aicardi and Chevrie (1982), several investigators have reported on atypical aspects of benign partial epilepsy (Fejerman et al. 2000; Saint-Martin et al. 2001a). A few children with rolandic foci and occasional nocturnal seizures experience atonic and/or myoclonic seizures, often grouped in clusters and repeated multiple times daily. This group was termed atypical benign partial epilepsy or Aicardi-Chevrie syndrome (Aicardi 2000; Fejerman et al. 2000) or pseudo-Lennox syndrome (Hahn et al. 2001) based on the atonic seizures and severe EEG anomalies. Atonic seizures are particularly prominent and may occur several dozen times daily, often with falls. The clusters may last 2–3 weeks separated by several months. The sleep EEG is similar to cases of continuous spike–waves during slow sleep (Aicardi and Chevrie 1982; Aicardi and Levy Gomes 1992), and the awakening EEG reveals multiple bilateral spike–wave discharges. Affected patients may be erroneously diagnosed with LGS because of their falls and the severe nocturnal paroxysmal activity. Although the course of this syndrome may be favourable with spontaneous remission before the age of 10 years and after two or more clusters, cases with a more severe outcome are known (Hahn et al. 2001). Cognitive and behavioural abnormalities can persist but have not been studied in detail. A precise nosology of this syndrome is not yet established (Deonna et al. 1986) but clearly fits within the spectrum of epilepsies with an EEG pattern of continuous spike–waves during sleep (CSWS). The atonic episodes may represent partial or secondarily generalised negative myoclonus. Such episodes have been reported in patients with benign partial epilepsy treated with carbamazepine (Caraballo et al. 1989). However, many patients with this syndrome have not received this drug (Aicardi and Levy Gomes 1992).

Episodes of opercular status epilepticus involving the face, tongue and pharyngo-laryngeal structures have been observed (Saint-Martin et al. 1999). The EEG reveals rhythmic spike–wave discharges with the spikes synchronising with facial jerking. Pseudobulbar symptoms such as drooling and dysarthria may be observed (Roulet et al. 1989; Boulloche et al. 1990; Deonna et al. 1993; Fejerman et al. 2000) and true aphasia is noted occasionally (Roulet et al. 1989). Some patients required corticosteroids for control (Fejerman and Di Blasi 1987).
Scheffé et al. (1995b) observed severe and permanent speech dyspraxia and difficulties of oro-buccal movements in several members of a family with an autosomal dominant inheritance and possible anticipation. Guerrini et al. (1999) reported the occurrence of paroxysmal activity in the form of writer’s cramp and ataxia as an autosomal dominant syndrome, but this condition is different from the usual benign presentation. Recently, Roll et al. (2006) have identified the Xq22 gene SRPX2 in patients with rolandic seizures associated with oral and speech dyspraxia and intellectual disability.

The common or typical form of rolandic epilepsy is likely to have a complex genetic inheritance. The genetic basis is unknown despite the recent identification of a low frequency of mutations (5% of cases) in the postsynaptic glutamate receptor subunit GRIN2A (Carvill et al. 2013; Lemke et al. 2013; Lesca et al. 2013) and DEPDC5, a cell growth regulator in the mTOR pathway (Lal et al. 2014). Other potential new candidate genes, RBFOX1 and RBFOX3 (Lal et al. 2013) have also been reported.

**Self-Limited (Idiopathic, Genetic) Occipital Epilepsies**

The occipital epilepsies of childhood form a heterogeneous group (Covanis et al. 2005; Pal et al. 2016). The most common type is an idiopathic and benign epilepsy initially described by Panayiotopoulos and now termed Panayiotopoulos-type occipital epilepsy or Panayiotopoulos syndrome.

**Panayiotopoulos-type Occipital Epilepsy**

Onset occurs in developmentally typical children between 1 and 10 years, with a maximum incidence around 3–4 years. Seizures are generally infrequent and occur mostly during sleep. They are marked mainly by eye deviation with disturbances of awareness that are difficult to assess in sleep. Autonomic symptoms are prominent, especially vomiting. The seizures most often last a few minutes but are often prolonged with up to 44% of cases (Ferrie et al. 1997) lasting minutes to hours with vomiting, unconsciousness and eye deviation. These seizures are easily mistaken for coma of toxic or metabolic origin (Panayiotopoulos 1989, 2000; Kivity and Lerman 1992) or emergency abdominal problems. Long-lasting seizures may culminate in prolonged unilateral convulsions. Atypical cases may also manifest as syncope that is difficult to differentiate from cardiac or vasovagal episodes. Visual symptoms are rare (see below for differential diagnosis with the Gastaut-type occipital epilepsy) but postictal headache is frequent.

The interictal EEG typically reveals paroxysmal activity localised to or predominating in the occipital area uni- or bilaterally, but is occasionally normal. Interictal discharges can be decreased or arrested by visual fixation. Such cases may constitute the most common benign epilepsy syndrome under the age of 5 years and are probably related to rolandic epilepsy. The extent of the syndrome is not fully defined: some atypical manifestations such as syncope and prolonged coma may be misleading; from the EEG point of view, the localisation and appearance of the paroxysmal activity is often variable as predominant extra-occipital paroxysms are noted in 10% of cases (Panayiotopoulos 2002). This group is often benign, although occasional atypical cases have been reported (Ferrie et al. 2002; Kikumoto et al. 2006).

**Gastaut-type Occipital Epilepsy**

This syndrome, is characterised by focal seizures with predominantly visual symptoms, associated with the presence of continuous or rhythmic, spike–wave activity over one or both occipital areas that is arrested or considerably diminished by eye opening. Onset occurs between 3 and 9 years (Gobbi and Guerrini 1998). Ictal visual manifestations may consist of negative (transient loss of vision) or positive symptoms such as simple visual hallucinations of colours and/or geometric shapes (Aso et al. 1987; Thomas et al. 2003). Non-visual seizures may also be the presenting or sole symptom (Panayiotopoulos et al. 1989). Postictal headache, often migrainous, occurs in one-third of cases.

**Idiopathic Partial Photosensitive Epilepsy**

This is a rare form of idiopathic occipital epilepsy (Guerrini et al. 1994b, 1995). Seizures are characterised by visual phenomena that are often long-lasting with a slow progression of the visual abnormalities. The syndrome is usually responsive to treatment and has a favourable outcome.

The overall outcome of the idiopathic occipital epilepsy syndromes is generally favourable but ‘benign’ cases may be difficult to distinguish from symptomatic cases in brain-damaged children (Newton and Aicardi 1983; Dalla Bernardina et al. 1993). For this reason we recommend the realisation of an MRI investigation for all children with occipital seizures.

**Autosomal Dominant Nocturnal Frontal Lobe Epilepsy (ADNFLE)**

More recently, several new syndromes predominantly characterised by focal seizures unassociated with brain lesions have been reported. Some are genetically transmitted (Picard et al. 2000; Pal et al. 2016), mostly in a dominant manner, and several genes have been identified. Evidence for genetic transmission is based on pedigree studies, and a genetic origin has only rarely been convincingly demonstrated.

The most important of these newly described syndromes are autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) and familial temporal lobe epilepsy (FTLE), the latter being reported only in adults. Familial epilepsy with multiple foci (Scheffé et al. 1998), FTLE with and without auditory symptoms and autosomal dominant rolandic epilepsy with speech dyspraxia have been observed in rare families (Andermann and Kobayashi 2005).
The diagnosis of ADNFLE may be suspected on clinical grounds. This disorder is characterised by brief hypermotor nocturnal seizures with hyperkinetic or tonic manifestations. Patients often experience an aura (fear, forced thinking) and may remain conscious throughout the events. Seizures are brief and stereotyped and mainly tonic or dystonic. They often recur in clusters of several episodes in one night, especially in drowsiness or shortly before awakening.

The epilepsy can begin at any age but usually presents in childhood and is usually life-long with considerable variations in severity. Interictal EEG studies are often non-diagnostic as the seizure-onset zone is typically a deep hemispheric source. Focal theta or delta rhythms or sharp waves may be recorded in the frontal area. Frustratingly, the ictal EEG is often unhelpful due to movement and muscle artefact. Most cases respond to carbamazepine, but up to 30% of cases may be difficult to control. Neuroimaging is normal.

Schefter et al. (1995a) originally described 47 affected persons in five families and other cases have now been reported (see Picard et al. 2000). Molecular genetic testing reveals pathogenic variants in CHRNA4, CHRNB2, CHRNA2, KCNT1, DEPDC5 or CRH in approximately 20% of individuals with a positive family history but in fewer than 5% of individuals with a negative family history (Kurahashi and Hirose 2015). The disorder has an autosomal dominant inheritance with a high penetrance (see also Table 16.2).

Only the autosomal dominant form of nocturnal frontal lobe epilepsy is included within the guidelines proposed by the ILAE Commission on Classification and Terminology. To improve the definition of the disorder and establish diagnostic criteria with levels of certainty, a consensus conference using formal recommended methodology was held in Bologna in 2015 (Tinuper et al. 2016). It was recommended that the name be changed to sleep-related hypermotor epilepsy (SHE), reflecting evidence that the seizures occur in sleep rather than wakefulness, arise from pre-frontal sites, and have stereotyped motor characteristics. The aetiology may be genetic or due to structural pathology, but most cases remain unknown. Diagnostic criteria were developed with three levels of certainty: witnessed (possible) SHE, video-documented (clinical) SHE and video-EEG-documented (confirmed) SHE.

Diagnosis may be difficult to establish as the ictal manifestations resemble some types of parasomnias and pseudoseizures. Dystonic seizures are probably identical to those described as nocturnal dystonia by Lugaresi et al. (1986). The nosological situation of ADNFLE and related cases remains unclear. A genetic basis has not been established in many cases, and sporadic cases and phenocopies may exist. Small areas of dysplasia in MRI-negative cases may mimic symptoms, and their presence is an important consideration. Localising the seizure onset zone may require ancillary studies such as PET or SPECT. Although a frontal lobe location is likely in most cases, onset outside the frontal lobe may have similar clinical characteristics (Arzimanoglou et al. 2004). Ryvlin et al. (2006) reported cases with a similar semiology that proved to be of insular origin.

Familial Temporal Lobe Epilepsy (FTLE)

Berkovic et al. (1996) described idiopathic cases in adults with a dominant transmission, a favourable course and symptoms suggesting mesial temporal epilepsy. To date, no case has been described in children. This ‘syndrome’ is defined by genetic data, as the clinical and EEG features do not differ significantly from those of more common temporal lobe epilepsies. The recognition that not all cases of temporal lobe epilepsy are due to underlying injury or are intractable is clearly significant for evaluation and prognosis.

To assess the clinical impact of DEPDC5 (DEP domain-containing protein 5) mutations in familial temporal lobe epilepsy, an Italian group (Striano et al. 2015) screened families with either autosomal dominant or recessive temporal lobe epilepsy (ADLTE) or familial mesial temporal lobe epilepsy (FMtLE). The probands of 28 families were classified as ADLTE and 17 families with FMtLE were screened for DEPDC5 mutations by whole genome or targeted massive parallel sequencing. They identified a DEPDC5 nonsense mutation (c.918C>G; p.Tyr306*) in only one family with two affected members, clinically classified as FMtLE. The proband had temporal lobe seizures with prominent psychic symptoms (déjà vu, dissociated and forced thinking); her mother had temporal lobe seizures, mainly consisting of visceral epigastric auras and anxiety. In total, they found a single DEPDC5 mutation in one of (2.2%) 45 families with genetic temporal lobe epilepsy, a proportion much lower than in other inherited focal epilepsies.

A second type of familial temporal lobe epilepsy with dominant inheritance is characterised by the presence of auditory ictal symptoms (Ottman et al. 1995; Cendes et al. 2005). This syndrome presents as a relatively mild epilepsy characterised by focal seizures with elementary auditory hallucinations, often generalised tonic–clonic seizures and dominant inheritance. Other symptoms, especially ictal dysphasia, may occur (Bisulli et al. 2004; Ottman et al. 2004). Response to medication is usually favourable. A gene (LTI11epitempin), mapped to chromosome 10q is responsible for some cases but other cases are not linked to this locus and sporadic cases are described (Bisulli et al. 2004).

Non-Idiopathic (Structural and/or Genetic) Focal Epilepsy Syndromes per Lobe

‘Non-idiopathic focal epilepsies’ refer to all focal epilepsies known or suspected to result from a brain lesion or abnormality. The terms ‘symptomatic’, ‘probably symptomatic’ or ‘cryptogenic’ are also used in the literature. As opposed to the much better defined category of idiopathic focal epilepsies, non-idiopathic focal epilepsies are a heterogeneous group of conditions with differing aetiology, pathology and clinical presentations (Arzimanoglou et al. 2004; Kahane et al. 2005), including genetic factors responsible for the brain lesions. The clinical expression of lesional epilepsy may not differ from idiopathic seizure expression.
Only a few reasonably well-defined syndromes are defined among the epilepsies of lesional origin (e.g. mesiotemporal epilepsy). The so-called topographic syndromes (frontal, temporal, parietal and occipital epilepsies) may designate large anatomical regions of seizure onset. Even within a same lobe, clinical semiology may differ and interictal or ictal EEG abnormalities are not a constant feature. Furthermore, prominent clinical symptoms often result from seizure propagation and do not necessarily indicate the seizure-onset zone. Consequently, the definition (and description) of the various focal non-idiopathic epilepsies is based on detailed description of the seizures and interictal EEG abnormalities. Thus, their cause and prognosis are often determined through an individual combination of signs and symptoms from multiple investigations, particularly neuroimaging, interictal and ictal EEG.

Accurate description of the semiology of focal seizures is especially important for topographic diagnosis and for a better orientation of the neuroimaging investigations. Clinical manifestations and ictal and interictal EEG features help localise seizure origin to a specific cortical area. However, epileptogenesis is a dynamic process and often propagates to neighbouring and distant areas by both normal and abnormal pathways.

Similarly, the relationship between the location of a lesion and that of the resulting epileptic discharge is complex, and there is no absolute concordance. With these reservations in mind, some elements of localisation can be tentatively described in topographic syndromes. What follows is a very brief description of their main characteristics.

Children with drug-resistant focal seizures of lesional origin typically harbour dysplastic lesions (Blümcke et al. 2011), developmental tumours or destructive lesions of pre-, peri- or postnatal origin. The extent of the causal lesion largely determines the diagnostic approach. Large lesions of prenatal origin may involve several lobes and raise formidable problems of treatment. However, even relatively small lesions may have a noxious effect on overall brain function and lead to behavioural and cognitive deterioration. Early resection of lesions may prevent the appearance of epileptic encephalopathy and improve long-term prognosis (Arzimanoglou et al. 2016c). Children with focal cortical dysplasias, particularly of the FCD ILAE Type II (Blümcke et al. 2011) are excellent candidates for excisional epilepsy surgery, particularly if the lesion spares eloquent cortex.

**Frontal lobe seizures**

Seizures of extratemporal origin in children are more frequent than those of temporal origin. Seizures of frontal lobe origin are the most common in large surgical series. The diagnosis of frontal lobe epilepsy may be challenging as their semiology may mimic nonepileptic paroxysmal events (sleep disorders or psychogenic seizures). Their presentation typically includes contralateral clonic movements, uni- or bilateral tonic motor activity and complex automatisms (Bancaud and Talairach 1992; Chauvel et al. 1992; Kellinghaus and Lüders 2004). Frontal lobe seizures are often nocturnal, maximal at onset, repetitive, usually of brief duration and having minimal or lacking postictal manifestation. Complex motor automatisms (hypermotor seizures) including thrashing of the extremities, body rocking and bicycling leg movements typically begin in the anterior to motor cortex (Licchetta et al. 2017). Other, less specific manifestations are also frequent: arousal from sleep; staring spells during wakefulness and sleepwalking. The yield of surface EEG may be limited due to the difficulty in detecting mesial or basal foci, and a diagnosis of nonepileptic events is common. Mesial frontal foci may be miss-lateralised (‘paradoxical lateralisation’). Anatomical and functional neuroimaging techniques, particularly MRI with epilepsy-specific sequences has helped delineate the epileptogenic source and specific aetiology in an increasing number of patients. Small tumours or dysplasias are the most frequently encountered aetiologies.

Salanova et al. (1995b) studied 150 seizures in 24 adolescent and adult patients. Symptoms and signs could be clustered into three groups:

1. Supplementary motor area group (n=9). Seizure discharges involving the supplementary motor area and adjacent frontal lobe, are associated with preserved consciousness. A sensory aura could be reported but the manifestations were predominantly motor with tonic contraction of one or both arms, sometimes with a classic ‘fencing’ posture, head version, bilateral tonic extension of the trunk or neck and vocalisation. As consciousness is preserved, these motor manifestations may be mistaken for generalised or pseudo-seizures (Bass et al. 1995; Laskowitz et al. 1995), however, they are usually symptomatic of a mesial frontal or precentral frontal lesion involving the supplementary motor area.

2. Focal motor group (n=7). Seizures in the vicinity of the frontal eye fields produce unilateral, face and/or arm clonic seizures, speech arrest, blinking and head version. Preservation of consciousness was an almost constant feature.

3. Complex partial seizures group (focal seizures with impaired awareness according to the most recent terminology) (n=8). In five patients, seizure onset was characterised by ‘staring’ or ‘looking ahead’. Partial or complete unresponsiveness was present in all cases. Although unilateral or bilateral arm tonic posture was similar to that of patients with supplementary motor area seizures, this symptom was never observed at seizure onset. Oroalimentary automatisms occurred rarely toward the end of the seizure.

In much younger children, motor features are common but their characteristics may differ (Fogarasi et al. 2016; Tinuper et al. 2016). Fogarasi et al. (2001) analysed 111 videotaped seizures from 14 patients aged 3–81 months (mean, 30 months) and with frontal lobe epilepsy (FLE) related to focal cortical dysplasia. Ictal events were categorised into behavioural, consciousness, automimic and sensory features and motor patterns including tonic, clonic, spasm and myoclonic components. Patients had a high seizure frequency, ranging up to 40 seizures per day, often in clusters. Mean
Seizure duration was short (29 seconds) and started in sleep in nearly half the patients. Motor manifestations were most common consisting mostly of tonic–clonic seizures and epileptic spasms. Behavioural change was frequent but hypermotor seizures were absent. Motor features were contralateral to the epileptic focus in five patients, including two with asymmetrical epileptic spasms. Secondly generalised tonic–clonic seizures were not observed, but had been described in two patients. Complex motor automatisms were absent, whereas oral automatisms appeared in three young children.

The same team (Fogarasi et al. 2005) analysed 177 seizures in 35 children (aged 11 months to 12 years) with extratemporal epilepsy (FLE compared to posterior cortex epilepsy) selected by postoperative seizure-free outcome. Twenty patients had FLE, and 15 had posterior cortex epilepsy (PCE). Patients from both groups had daily seizures without significant differences in frequency but evidencing nocturnal dominance in children with FLE (P<0.05). Visual aura, nystagmus, and versive seizure activity were observed exclusively in the PCE group, whereas somatosensory aura and hypermotor seizures appeared only in FLE. Tonic seizures were significantly more frequent in FLE (P<0.01). Myoclonic seizures, epileptic spasms, psychomotor seizures, atonic seizures, oral and manual automatisms, as well as vocalisation and eye deviation appeared in both groups without significant differences in frequency. The study showed that, especially in infants and preschool children, the characteristic features of adult extratemporal epilepsy were frequently absent.

Children with FLE are particularly at risk of misdiagnosis (Fusco et al. 1990; Stores et al. 1991) because of their unusual clinical features and frequent lack of EEG abnormalities. Automatisms do not involve oromotor movements but are gestural, complex and often violent with rocking, kicking and dystonic activity. The bizarre appearance of these seizures often suggests pseudoseizures, the more so as screaming, shouting and the utterance of abusive language are common.

The clinical and EEG features of FLE were compared to mesial temporal lobe epilepsy (MTLE) in 56 children (17 children undergoing video-EEG monitoring for presurgical evaluation (Lawson et al. 2002). Frontal lobe seizures were significantly rarer, had different motor characteristics, were more frequent and occurred predominantly during sleep. The rates of bilateral epileptiform interictal and ictal EEG abnormalities were significantly higher in FLE, and patients were more likely to have a normal MRI.

Seizures from the central region
Seizures of central hemispheric region including primary sensorimotor cortex exhibit a jacksonian march or narrowly localised clonic or tonic motor phenomena, suggesting primary involvement of the Rolandic strip. Tingling, a feeling of electricity and loss of muscle tone are common. Reflex activation of simple motor seizures occurs with sudden contact or the contraction of specific muscles. Facial bucco-lingual, tonic–clonic contractures with aphemia, swallowing, salivation and masticatory movements that are often accompanied by sensory symptoms, including tongue sensations of crawling, stiffness, coldness, gustatory hallucinations, and/or laryngeal symptoms suggest involvement of lower peritonal cortex in the upper bank of the Sylvian fissure (Lombroso 1967; Loiseau and Beaussart 1973; Wieser and Williamson 1993). More extensive insular involvement is accompanied by vegetative symptoms, which may be digestive, urogenital, cardiovascular or respiratory. These manifestations are easily misinterpreted as being of temporal lobe origin.

Insular lobe seizures
Ictal semiology of insular lobe seizures is highly variable. Several clinical signs (emotional sensations; autonomic symptoms such as vomiting, cardiac arrhythmias; automotor or hypermotor manifestations; subjective signs of variable expression, etc.) have been reported (for a review see Dimova 2016). At least three patterns can be distinguished: temporal lobe pattern, in which somatosensory or motor ictal symptoms usually precede the typical mesiotemporal semiology (see below); temporoparietal pattern characterised by laryngeal discomfit, dyspnœa, unpleasant paraesthesias affecting the perioral region or larger somatic territories; frontal lobe seizures pattern with predominantly hypermotor manifestations often preceded by somatosensory symptoms. Overall the semiology in children does not substantially differ from descriptions in adults, although precise descriptions are difficult to obtain from very young children. Ictal scalp EEG abnormalities are often widespread involving multiple lobes which suggests a deep seizure focus.

Temporal lobe seizures
Seizures of temporal lobe origin (Fig. 16.12a–d) are thought to account for most cases with altered consciousness. However, altered consciousness may be even more common with extratemporal seizures, especially in children (Fusco et al. 1990; Chauvel et al. 1992; Williamson et al. 1993a, b). Seizures with and without alteration of consciousness often coexist in the same patient. Seizures are usually prolonged, lasting 1–2 minutes. Autonomic manifestations, psychic and sensory symptoms represent the whole or only the onset (aura) of a more complex episode evolving with altered consciousness (Bancaud 1987).

Focal seizures of temporal lobe origin in children are generally similar to those in adults (Kotagal et al. 1987; Devinsky et al. 1988) but tend to have an atypical and minimal expression in younger children and only progress to a more characteristic picture with increasing age (Brockhaus and Elger 1995; Fogarasi et al. 2002; Villanueva and Serratos 2005). Analysis of video recordings of 29 children aged 18 months to 16 years with temporal lobe epilepsy (TLE) (Brockhaus and Elger 1995) showed that clinical features of temporal lobe seizures can be misleading in younger children, including symmetrical motor phenomena, postures similar
to frontal lobe seizures in adults, and head nodding similar to infantile spasms. Fogarasi et al. (2002) reached a similar conclusion by performing a video analysis of 83 seizures from 15 children (aged 11–70 months). Parallel with age, the frequency of motor components decreased, and in five of 11 children older than 3 years, motor features were totally absent.

In infants and children under 2 years of age, tonic posturing and head rotation are often the initial and dominant manifestations. The duration of seizures is usually longer than for absences (60–120 seconds) and seizures are followed by a period of confusion or of intense tiredness. Onset is often with behavioural arrest and staring. Oroalimentary automatisms tend to predominate in young children (Duchowny 1987) and include licking, lip-smacking, chewing or swallowing movements, while in older children, gestural automatisms such as fingering or fumbling with clothes are also frequent (Holmes 1986; Wyllie et al. 1993; Fogarasi et al. 2002). In young children, the most common aura is an epigastric sensation often associated with fear. In older children, temporal lobe seizures may be preceded by auras with affective or other psychic phenomena such as hallucinations or illusions affecting various sensory modalities (Arzimanoglou et al. 2004; Fogarasi 2016).

TLE can be schematically divided into those of mesiotemporal or lateral neocortical origin. **Mesial temporal lobe syndrome** is defined not only on topographic criteria and MRI evidence of hippocampal involvement (Fig. 16.15) but also on clinical, EEG and evolutive features (Cendes et al. 2005). The syndrome frequently occurs in patients with a history of complex febrile convulsions in infancy, with long-lasting unilateral seizures in at least 40% of cases. The initial ictus is followed by a second phase of variable duration. Focal seizures mark the third phase of chronic epilepsy, which often appears during the second half of the first decade; however, earlier onset is not unusual with focal epilepsy starting within a few years after febrile seizure onset (Abou-Khalil et al. 1993; Williamson et al. 1993a; Harvey et al. 1995). This ‘roller-coaster course’ (Berg et al. 2006) of TLE probably explains the very long delays in recognising its intractable character and referral for surgical treatment (Arzimanoglou et al. 2005).

Seizures are marked by behavioural arrest and staring followed by automatisms involving especially the oroalimentary muscles (lip-smacking, licking, swallowing). A significant proportion of these automatisms are conscious (Munari et al. 1994; Ebner et al. 1995). Dystonic posturing of the contralateral arm is often observed (Kotagal et al. 1989), while simple automatisms may involve the ipsilateral arm.

The EEG usually demonstrates an interictal anterior temporal spike focus or paroxysmal theta activity (Gastaut et al. 1988), while the ictal EEG reveals focal discharging that may be diffuse and involve the contralateral temporal lobe. MRI reveals loss of hippocampal architecture and increased T2 signal (Jackson et al. 1990; Cross et al. 1993; Cendes et al. 2005). Hippocampal sclerosis has recently been shown to be a progressive disorder (Fuerst et al. 2003). Progressive mesial temporal volume loss in relation to the duration of epilepsy is probably not limited to the hippocampus but also affects entorhinal cortex and amygdala (Bernasconi et al. 2005).

Fluorodeoxyglucose PET scanning reveals localised hypometabolism while SPECT shows reduced blood flow to the mesial temporal lobe interictically and ictal hyperperfusion (Harvey et al. 1993a, 1995). Both interictal FDG-PET and ictal SPECT appear comparable in utility (Desai et al. 2012). PET is quantifiable and has higher resolution than SPECT, but SPECT ligands have a longer half-life and are easier to use (Gaillard et al. 2009, 2011, 2016). Both PET and SPECT use ligands that are designed to target different physiological processes, but in practice only markers of blood flow have been used in SPECT.

In a prospective randomised study (Wiebe et al. 2001), 80 adult patients with TLE were randomly assigned to surgery (40 patients) or medical treatment for 1 year (40 patients). Twenty-three patients were seizure-free in the surgical group compared to three in the medical group (*P*<0.001). This difference emphasises that surgery is superior to prolonged medical therapy in this patient cohort. Patients in the surgical group had fewer seizures impairing awareness and improved quality of life (*P*<0.001 for both comparisons). Four patients had adverse effects of surgery, and one patient in the medical group died.

Most studies on epilepsy surgery of intractable TLE concern adult patients with a long history of epilepsy, and randomised trials are rare (Engel et al. 2003; Schmidt et al. 2004). Surgical outcome is often favourable (Abou-Khalil et al. 1993). More than two-thirds of patients with drug-resistant

![Figure 16.15](image-url)
TLE are free of disabling seizures with continued medical treatment after temporal resection. Of those, almost one-third will achieve complete discontinuation of AEDs (Schmidt and Loscher 2003). Extrapolation of these data to children is difficult. Prospective studies are necessary to characterise benign mesial TLE with hippocampal sclerosis, define its incidence and prevalence relevant to the severe form, and determine whether the benign and severe forms represent two different pathophysiological conditions, or fall on a spectrum (Wieser 2004). This differentiation is of extreme importance particularly when discussing evolution, not only in terms of seizures but also in terms of socio-cognitive development (Arzimanoglou et al. 2005). For patients who are compromised by such seizures, referral to an epilepsy surgery centre should be strongly considered early in the course of the disorder since, based on retrospective cohort data in children, failure of a first AED trial accurately predicts refractory TLE at 2 years after onset (Dlugos et al. 2001). The long-term neuropsychological impact of surgery in children with hippocampal sclerosis are only beginning to be understood (Krsek et al. 2016). This is another reason why referral to specialised epilepsy centres, having the capacity to prospectively follow these children and constitute comparable cohorts, is of crucial importance.

Seizures associated with small mesial temporal developmental tumours are very similar in clinical expression (Wyllie et al. 1993; Raymond et al. 1994; Arzimanoglou et al. 2004). Such patients have no antecedent history. Wyllie et al. (1993) emphasised that, contrary to mesial temporal sclerosis in which the ictal and interictal EEG anomalies are usually localised to the anterior temporal area, the EEG is often diffusely abnormal in small tumours diagnosed on MRI.

Patients with focal cortical dysplasia represent a heterogeneous group (Blümcke et al. 2011; Desikan and Barkovich 2016). Different age at epilepsy onset and transient responsiveness to AEDs may reflect different dynamics in epileptogenicity of the underlying FCD (Fig. 16.16a–b). Dual pathology is common in children (Mohamed et al. 2001) and may be associated with different pathological mechanisms in patients with and without febrile seizures (Fauser et al. 2006). Recent studies emphasise the role of neuronal glial tumours especially gangliogliomas and developmental neuroepithelial tumours as a cause of chronic epilepsy with long-standing monosymptomatic focal seizures.

To distinguish benign tumours causing drug-resistant epilepsy from other brain tumours, with seizures as an epi-phenomenon, the term LEAT (long-term epilepsy-associated tumours) has been coined by Luyken et al. (2003). In LEATs, seizures are the presenting symptom, usually early in life, tumoural growth, if any, is rather slow and localisation preferentially occurs within the temporal neocortex (Holthausen et al. 2016). Taylor-type and other types of cortical dysplasia are also frequent (Blümcke et al. 2011). These lesions are all highly epileptogenic (Fig. 16.17), and the related epilepsy is resistant to drugs in most cases. This is a rapidly expanding field of knowledge, as improved imaging and genetic methodologies, the underlying molecular and pathobiological characteristics of several malformations of cortical development are being elucidated (Desikan and Barkovich 2016; Holthausen et al. 2016; Holthausen and Blümcke 2016).

Lateral (or neocortical) temporal origin is typically characterised by auditory or complex perceptual visual hallucinations, illusions, a dreamy state or vertiginous symptoms. Impairment of consciousness may begin with motor arrest or staring, followed by oroalimentary automatisms. However, automatisms may appear while the patient is still responsive or when consciousness is fluctuating. Amnesia for the ictal event is the rule after alteration of consciousness but may be present even when the patient had apparently remained conscious. According to Blume et al. (1993) and Munari et al. (1994), the
neocortex is responsible for many features of all temporal lobe seizures. Postictal confusion and, in small children, postictal sleep are frequent. Temporal lobe seizures of neocortical origin are less frequent than limbic seizures.

Temporal lobe seizures in children may arise from the basolateral temporal region rather than mesial temporal structures (Duchowny et al. 1994). Such seizures are marked by behavioral arrest followed by automatism that begins several seconds after seizure onset. Propagation of mesio-basal seizures is rapid and mainly spreads to the contralateral hippocampus, but may spread to the cingulate gyrus or to orbital and lateral frontal cortex. The concept of temporal ‘plus’ epilepsy was proposed to unify and better individualise specific forms of multilobar epilepsies. Seizures are characterised by electroclinical features primarily suggestive of temporal lobe epilepsy with MRI findings that are either unremarkable or reveal hippocampal sclerosis, and intracranial recordings that reveal seizure origin within a complex epileptogenic network including brain regions within the temporal lobe and neighbouring structures including orbitofrontal cortex, the insulo-opercular region, and the temporo-parieto-occipital junction (Kahane et al. 2015; Barba et al. 2015).

In general, localisation of focal seizures to a particular cortical area is difficult, and distinction between seizures of temporal and frontal lobe origin only on the basis of clinical symptoms may be impossible without intracranial investigation (Manford et al. 1996a).

**Posterior cortex seizures**

Seizures originating from the parietal and occipital lobes (posterior cortex seizures, including the anatomically and functionally adjacent temporal cortex) have a complex semiological presentation. For this reason, localisation based on clinical presentation is difficult and partly explains why they may be under-appreciated, particularly in children.

**Symptoms of ictal involvement of the parietal lobe** may be difficult to diagnose (Salanova et al. 1995a), especially in children, as they are typically subjective and overshadowed by symptoms arising from contiguous central, temporal and occipital cortex. Somatosensory seizures may have a jacksonian march (Mauguière and Courjon 1978) and are often associated with motor phenomena. Focal seizures arising from the parietal lobe are characterised by positive or negative somatosensory symptoms, rarely pain (Young et al. 1986; Trevathan and Cascino 1988; Ho et al. 1994), or by nausea or an intra-abdominal sensation, illusions of movement or loss of awareness of a part of the body (asomatognosia—especially with non-dominant hemisphere involvement), vertigo or spatial disorientation. Receptive or conductive aphasia (with dominant hemisphere involvement) and postural or rotatory movements may also be seen, and visual symptoms may appear with involvement of the parieto-temporo-occipital junction. Inferior parietal involvement may be accompanied by contralateral or ipsilateral rotatory movements with posturing of the limbs contralateral to the involved hemisphere. Visual illusions, such as macropsia or micropsia or meta-morphopsia suggest involvement of the posterior parietal cortex or parieto-temporo-occipital junction.

**Symptoms of occipital lobe** involvement are subjective and may be overshadowed by manifestations resulting from spread to contiguous cortex. Epileptic discharges affecting the primary visual cortex are characterised by elementary visual phenomena, which may be either positive (flashes, phosphenes, rotating colours) or; less frequently, negative (scotomata, hemianopsia, amaurosis). Location is in the hemifield contralateral to the lobe involved. With discharges located more anteriorly, head and eye version is common but not necessarily contralateral. Eye deviation may be periodically interrupted by jerks that return the eyes to the primary position (‘epileptic nystagmus’). Additional manifestations include eyelid flutter.
or forced closure of the eyelids and a sensation of eye-pulling (Salanova et al. 1992; Williamson et al. 1992).

In a cohort (Liava et al. 2014) of 62 children undergoing surgery for drug-resistant posterior cortex epilepsy before age 16 years (mean age at epilepsy onset was 3.2 years), 28 children (45%) had onset before age 1 year. Daily seizures were present in 63%. MRI was positive in 58 cases (93.5%) and invasive stereo-EEG (SEEG) was indicated in 24/62 (39%). Surgery was confined to the parietal lobe in 11 children, the occipital lobe in eight, the occipito-parietal region in four, the occipito-temporal region in 18, and involved both the temporal and parietal lobes in the remaining 21. Following surgery, 53 participants (85.5%) were seizure-free. Among patients undergoing SEEG, 75% achieved seizure-freedom. Focal cortical dysplasia was the most frequent histopathological diagnosis (50%), followed by tumoural (24%) and gliotic lesions (14.5%). Older age at epilepsy onset, a restricted epileptogenic area, and complete resection of the epileptogenic zone predicted a favourable surgical outcome.

These results demonstrate that a good surgical outcome is possible in children with drug-resistant posterior cortex epilepsy. Accurate analysis of the chronology of ictal semiology and electrophysiological features, viewed in the context of the complete electroclinical pattern, provides a topographical orientation for posterior cortex epilepsy and, together with the presence of a lesion detectable on imaging, may improve the rate of surgical success of posterior cortex epilepsy in childhood (Francione et al. 2015; Ramantani et al. 2017).

Some Special Epilepsy Syndromes of Lesional Origin

Hypothalamic Hamartoma is a syndrome of gelastic (giggling attacks and/or ‘impression to laugh’) and sometimes dacrystic (crying) seizures of early onset (often in the first year and usually before 2 years of age) is associated with hamartomas of the hypothalamus (Fig. 16.18). The seizures are frequently repeated and highly resistant to treatment (Berkovic et al. 1988; Arzimanoglou et al. 2003; Mullatti 2003; Parvizi et al. 2011; Wilfong and Curry 2015; Kerrigan et al. 2016). Many patients experience cognitive decline and neuropsychiatric comorbidities. Precocious puberty is a frequent feature. The seizure discharge arises from the tumoural core, and surgical excision, although challenging, usually leads to a favourable outcome (Kahane et al. 2003; Kerrigan et al. 2016). Surgical dysconnection or excision yields good results, and several radiosurgery techniques are also used or under evaluation (Fohlen et al. 2003; Polkey 2003a, b; Kerrigan et al. 2016).

Cerebellar hamartomas may produce repeated brief episodes of tonic facial contraction of early onset, similar to the facial hemi-spasm of adults (Al-Shahwan et al. 1996). Harvey et al. (1996) and Arzimanoglou et al. (1999) showed that these may correspond to a typical epileptic EEG discharge within the lesion. AEDs are usually ineffective and polytherapy is not indicated. When possible, surgical resection of the hamartomatous lesion is the most efficacious treatment (Harvey and Arzimanoglou 2016).

Epilepsy related to hypothalamic and cerebellar hamartomas should be evaluated early and referred to specialised referral programmes with clinical and surgical experience.

Abnormalities of cortical development (see Table 16.4) represent the most frequent cause of focal non-idiopathic epilepsies and nearly 40% of drug-resistant cases. This is a rapidly expanding field and a detailed review of these lesional epilepsies is beyond the scope of this chapter. Excellent detailed publications provide an overview of the topic (Guerrini et al. 2003; Blümcke et al. 2011; Kwon et al. 2016; Desikan and Barkovich 2016; Holthausen et al. 2016; Tassi et al. 2016; Barba et al. 2016).

The syndrome of occipital epilepsy associated with uni-or bi-lateral occipital calcifications (Fig. 16.19)
may run a benign course (DeMarco and Lorenzin 1990) or be more severe with secondarily generalised seizures and cognitive deterioration (Gobbi et al. 1988; Tiacci et al. 1993; Gobbi 2005). Such cases are closely reminiscent of Sturge–Weber syndrome (Fig. 16.20) without cutaneous angioma, and similar vascular abnormalities have been reported (Bye et al. 1993) but are inconstant (Totti et al. 1996). However, there is only minimal or no brain atrophy, and there is no enlargement of the choroid plexus or abnormal deep venous drainage. Most if not all cases of epilepsy with occipital calcification are associated with coeliac disease, and likely to be lesional in nature, although their expression may be reduced to villous atrophy of the intestinal mucosa (Gobbi 2005). The relationship between the coeliac disease and the calcification is not understood.

Occasional and Unusual Epileptic Seizures of Late Childhood and Adolescence

Occasional seizures may rarely occur with acute febrile diseases in older children. They can also occur in a well child or adolescent without fever (Aicardi 1994). Isolated afebrile seizures in adolescents are relatively common. Seizures may be generalised or focal. About half remain single as an isolated cluster lasting less than 36 hours (Loiseau and Louiset 1992; Capovilla et al. 2001). For that reason, treatment of the first afebrile seizure is not recommended unless specific reasons militate for immediate therapy. Isolated convulsions are especially frequent in adolescents during stress and sleep deprivation.

Caraballo et al. (2004) have emphasised that seizures in adolescents usually do not recur when the EEG is normal. This syndrome of partial benign epileptic seizures in teenagers accounted, in their experience, for 24% of all partial seizures beginning in adolescence. The course is benign, but distinction from lesional cases is difficult and neuroimaging studies are required.

Epileptic seizures can disturb all brain functions, and a wide variety of ictal phenomena have been reported, more frequently as isolated case reports. Abdominal epilepsy is characterised by episodes of epigastric or periumbilical pain and/or repeated episodes of unexplained vomiting. However, epilepsy is rarely the cause of the syndrome of recurrent abdominal pain and periodic vomiting, which is probably more often a manifestation of migraine (Arzimanoglou et al. 2004). In true abdominal epilepsy, loss of consciousness is an important feature.

Seizures limited to vomiting (ictus emeticus) occur rarely (Kramer et al. 1988; Thomas and Zifkin 1999; Shuper and Goldberg-Stern 2004). Other autonomic phenomena that can be the sole or main manifestation of a seizure include cardiac arrest (Kiok et al. 1986; Smaje et al. 1987), ictal arrhythmias (Gilchrist 1985), and apnoea and cyanosis (Southall et al. 1987; Donati et al. 1995; Hewerton et al. 1996). Unusual visual episodes may affect eye movements with ictal gaze deviation or epileptic nystagmus (Thurston et al. 1985) and ictal blindness (Barry et al. 1985). Pain as a seizure phenomenon is rare (Young et al. 1986; Trevathan and Cascino 1988). Shuddering attacks in children were reported by Holmes and Russman (1986), and isolated disturbances of memory (Gallassi et al. 1988) and of sleep with repeated nocturnal awakenings (Peled and Lavie 1986) have also been described.
STIMULUS SENSITIVE (REFLEX) EPILEPSIES

The precipitation of seizures by specific stimuli occurs in many idiopathic and symptomatic epilepsy syndromes. Also termed 'reflex epilepsies', stimulus-evoked seizures are classified as a discrete syndrome only if the patient had solely or predominantly precipitated seizures, which is rare (Wolf et al. 2004; Wolf and Inoué 2005; Koepp et al. 2016). A certain degree of confusion is also due to the fact that the terms ‘provoked’ and ‘triggered’ are sometimes used interchangeably (Pohlmann-Eden et al. 2006). Aird (1983) indicated that 40 seizure-precipitating mechanisms are known. These include tension states, alteration of the level of attention or of consciousness, sleep, psychological factors and hydration state.

With increasing age at onset the complexity of stimuli increases from simple sensory to complex cognitive-emotional. The topography of physiological networks involved follows the posterior-to-anterior trajectory of brain development, reflecting age-related changes in brain excitability. Reflex seizures and traits probably represent the extremes of a continuum, and understanding of their underlying mechanisms might help to elucidate the transition of normal physiological function to paroxysmal epileptic activity (Koepp et al. 2016).

PHOTOSENSITIVE EPILEPSIES

Epileptic seizures triggered by photic (intermittent) stimulation is observed in various epilepsy syndromes and do not constitute a separate entity (Harding and Jeavons 1994). Photosensitivity is especially frequent in adolescents with idiopathic generalised epilepsy (Harding and Jeavons 1994), eyelid myoclonia with absences, and some types of myoclonic epilepsy (Newmark and Penry 1979; Guerrini et al. 1995). Self-provocation is not rare in such patients. The role of television was emphasised by Harding and Jeavons (1994) and Kasteleijn-Nolst Trenité et al. (2002), although other investigators found it limited (Mayr et al. 1987). However, as delivery of the screen image is now digital the provocative role of television viewing is significantly reduced.

Among the factors provoking paroxysmal discharges with analogue television, some seem crucial: the frequency of the television screen refreshment (the 100Hz screen are significantly safer than the 50Hz), the distance from the screen (100cm safer than 50cm), and, particularly for the 50Hz screen, the specific pattern of the images and the act of playing (Badinand-Hubert et al. 1998). Provocation by video games (Maeda et al. 1990; Ferrie et al. 1994; Graf et al. 1994) is also possible but is a reflex rather than a photosensitive epilepsy; computer screens are not associated with photosensitive epilepsy unless the visual image has a flickering or bursting presentation. This problem, as well as that of pattern-sensitive epilepsy, was studied in detail by Harding and Jeavons (1994).

Photosensitive epilepsy is amenable to AED therapy, especially sodium valproate and in some cases levetiracetam. Additional measures in the rare circumstance of analogue television viewing include the use of polarised glasses as well as precautions when watching television; drug therapy is unnecessary if the patient can avoid the stimulus by appropriate measures such as watching television at a distance of 2–3m and wearing dark glasses. Self-induced photogenic or pattern-induced seizures (Harding and Jeavons 1994) are difficult to control. Fenfluramine has been used in such cases together with antiepileptic agents, with some measure of success (Aicardi 1994).

STARTLE EPILEPSY AND MOVEMENT-INDUCED SEIZURES

Startle epilepsy is relatively common in children with early-acquired brain damage (Arzimanoglou et al. 2004). Many patients have congenital hemiparesis but others have diffuse brain dysfunction including Down syndrome. Seizures are usually tonic, involving one or both sides, and follow the startle reaction induced by sudden unexpected stimuli (Chauvel et al. 1992). Sound is often particularly effective but proprioceptive or exteroceptive stimuli can also be the cause and some patients respond electively to particular stimuli. Most cases begin in infancy and many patients have mild to severe intellectual disability. However, Manford et al. (1996b) found that about half the patients with the condition have normal intelligence and a normal neurological profile, and these cases may be associated with cortical dysplasia rather than destructive lesions. Treatment with AEDs is utilised but the occurrence of startle seizures usually implies difficult-to-treat epilepsy. Such seizures should be distinguished from excessive startle disease and from paroxysmal dystonias (see Chapter 19 on Movement Disorders). Touch epilepsy (Ricci et al. 1995) and movement-induced epilepsy are rarer than startle epilepsy.

OTHER ‘REFLEX’ EPILEPSIES

A host of specific stimuli can induce seizures. These include sound, music, and complex and sometimes specific cognitive activities (Wilkins and Lindsay 1985). Eating epilepsy (Fiol et al. 1986) may occur with temporal lobe lesions. Reading epilepsy is a well-defined syndrome but rare in childhood (Wolf 1994; Wolf and Inoué 2005). Seizures induced by immersion in hot water (bathing epilepsy) (Roos and Van Dijk 1988) should be distinguished from syncope (Stephenson 1990), which is probably more common. Other unusual precipitating factors have been reviewed by Wilkins and Lindsay (1985), Aicardi (1994), Arzimanoglou et al. (2004) and Wolf et al. (2004).

The genetic background of reflex seizures and epilepsies is heterogeneous and mostly unknown with no major gene identified in humans (Italiano et al. 2016).
While the cause of epilepsy in approximately one-third of all children with epilepsy remains unknown (van Campen et al. 2013) there is growing recognition that some cases may have an underlying immunological basis. Careful studies of blood, CSF and neural tissue in cryptogenic patients reveal the presence of auto-antibodies to specific neural membrane proteins (Aarli 1980). The first clinical recognition of the potential importance of this mechanism occurred when glutamate receptor antibodies (GluR3) were identified in patients with Rasmussen encephalitis (Rogers et al. 1994). One demonstrated a favourable response to plasma exchange suggesting that this condition was immune-responsive (Vincent et al. 2011). The number of disorders now believed to be immune-related has increased significantly and includes several important clinical disorders (Wright and Vincent 2016). Antibodies associated with neurological disorders and epileptogenesis usually target extracellular loci on neuronal cell membranes and are best identified through assessment of the patient’s immunoglobulin to the native receptor.

**Limbic Encephalitis**

Originally described as a paraneoplastic condition, limbic encephalitis is currently acknowledged to also be an important non-neoplastic entity that is more prevalent and immune-responsive than the neoplastic subtype. Affected patients typically present with cognitive confusion, affective disturbances, amnesia and seizures that primarily involve the temporal lobes. Temporo-medial T2 fluid attenuated inversion recovery (FLAIR) signal abnormalities are common on MRI while histopathological tissue examination reveals lymphocytic-micronodular encephalitis involving mesial temporal structures. A normal MRI is observed in almost half of affected patients and PET may be more sensitive for detection. Temporal hypermetabolism appears early in the course of the illness while hypometabolism occurs later in the course. EEG abnormalities are usually observed in the temporal lobes. Evolution of limbic encephalitis to chronic temporal lobe epilepsy and hippocampal sclerosis is known to occur in adults but has also been described in children (Kröll-Seger et al. 2009). Patients affected with limbic encephalitis share important similarities in clinical presentation but specific auto-antibodies are associated with variation in clinical phenotype.

**Voltage-Gated Potassium Channel (VGKC)-Antibody Receptor Encephalitis**

This entity is the most common form of limbic encephalitis. Most of the antibodies thought to be detected against the VGKC receptors are directed toward other proteins including LG11 (leucine rich glioma inactivated), CASPR2 (contactin associated protein like 2) and contactin.

The onset of VGKC-antibody encephalitis is more prevalent in the adult years where it may present with an acute or subacute onset. Severe permanent amnesia will result unless prompt immunotherapy is provided. Hyponatremia due to inappropriate antidiuretic hormone (ADH) secretion is common while REM sleep abnormalities, autonomic dysfunction, ataxia and neuropathic pain occur more rarely. Seizures of extratemporal origin consisting of limb posturing and facial grimacing have been reported in rare circumstances (Irani et al. 2008). The occurrence of VGKC-antibody receptor encephalitis may be more prevalent in children than previously recognised. A retrospective review of children with encephalitis of unknown origin presenting in status epilepticus detected VGKC antibodies in four out of ten cases as compared to one out of 69 paediatric controls (Suleiman et al. 2011). Testing for infectious causes was negative.

To assess the clinical and immunological findings in children with VGKC, Hacozen et al. (2015) retrospectively reviewed the medical records of 39 paediatric patients. They concluded that positive voltage-gated potassium channel-complex antibodies did not indicate a specific clinical syndrome in children but appeared to be a nonspecific marker of neuroinflammatory conditions, particularly encephalopathy. In many paediatric patients, the specific neuronal target remains unidentified in voltage-gated potassium channel-complex-mediated encephalopathy, and it is possible that antibodies bind to intracellular epitopes of the voltage-gated potassium channel-complex and arise secondary to other inflammatory aetiologies (Hacozen et al. 2015).

**N-Methyl-D-Aspartate Receptor (NMDAR)-Antibody Encephalitis**

While this disorder occurs in all age groups, it is more common in childhood than VGKC-antibody receptor encephalitis. Onset is typically insidious with gradual deterioration in psychiatric and cognitive functioning as the cardinal presenting signs. Seizures eventually manifest in the majority of cases and sleep disturbances are common. Many patients experience anxiety and agitation during the prodromal period but often progress to coma, autonomic dysfunction, dyskinesia and hypoventilation. Girls are over-represented and may show a different initial clinical presentation from boys who are more likely to present with focal seizures and show a delay in psychiatric symptoms. However, the ultimate clinical evolution and outcomes are similar for both sexes (Viacoz et al. 2014).

A large group of 81 patients with NMDAR encephalitis who were positively identified via referral to a single institution over an 8-month period included 32 children (Florance et al. 2009), eight of whom were diagnosed at a single institution. While ovarian teratomas were found in 56% of women over age 18 years and 31% of girls younger than age 18 years,
no male had a tumour. Paediatric patients ranged in age from 23 months to 18 years. Younger patients had the lowest likelihood of harbouring an underlying tumour. Children were also more likely to evidence more subtle psychiatric signs such as irritability and temper tantrums, and to have subclinical seizure activity. Relapse after treatment occurred in a small proportion of cases.

Glutamate Receptor Epsilon 2 Antibody Encephalitis

This condition is diagnosed by demonstrating antibodies to glutamate receptor epsilon 2 subunits utilising western blotting or recombinant antigen. Despite the antibody response, its immunological target is identified as the NMDAR NR2B subunit expressed in cell lines. While rare, most cases are reported in children (Sakuma 2009). Affected patients typically develop refractory repetitive focal seizures (AERRPS) following an acute infectious process. Most cases either remit spontaneously or are immune treatment-responsive but permanent cortical atrophy and intellectual impairment may occur (Ito et al. 2005).

Glutamic Acid Decarboxylase (GAD) Antibody Encephalitis

The existence of this disorder is somewhat controversial as the target of GAD antibodies is intracellular rather than located on the cell surface. However, apart from limbic encephalitis, GAD antibodies have been identified in other neurological conditions including cerebellar ataxia and stiff-person syndrome (Saiz et al. 2008). Regardless of their significance, GAD antibodies serve as a useful marker of limbic encephalitis. There are now reports of patients with drug-resistant focal epilepsy and anterograde amnesia being diagnosed with this disorder (Mata et al. 2008). Cases of limbic encephalitis with high GAD antibody titres are associated with the development of temporal lobe epilepsy and cognitive disturbance in conjunction with characteristic MRI findings.

Limbic Encephalitis Associated with AMPAR Receptor Encephalitis

This rare disorder occurs primarily in adult women with tumours. It responds well to a combination therapy regimen including tumour and immune suppression but may have a relapsing course. Psychosis has been described (Graus et al. 2010).

Limbic Encephalitis Associated with GABA<sub>n</sub>R Antibodies

Seizures are common in this disorder which occurs in patients both with and without tumours. Affected patients respond favourably to immunotherapy (Lancaster et al. 2010).

OUTPATIENT PAEDIATRIC IMMUNE EPILEPSIES

While immune-related mechanisms are increasingly recognised in paediatric patients with non-infectious encephalitis and temporal lobe epilepsy, there is accumulating evidence that immune dysfunction may also play a role in patients with cryptogenic epilepsy without encephalitis. Indeed, this awareness has suggested that a new aetiology of ‘autoimmune epilepsy’ be considered in the evaluation of cryptogenic cases (Quek et al. 2012). The recognition of an immune-related basis has obvious treatment implications particularly as the presence of antibodies has been associated with resistance to AEDs. While it is not yet possible to diagnose immune-related epilepsy on clinical or electrographic criteria, correlational studies hold promise for early recognition and treatment.

Approximately one-sixth of unselected adults with focal epilepsy of unknown cause and with temporal lobe epilepsy and hippocampal sclerosis demonstrate a variety of serum auto-antibodies (Ekizoglu et al. 2014). In comparison to sero-negative controls, patients with positive auto-antibodies evidence significantly higher rates of psychosis and white matter changes on MRI. Affected individuals also show a trend toward higher seizure frequency and AED non-responsiveness. Identified antibodies include GLY-R, CASPR-2, NMDAR and the VGKC complex. Of note, the GLY-R antibody also occurs in patients with progressive encephalomyelitis with rigidity and myoclonus (Hutchinson et al. 2008). The high association of psychosis in this cohort suggests that all patients with focal seizures and psychosis should be screened for the presence of serum auto-antibodies.

Antibodies to neuronal antigens have also been identified in children with new-onset seizures, typically focal seizure disorders (Suleiman et al. 2013b). Eleven of 114 children (9.7%) screened for the presence of serum auto-antibodies to a range of antigens were found to be sero-positive. Auto-antibodies were detected to the VGKC complex, CASPR-2 and NMDAR receptors. A wide variety of epileptic disorders were represented including specific electroclinical syndromes such as Dravet, Lennox–Gastaut and Panayiotopoulos syndromes and BECTS. However, there were no demographic or clinical features that differentiated seropositive from seronegative patients.

TREATMENT OF IMMUNE-MEDIATED SEIZURES

Similar to other CNS disorders involving autoimmune mechanisms, aggressive intravenous corticosteroid therapy and immune globulin are first-line treatments. Plasma exchange has been employed in some patients. Although a favourable response within the first week of treatment occurs in some patients, most do not respond as rapidly. For this reason, medications that cross the blood brain barrier including...
Rituximab which targets B cells, and cyclophosphamide have been advocated for resistant patients.

Consensus guidelines and controlled trial data on treatment are lacking but diagnostic and treatment guidelines have been published (Suleiman et al. 2013a; Lim et al. 2015; Graus et al. 2016). These guidelines contain diagnostic criteria for autoimmune encephalitis/epilepsy based on para-clinical and clinical features even without a positive antibody result. This is important (Wright and Vincent 2017) as a recent study demonstrated that some paediatric autoimmune encephalitis patients without neuronal antibodies detected in the serum or CSF can make a significant clinical response to immunotherapy (Hacohen et al. 2013). In the future, it may become possible to target specific antigens to achieve a more optimal outcome.

Status epilepticus is defined as ‘an epileptic seizure that is sufficiently prolonged or repeated at sufficiently brief intervals so as to produce an unvarying and enduring epileptic condition’ (Gastaut 1973). There are two major categories of status epilepticus: convulsive status (generalised or localised), and non-convulsive, which is subdivided into partial nonconvulsive status and generalised nonconvulsive status (also incorrectly known as ‘petit mal status’). Electrical status epilepticus during slow sleep (ESES) is a separate entity that is included for discussion in this section.

The precise definition of status epilepticus is currently undergoing critical re-examination. In the ‘classic’ definition, status epilepticus is diagnosed whenever there is either continuous seizure activity or recurrent seizures without returning to baseline for at least 30 minutes (Commission 1993). This definition is based on experimental and clinical evidence that continuous seizure activity occurring for this amount of time increases the risk of structural brain damage, particularly hippocampal sclerosis (Van Landingham et al. 1998).

This ‘injury-based’ definition is useful for epidemiological investigation but fails to more narrowly account for the critical stage of evolving status epilepticus whereby inhibitory mechanisms controlling seizure termination are rendered inoperative. While seizures in most children last less than 2 minutes, approximately 25% are more prolonged (Shinnar et al. 2001). The longer the seizure duration, the less likely the seizure will stop within the next few minutes. This recognition suggests a second definition (‘impending’ status epilepticus) in biologically predisposed children, and further indicates that earlier intervention should be instituted, perhaps as early as the 5-minute mark (Shinnar and Hesdorffer 2010). As the median time from seizure onset to arrival in the emergency department is documented to be 33 minutes (Seinfeld et al. 2014) it is imperative that prehospital treatment protocols are established.

A more recent initiative to re-define and re-classify status epilepticus has been undertaken by an ILAE Task Force (Trinka et al. 2015). The Task Force re-examined the concept of status epilepticus with regard to recent evidence suggesting that seizure duration was crucial for its definition. Two time points in seizure development were distinguished – an early one (t1) beyond which a seizure was clinically regarded as being continuous, and a later point (t2) defined as the time point when the risk of structural brain injury increased.

The Task Force further sought to classify status epilepticus on the basis of four clinical axes:
1. Semiology-motor versus non-motor symptoms;
2. Aetiology;
3. Electroencephalography;
4. Age.

In proposing these classification criteria, the Task Force acknowledged that a precise determination is not always possible, particularly at first presentation. The practical advantages of this novel classification schema were also not specified.

**CONVULSIVE STATUS EPILEPTICUS**

**TONIC–CLONIC STATUS EPILEPTICUS**

Convulsive tonic–clonic status epilepticus may present as a succession of tonic–clonic seizures without recovery of consciousness between individual episodes or as a single, prolonged convulsive seizure, most often of a purely clonic type. The duration necessary to diagnose convulsive status epilepticus is variably estimated (Shorvon 1994; DeLorenzo et al. 1999; Lowenstein et al. 1999; Trinka et al. 2015). The difficulties for a universally accepted definition based on duration derive directly from the fact that in everyday clinical practice, a treatment is applied to all seizures lasting longer than 5 or 10 minutes, while changes in metabolism and vital functions usually appear after 30 minutes. If a duration component is included in the definition of status – to evaluate new drugs or for epidemiological studies – this should be the minimum duration (5 minutes) after which medical care is usually applied (Arzimanoglou et al. 2004; Trinka et al. 2015). Care should be taken to exclude the postictal period. Lowenstein et al. (1999) discussed the need for a revised, more operational, definition of status epilepticus. The findings by Theodore et al. (1994), who evaluated the overall duration of the convulsive part of a ‘typical’ isolated seizure as being slightly more than 1 minute and rarely in excess of 2 minutes, support the operational definition for status proposed by Lowenstein et al. (1999).

Exclusively or predominantly unilateral seizures are more common in childhood than bilateral convulsive status.
(Aicardi and Chevrie 1983). In most patients, clonic jerks may wax and wane in intensity and the involved territory may vary from moment to moment as does the rhythm of the jerks, which, generally, are not synchronous in the affected segments.

Convulsive status epilepticus is often preceded by a premonitory stage of serial seizures, during which treatment is particularly effective (Shorvon 1994; Pellock et al. 2004). Established convulsive status can be divided into an early or compensated stage during which physiological mechanisms are sufficient to meet the metabolic demands and cerebral tissue is protected from hypoxic or metabolic damage, and a stage of decompensation when compensatory mechanisms break down and brain damage may occur. As the duration of status increases, the clinical seizures often become less conspicuous, eventually evolving into unresponsiveness with minimal jerks or without visible movements, while autonomic changes become more prominent with resulting respiratory and circulatory impairment, often associated with hyperthermia.

The EEG features of convulsive status epilepticus are variable. Generalised paroxysmal activity, as described in adults (Treiman 1993; Shorvon 1994), is less common in children than asymmetrical slow waves irregularly interspersed by spikes and sharp waves. In cases of prolonged status epilepticus, episodes of ‘flattening’ of the EEG frequently occur. Periodic generalised or lateralised epileptiform discharges may be seen in very long episodes and indicate a poor prognosis (Garg et al. 1995).

The term focal or partial convulsive status epilepticus (see below) applies only to those cases in which convulsive activity remains localised to a restricted segment on one side of the body without generalisation or diffusion to the whole of the affected side. When segmental myoclonic jerks are continuous, the condition is known as epilepsy partialis continua. In such instances, intermittent somatomotor seizures may start from the area of the body that is involved by permanent myoclonus; this association defines the Kojenikowski syndrome.

Convulsive status epilepticus is a major complication of epilepsy and remains a dangerous condition, even though its prognosis has improved in past decades. The pathogenesis of convulsive status epilepticus and of its consequences has been extensively studied (see Brown and Hussain 1991a; Shorvon 1994; Wasterlain and Treiman 2006). It involves multiple factors that include progressive hypoxia, substrate failure, ATP depletion and intracellular acidosis. These, in turn, eventually produce a fall in cardiac output, hyperkalaemia, metabolic acidosis and cerebral oedema, all of which produce sequelae, but fortunately only rarely appear when convulsive status lasts less than 90–120 minutes (Aicardi and Chevrie 1983). The role of excitotoxicity due to excessive activation of the excitatory neurotransmitters, especially glutamate (glutamate cascade), with consequent massive influx of Ca²⁺ ions in neurons leading to apoptosis or cell necrosis is now considered to be the primary deleterious phenomenon. Blocking this excitotoxic cascade may be important for neuroprotection (see corresponding chapters in Wasterlain and Treiman 2006).

Systemic factors also play an important role in the production of sequelae. However, it seems that the epileptic activity itself, in the absence of systemic complications, can generate brain lesions, especially in the temporal lobe (Holmes 2002; Lado et al. 2002; Wasterlain and Treiman 2006), probably at least in part by a mechanism of glutamate-induced excitotoxic damage.

The incidence of convulsive status epilepticus ranges from 3% to 16% of all patients with epilepsy (Hauser 1994; Wu et al. 2006) in childhood series of epilepsy. Contrary to adults, status is often the first epileptic presentation in infants and children. This was found in 77% of the 239 patients in the Aicardi and Chevrie (1970) historical series. Similarly, 24% of all children with a first febrile seizure before the age of 10 years in Minneapolis (Hauser 1983), presented with convulsive status epilepticus. Convulsive status epilepticus is especially common in the first 2 years of life, and approximately 75–85% of cases occur before the age of 5 years (Aicardi and Chevrie 1970). After age 3 years, the annual frequency remains stable at around 3–5% until age 15 (Aicardi and Chevrie 1970).

The overall incidence of convulsive status epilepticus has not declined. A prospective population-based study performed by the North London Status Epilepticus in Childhood Surveillance Study (NLSTEPSS) group enrolled 226 children, 176 of whom had had a first ever episode of convulsive status epilepticus (Chin et al. 2006). Ninety-eight children (56%) were neurologically healthy before their first episode, and 56 (57%) of those children experienced a prolonged febrile seizure. Eleven (12%) children with their first febrile convulsive status epilepticus had acute bacterial meningitis. A conservative estimation of 1-year recurrence of convulsive status epilepticus was 16% (10–24%). Case fatality was 3% (2–7%).

Convulsive status epilepticus can be symptomatic, resulting from underlying CNS diseases that may be acute, such as trauma, vascular collapse, electrolyte disorders, meningitis or encephalitis, or progressive such as brain tumours or progressive encephalopathies; remote symptomatic, due to chronic progressive brain lesions such as glial scars or late sequelae of infectious or anoxic events; or cryptogenic, occurring at the onset of the epilepsy or in the course of a recurring seizure disorder (Hauser 1993). In this case, interruption of treatment is often a precipitating event. It may also represent an occasional seizure, in practice mostly a febrile seizure that fails to stop for unknown reasons. Such cases differ from common febrile seizures only in duration, not in nature.

Knowledge about the aetiology potentially underlying status epilepticus may help to guide diagnostics and eventually influence treatment decisions. Some epilepsy syndromes engender a very low risk of convulsive status epilepticus (Bast 2014) while it is much higher in others (Neubauer and Hahn 2014). Currently, it appears that a large majority of cases of status observed in industrialised countries are of symptomatic origin especially in infants. The dramatic decrease in the frequency of cryptogenic status probably results in large part from a better and more prompt treatment of epilepsy and
of incipient febrile status. The improved outlook for status should not lead to underestimation of the potential risks or failure to instigate immediate vigorous therapy.

In a prospective cohort of 1382 children with convulsive status epilepticus, average age at onset was 3.4 years and seizure duration ranged between 21 and 60 minutes (Singh et al. 2010). The most common presentation was a cryptogenic febrile convulsion. The most common acute precipitating event was CNS infection while cortical malformation was the most common remote symptomatic aetiology. Neuroimaging studies provided a diagnosis in only 30% of cases. Continuous EEG provided evidence of nonconvulsive status in five patients (4%) underscoring the important role of continuous EEG monitoring in all children presenting with status epilepticus.

A once common syndrome of convulsive status epilepticus is the hemi-convulsion–hemiplegia or H–H syndrome (Gastaut et al. 1960; Arzimanoglou and Dravet 2003), characterised by the occurrence, in the course of a febrile disease in a child of less than 4 years of age, of prolonged clonic seizures with a marked unilateral predominance. This phase is followed by long-lasting hemiplegia, and after 1 to several years, partial epilepsy, with seizures originating in the hemisphere contralateral to the hemiplegia (hemi-convulsion–hemiplegia–epilepsy or HHE syndrome); 85% of affected children are intellectually deficient. Computed tomography (CT) and MRI are characteristic showing initial oedematous swelling of one hemisphere followed by global atrophy independent of any vascular territory (Fig. 16.21). The incidence of the syndrome has declined considerably over the past 20 years in industrialised countries, probably because of prompt treatment with benzodiazepines; however, cases are still frequent in developing countries.

**Outcome of Tonic–Clonic Status Epilepticus**

The quality of available studies on the outcome of convulsive status epilepticus is influenced by a number of factors: prospective or retrospective; population-based or hospital-based; duration of follow-up, short-term versus long-term outcome; aetiological groups considered; and definition of variables, particularly those related to morbidity issues. In an excellent methodological review (Raspall-Chaure et al. 2006) of 1727 potentially eligible studies, only 63 met the criteria for entry into the review. Population-based studies scored better than hospital-based ones.

The outcome of convulsive status epilepticus has improved considerably over the past four decades. Aicardi and Chevrie (1970) found a mortality rate of 11% in a series of 239 children younger than 15 years. More recently, long-term mortality after a first episode of afebrile status was evaluated in a population-based retrospective cohort study in the Rochester Epidemiology Project Records (Logroscino et al. 2002). In this study, 19 patients (13%) were aged below 1 year, and 35 (24%) were between the ages of 1 and 19 years. At 10 years, the cumulative mortality among 30-day survivors was 43%

(62 deaths); mortality among patients 65 years and older was 76%, but in the under 1 year and 1–19 year age groups, respectively, it was only 5% and 2%.

Case fatality for first ever episodes of convulsive status epilepticus was 3% in the NLSTEPSS prospective, population-based study of convulsive status epilepticus in childhood (Chin et al. 2006). Three children had acute bacterial meningitis, one had glutaric aciduria Type 1, and three had progressive neurodegenerative disorders that, despite investigation, did not have syndromic diagnoses. The most common cause of convulsive status epilepticus in this series was a prolonged febrile seizure, which is probably associated with low morbidity and mortality. In a subgroup analysis of 95 children with first ever episodes of convulsive status epilepticus associated with fever (temperature >38°C at presentation), 11 children (12%, 95% confidence intervals 6–18%) had acute bacterial meningitis and seven (8%, 95% confidence intervals 2–13%) had a viral CNS infection. The remaining children had either prolonged febrile seizures (n=56, 59%) or a previous neurological abnormality with a febrile intercurrent illness (n=21, 22%).

According to the Raspall-Chaure et al. (2006) systematic review, short-term mortality after convulsive status epilepticus is 2.7–5.2% if studies with the highest quality scores are considered. If only children admitted to ICU are included, mortality is estimated at between 5% and 8%.
Mortality rates in children have decreased, probably due to earlier administration of benzodiazepines treatment and better intensive care facilities. Most paediatric deaths occur between the ages of 1 and 4 years with underlying aetiology being the main determinant; death during status is typically associated with respiratory or cardiac arrest. Mortality rates are higher for acute symptomatic status epilepticus in new neurological conditions (encephalitis, trauma) as compared to convulsive status epilepticus in relation to a first seizure in idiopathic epilepsy or febrile status epilepticus.

Long-term complications include secondary epilepsy, cognitive deterioration of variable degree, behavioural problems and focal neurological deficits. Available figures are difficult to interpret because the sequelae may represent complications of the underlying condition rather than the status itself, or they may have antedated the convulsive episode. Neurocognitive assessment is often not available and eventual sequelae are not always reported. Cognitive and neurological deficits are often comorbid with the epilepsy. Quality of the studies and study design are also important determinants. When considering only the highest-scored studies, neurological sequelae are reported in fewer than 15% of children. Rates as high as 50% are reported in younger children, an age range with a higher incidence of acute symptomatic convulsive status epilepticus.

In the classic series of Aicardi and Chevrie (1970), epilepsy persisted after the episode of status in 44% of children, compared with an incidence of 23% with epilepsy before the status. Outcome in symptomatic cases is significantly poorer than in cryptogenic cases. Other unfavourable factors include younger age and longer duration of convulsive status. The proportion of cases with neurological or cognitive sequelae has been considerably reduced in more recent series. The incidence of H–H syndrome, which was once common, has decreased in industrialised countries. However, hippocampal sclerosis may develop after an episode of status. Longitudinal studies of cohorts with prolonged febrile seizures (see FEBSTAT studies in the Febrile Convulsions section) will allow a more comprehensive characterisation of outcomes.

The risk of recurrent status following a first episode of convulsive status epilepticus has also decreased. Recurrence is more frequent in cases with an underlying chronic or degenerative neurological condition. According to Shinnar et al. (1997), new episodes occur mainly in symptomatic cases and in children with abnormal neurological signs that predate the first status; these latter children account for 88% of the recurrences. Idiopathic or febrile status epilepticus in typically developing children is largely an isolated event. The recurrence risk for convulsive status in idiopathic cases was only 4% for initial idiopathic status and 3% for febrile status, but this increased to 11% for cases of acute symptomatic status and to 44% for remote symptomatic cases. In the NLSTEPSS study (Chin et al. 2006) a substantial proportion (16%) of children with first ever convulsive status epilepticus had a recurrence within a year, and those with a previous neurological abnormality were more likely to have a recurrence ($P=0.04$).

### Treatment of Tonic–Clonic Status Epilepticus

The treatment of convulsive status epilepticus in hospital is summarised in Table 16.14 (see also Brown and Hussain 1991b; Shorvon 1994; Arzimanoglou et al. 2004; Treiman and Walker 2006; Wasterlain and Treiman 2006).

Treatment is indicated in all cases after exclusion of pseudo-status epilepticus. The two objectives of treatment are to quickly stop seizure activity and to maintain adequate respiratory, cardiovascular and metabolic functions. Clearly, the prevention of respiratory and circulatory complications has a major place in the prevention of residual damage. There is, however, experimental and clinical evidence that convulsive activity alone is probably harmful. Efforts should therefore be made to arrest the status before systemic signs intervene (see evolution of the concepts in reviews by Meldrum 1978; Aicardi and Chevrie 1983; Brown and Hussain 1991a; Wasterlain and Treiman 2006). Prompt intervention is imperative because the outcome is related to the duration of the convulsive event and because therapy becomes progressively less efficacious and more hazardous the longer the seizures continue (Shorvon 1994; Chin et al. 2006).

In the premonitory and early phases of serial seizures and incipient status (usually outside the hospital) emergency treatment is based on intravenous, rectal, buccal or nasal administration of benzodiazepines. In a prospective randomised study (Laht et al. 2000), seizures were controlled more quickly with intravenous diazepam than with intranasal midazolam, although midazolam was as safe and effective. The overall time to cessation of seizures after arrival at hospital was faster with intranasal midazolam than with intravenous diazepam.

In another prospective randomised trial (McIntyre et al. 2005), buccal midazolam was more effective than rectal diazepam for children presenting to hospital with acute seizures and was not associated with an increased incidence of respiratory depression. Chamberlain et al. (1997) reported that intramuscular midazolam was an effective anticonvulsant for children with motor seizures. Compared to intravenous diazepam, intramuscular midazolam resulted in more rapid cessation of seizures because of more rapid administration. Intravenous lorazepam has a more prolonged effect and may be equal or superior to phenytoin (Treiman and Walker 2006).

Dieckmann (1994) and Alldredge et al. (1995) have adduced evidence that prehospital treatment reduces significantly both the duration of seizures and the likelihood of recurrent seizures in the emergency department, and is reasonably safe. They did not encounter respiratory depression that has led other authors (e.g. Phillips and Shanahan 1989) to advise against emergency benzodiazepine treatment.

Recent availability of easier to administer rescue drugs (buccal or nasal midazolam versus rectal diazepam) could modify clinical practice. However, the first need today remains to establish the acceptance of available therapies among those...
treating children (Arzimanoglou et al. 2014). Rescue medication unavoidably involves parents, family friends and schoolteachers. Results of a health care providers survey have identified several clear gaps that need to be addressed: clearer guidance that spans all settings of care, greater dissemination of such guidelines across the chain of care, more open communication and better links between health care providers and schools, and systematic training of all relevant caregivers on the appropriate management of prolonged convulsive seizures (Arzimanoglou et al. 2014). Currently available evidence allows us to confidently prescribe available rescue drugs when indicated. Once a child is identified as being at risk, time for rescue administration must be determined on an individual basis. The ’5 minutes’ represent a reasonable, and easy to teach, reference frame. The treating physician, who will also have to consider the habitual duration of seizures of a patient, can then adapt it and appropriately advise the caregivers (Arzimanoglou and Lagae 2013).

During convulsive status epilepticus the patient should be placed in the lateral prone position and the airway cleared. During transportation, the same position should be maintained. In the hospital, ICU treatment is preferable. Maintenance of adequate oxygenation and circulation is clearly essential. Hypoxia is usually more severe than anticipated on clinical grounds, and ventilatory support should not be delayed. Pressor therapy (dopamine) is often necessary in protracted status. Any hypoglycaemia, acidosis and electrolyte disorders should be corrected. Regular monitoring, including

*bFamilies and caregivers of children with epilepsy known to be at risk of convulsive status epilepticus (or serial seizures) should be educated on how to administer either buccal midazolam or rectal diazepam early (pre-hospital setting), in situations of unusually prolonged seizures. |
*cLorazepam has a longer half-life than diazepam and no long-life metabolite. It may be less of a respiratory depressant than diazepam, especially in patients who have previously received phenobarbitone. |

**Chapter 16 Epilepsy and Other Seizure Disorders**

923
if necessary oximetry, central venous pressure and, if possible, continuous EEG, should be established and a rapid search for an underlying cause should be performed following immediate anticonvulsant drug administration. The possibility of pleocytosis due to status epilepticus should be kept in mind when meningitis is suspected. Transient CT and MRI changes (Henry et al. 1994) resulting from convulsive activity can wrongly suggest a lesional cause.

For detailed information on drug treatment, the reader is referred to Shorvon (1994) and Wasterlain and Treiman (2006). Overtreatment is dangerous as anticonvulsant drugs in high doses can induce respiratory depression and hypotension. Maintenance treatment should therefore, be substituted for acute therapy as soon as possible. In exceptional cases (Gorman et al. 1992;Alexopoulos et al. 2005; Schrader et al. 2013; Oderiz et al. 2015) and for rather specific aetiologies neurosurgical treatment has been used successfully.

GENERALISED TONIC STATUS EPILEPTICUS

Generalised tonic status, although it is a form of convulsive status epilepticus, will be studied with nonconvulsive status epilepticus with which it is often associated and shares aetiological factors.

MYOCLONIC STATUS EPILEPTICUS

Myoclonic status epilepticus may be observed following hypoxia due to cardiac arrest (Shorvon 1994) or in the late stage of convulsive status (Treiman 1993). A subtle form occurs in children with congenital nonprogressive encephalopathies (Dalla Bernardina et al. 1992) or with Angelman syndrome (see Chapter AA to supply). Some myoclonic activity, usually erratic in type, is common in nonconvulsive status epilepticus.

PARTIAL CONVULSIVE STATUS EPILEPTICUS (RASMUSSEN ENCEPHALITIS)

Partial convulsive status epilepticus (epilepsia partialis continua) may be a feature of localised static brain damage involving the motor strip. Focal dysplasia (Kuzniecky et al. 1988; Kuzniecky and Powers 1993) and hemimegalencephaly (Fusco et al. 1992) are common causes but destructive lesions are sometimes encountered (Cockerell et al. 1996). Epilepsia partialis continua may also be a feature of progressive conditions, including indolent tumours, strokes associated with mitochondrial diseases (Chevrie et al. 1987; Antozzi et al. 1995), subacute measles encephalitis in immunosuppressed children (Chapter 11) and Alpers polydystrophy (Chapter 10). Marked hyperglycaemia without ketosis may cause focal status in adults. A similar syndrome of focal spinal myoclonus with extreme hyperglycorrhachia due to accidental dislocation of a venous catheter into a perispinal vein has been reported in a neonate (Bass and Lewis 1995).

A frequent cause of focal convulsive status epilepticus is Rasmussen encephalitis (Rasmussen and Andermann 1989; Hart 2004), a slowly progressive disease that involves exclusively or predominantly one hemisphere, especially the frontotemporal region. Focal seizures are the first symptom and epilepsy partialis continua develops at some stage in over half the patients. Progressive hemiplegia, aphasia, hemianopia and intellectual deterioration become apparent after months or years of seizure activity. The EEG shows diffuse paroxysmal activity and a slow background tracing over the involved hemisphere. Neuroimaging shows progressive atrophy that usually begins in the frontotemporal area and later spreads to the whole hemisphere and occasionally to the opposite side.

Advances in neuroimaging suggest that progression of the inflammatory process seen with MRI might be a good biomarker in Rasmussen encephalitis. Pathologically, perivascular cuffing and glial nodules are present in areas of neuronal loss and glial proliferation (Vinters and Wasterlain 1996). The disorder may be associated with the presence of antibodies to the R3 glutamate receptors. Although these have been shown experimentally to be capable of stimulating the receptors and might thus be a cause of the epilepsy, their role seems limited. AED treatment of the disorder is often ineffective and surgery is often necessary (Hart 2004). Only large sections (hemispherectomy) are effective in the majority of cases (Andermann et al. 1992; Vining et al. 1993, 1997).

Long-term outcome after surgery was reported in 23 patients with Rasmussen encephalitis by a Brazilian epilepsy team (Terra-Bustamante et al. 2009). In this retrospective study patients were divided into two groups: fast evolution and slow evolution to hemiparesis and epilepsy partialis continua. According to the authors these groups may represent different Rasmussen encephalitis substrates. Fourteen patients achieved satisfactory seizure control, three had a partial response to surgery, and five were unchanged. All patients with left-side involvement presented with language disturbance that did not improve after surgery in 66.6% of patients. Cognitive evaluation showed that the majority of the patients did not have any significant improvement, and 38.1% had cognitive deterioration after surgery. For many patients, families, and doctors, choosing the right time to undertake surgery is a therapeutic dilemma (Varadkar et al. 2014). Decisions of whether or when surgery should be undertaken are challenging in the absence of a dense neurological deficit, and vary by institutional experience. Further, the optimum time for surgery, to give the best language and cognitive outcome, is not yet well understood.

Corticosteroid and immunoglobulin treatment can be partly effective (Chinchilla et al. 1994; Hart et al. 1994) but seem only to slow rather than halt disease progression in Rasmussen encephalitis, without changing the eventual outcome (Varadkar et al. 2014). Encouraging preliminary results of plasmapheresis (Prasad et al. 1996) have not been confirmed or are transient. The disorder appears less severe in adolescents (Hart et al. 1997). A study in 13 patients demonstrated that most of the brain injury occurs during the
first 8–12 months of the disease (Bien et al. 2002). A viral infection has been proposed, and both cytomegalovirus and Epstein–Barr virus have been suspected without definite proof. Herpes simplex virus Type 2 has been reported as the cause of smouldering encephalitis with temporal lobe epilepsy in two adult patients with many features reminiscent of Rasmussen syndrome (Cornford and McCormick 1997).

A European Consensus Statement on formal diagnostic criteria and a treatment algorithm was published in 2005 (Bien et al. 2005).

**NONCONVULSIVE STATUS EPILEPTICUS**

Nonconvulsive status epilepticus almost always occurs in children with known epilepsy (Porter and Penry 1983; Shorvon 1994). It may belong to several epilepsy syndromes. A clear-cut differentiation, on clinical and even electroclinical grounds, between generalised and partial nonconvulsive status epilepticus is difficult and often arbitrary (Arzimanoglou et al. 2004; Sutter and Kaplan 2012). The definition depends upon the criteria to be applied (type of seizures and/or type of epilepsy and/or characteristics of EEG abnormalities and/or actiology). Beniczky et al. (2013) proposed a unified terminology and classification system for NCSE, using, as a template, the standardised computer-based organised reporting of EEG (SCORE). This approach integrates the terminology recently proposed for the rhythmic and periodic patterns in critically ill patients, the electroclinical classification of NCSE (type of NCSE) and the context for the pathologic conditions and age-related epilepsy syndromes.

**GENERALISED NONCONVULSIVE STATUS EPILEPTICUS (RING CHROMOSOME 20)**

Generalised nonconvulsive status epilepticus may occur following an initial convulsive seizure (Cascino 1993) or can culminate in a generalised convulsion. It is characterised clinically by variable degrees of clouding of cognitive processes, from simple slowing of ideation to complete unconsciousness, and electrically by bilateral discharges of spike–wave complexes. Various terms have been used in the literature (absence status, petit mal status, spike–wave stupor, epilepsy minoris continua, or epileptic twilight state), none being entirely satisfactory.

Two subgroups are recognised, although their clinical and even electroclinical differentiation is not always evident. Typical absence status occurs in the course of idiopathic generalised epilepsy; atypical absence status occurs largely in secondarily generalised epilepsies, specifically in Lennox–Gastaut and Dravet syndromes and some of the myoclonic epilepsies, including the spectrum of epilepsies with predominantly myoclonic–astatic seizures. They are difficult to differentiate as the EEG discharge is infrequently of a classic, regular, 3Hz type reminiscent of typical absences, and in many cases the spike–wave discharge is broken up into frequent bursts, is arrhythmic in frequency or is of less than 3Hz (Cascino et al. 1993). Consciousness is variably impaired from a simple slowing of ideation and expression to profound obtundation or lethargy (Shorvon 1994).

Patients with the Lennox–Gastaut syndrome frequently have prolonged episodes of diminished consciousness, often associated with erratic myoclonus and/or brief head drops due to localised muscle atonia or myoclonic jerks. These episodes are sometimes accompanied by an increase in abnormal EEG activity, but it may be difficult to distinguish between ictal and non-ictal states (Erba and Browne 1983). Thus, such cases are often excluded from nonconvulsive status. Repeated tonic seizures often interrupt such episodes or may replace them, a transition that is sometimes produced by the use of benzodiazepines (Alvarez et al. 1981; Di Mario and Clancy 1988).

Another nosological issue is raised by the occurrence of episodes of status identical to those observed in primary or secondary generalised epilepsies in children with focal epilepsies as evidenced by the occurrence of focal seizures, discrete EEG foci, and localised lesions. In such cases, paroxysmal EEG activity during status is bilateral, although at times asymmetrical, and it is difficult to decide whether they should be classified under partial or generalised nonconvulsive status (Arzimanoglou et al. 2004).

**Absence status** occurs before age 20 in 75% of cases, mostly during the first decade, and is rarely the first manifestation of epilepsy. A form of ‘de novo’ absence status of late onset has been described in middle-aged and elderly patients, usually related to benzodiazepine withdrawal (Thomas et al. 1992). The outcome of absence status is probably related more to the type and cause of the underlying epilepsy than to the duration of repetition of the episodes. The role of sub-continuous EEG paroxysmal activity, with few or even no clinical manifestations, as a cause of cognitive or behavioural deterioration in several epilepsy syndromes, remains debatable.

The diagnosis of generalised nonconvulsive status is often challenging. Intoxications must be considered with unexplained obtundation; coma or confusion of metabolic origin common in children.

Episodes of pure **tonic status** are frequent in Lennox–Gastaut and related syndromes. They may last several days or weeks, the individual seizures becoming shorter and less intense, while autonomic impairment increases with the duration of status.

**Atonic status** is characterised by the occurrence of near-repetitive brief losses of tone (negative myoclonus) involving axial and limb musculature. Diminished consciousness is typically associated, and erratic myoclonic jerks are often present. Such episodes, lasting hours or days, frequently complicate the course of myoclonic (myoclonic–astatic) epilepsy but may also occur with focal epilepsy, lesional or...
nonlesional. Episodes of myoclonic or atypical absence status epilepticus occur in the majority of cases with Angelman syndrome (Battaglia and Guerrini 2005).

A specific epilepsy syndrome, associated with the ring chromosome 20, has been described (Inoue et al. 1997; Petit et al. 1999; Ville et al. 2006) as a recognisable entity with almost daily episodes of atypical absence status. The syndrome is characterised by mild to moderate intellectual disability, presenting around age 6 years after initially normal development, a behavioural disorder, the lack of specific dysmorphic features and epilepsy. Seizures usually begin in childhood, and are reported as a fluctuating alteration of awareness lasting several minutes. These may be associated with automatic behaviour, wandering hallucinations, and a sensation of fear. Brief motor seizures and tonic-clonic seizures are also observed. The ictal EEG during nonconvulsive status reveals high-amplitude rhythmic slow activity with superimposed spikes or spike–waves over the frontal regions.

The importance of EEG monitoring and aggressively treating nonconvulsive status epilepticus is underscored by a recent prospective observational study of 300 critically ill children with encephalopathy (Wagenman et al. 2014). All children underwent continuous EEG monitoring to determine the relationship of electrographic seizures and electrographic status epilepticus and long-term neurological outcome. Follow-up at a mean of 2.7 years revealed that nonconvulsive status epilepticus but not electrographic seizures was associated with lower cognitive performance and diminished quality of life. Children with no prior history of seizures were at increased risk of subsequently being diagnosed with epilepsy.

Treatment of generalised nonconvulsive status epilepticus with benzodiazepines (diazepam, midazolam, clonazepam or lorazepam) usually rapidly controls primary generalised episodes. Valproate is used to treat absence or myoclonic status (Aldenkamp et al. 2006). Atypical absence status, however, is often resistant to drugs. High doses are best avoided, and benzodiazepine administration must be immediately interrupted if tonic components become apparent. Tonic status is highly resistant to therapy (Livingston and Brown 1987). Dexamethasone may be helpful (Shorvon 1994).

**PARTIAL NONCONVULSIVE STATUS EPILEPTICUS**

Partial nonconvulsive status, rare in children, can occur in the course of temporal lobe or other lesional epilepsies, particularly involving the frontal lobe. It may present as frequently recurring focal seizures with alteration of consciousness and automatisms without full recovery of cognitive activity between seizures, or as continuous long-lasting episodes of cognitive confusion and/or behavioural disturbances with or without automatisms (Arzimanoglou et al. 2004). An alternation of periods of complete unconsciousness and of partial responsiveness is possible. The differential diagnosis with generalised nonconvulsive status depends on the EEG which shows permanent or repetitive localised paroxysmal activity, although with variable localisation (McBride et al. 1981; Bauer et al. 1989). Lasting postictal memory deficits are described in adults (Shorvon 1994).

Depending on the location and propagation of the discharges, partial nonconvulsive status may also manifest as episodes of prolonged unmotivated fear, prolonged aphasia, prolonged ictal blindness (status epilepticus amnesticus) or visual hallucinations. Prolonged ictal paralysis (somato-inhibitory status) is another form of nonconvulsive status that may be difficult to distinguish from Todd paresis. Nonconvulsive status may also take the form of a prolonged ‘aura’, characterised by prolonged visceral or sensory symptoms. Among other lesional causes cortico–cerebellar dysplasia may explain many prolonged episodes. Therapeutic options to control partial nonconvulsive status epilepticus do not differ from that of status in general. However, the urgency of administration and the choice of medication may be unclear. Data addressing treatment of convulsive status epilepticus may lead to ‘overtreatment’ of nonconvulsive status as sedating medications may prolong hospitalisation and worsen outcome. Non-sedating antiepileptic drug use is favoured by many neurologists as their side effect profile is superior to sedating medications (Wasim and Husain 2015).

**REFRACTORY STATUS EPILEPTICUS**

Refractory status epilepticus (RSE) is defined as status epilepticus that does not respond to the administration of conventional antiepileptic medications (Shorvon and Ferlisi 2011). This clinical situation is not rare and occurs in up to one-quarter of patients presenting in status epilepticus. Morbidity and mortality are particularly high given the long periods of continuous seizure duration (Novy et al. 2010). It is therefore important to document medication unresponsiveness as early as possible.

Whereas convulsive status epilepticus does not generally present difficulties in diagnosis, nonconvulsive status epilepticus may be overlooked, particularly in comatose patients. For this reason, continuous EEG monitoring in the intensive care setting is mandatory. Persistence of nonconvulsive status epilepticus in patients successfully treated for convulsive status epilepticus is not uncommon. Cases of RSE that continue 24 hours or more have been termed ‘super-refractory status epilepticus’ (Shorvon and Ferlisi 2010). While constituting a small percentage of RSE patients, this group is at extremely high risk for poor outcome.

Patients with RSE must be managed in an intensive care setting as anaesthetic agents are typically employed and a variable degree of coma is generally achieved. Once first and second-line anti-seizure medications have failed, coma should
be induced with midazolam, thiopental sodium or propofol (Capovilla et al. 2013). The choice of anaesthetic agent is typically dictated by local protocol. Each agent carries individual risks. Induction of thiopental is associated with hypotension and heart failure and is contra-indicated in the presence of cardiogenic shock or sepsis. Intravenous propofol in high doses for prolonged periods is associated with the ‘propofol infusion syndrome’ characterised by metabolic acidosis, rhabdomyolysis, hepatomegaly and renal failure. Fatal outcomes have been reported (Riker et al. 2009). Midazolam can produce respiratory depression and metabolic acidosis.

Several other agents have been employed in the treatment of RSE. Most have only been investigated in small, open-label, non-randomised and non-blinded clinical studies. Ketamine, an NMDA glutamate receptor agonist and isofluorane have been utilised successfully to treat RSE in children (Kofke et al. 1989; Rosati et al. 2012). While the experience with ketamine in children with RSE is small, its adverse effects appear restricted to hyper-salivation and alterations in liver enzymes.

Although the prognosis of RSE remains generally poor, reasonably good outcomes are occasionally reported after prolonged coma and hospitalisation (Cooper et al. 2009). Long-term prognosis is heavily influenced by predisposing aetiology. A particularly poor prognosis occurs in patients with RSE in the course of encephalitis (Kramer et al. 2005).

**ELECTRICAL STATUS EPILEPTICUS OF SLOW WAVE SLEEP**

**ENCEPHALOPATHY WITH STATUS EPILEPTICUS DURING SLOW SLEEP**

Encephalopathy with status epilepticus during slow sleep (ESES) is an epileptic encephalopathy with heterogeneous clinical manifestations (cognitive, motor, and behavioural disturbances in different associations, and various seizure types) related to a peculiar EEG pattern characterised by paroxysmal activity significantly activated during slow wave sleep that is a condition of continuous spikes and waves, or status epilepticus, during sleep (Fig. 16.22). In the first descriptions, dealing with the most severe cases, diffuse bilateral slow (<2.0Hz) spike–wave complexes occupied 85% or more of the slow sleep time (Jayakar and Seshia 1991; Tassinari et al. 1992; Bureau 1995; Beaumanoir 1995).

However, cases with a spike–wave index of 50–85% are frequent and usually have a similar evolution. We believe that in fact what characterises the syndrome is not the percentage of the characteristic EEG pattern during sleep but the combination of signs of neurocognitive impairment appearing together with a significant increase in EEG abnormalities during sleep. Tassinari, very elegantly labelled ESES as the ‘Penelope syndrome: Spinning during the day, spiking during the night’, in which the diurnal ‘spinning’ to make up a thread

![Figure 16.22](image-url)
Part VII Paroxysmal Disorders

(a neuronal network) is erased by the 'EEG spiking' during sleep (Tassinari et al. 2009).

Bursts of diffuse spike–wave complexes, sometimes with atypical absences or myotonic seizures, often occur during wakefulness. Seizures occur in 70% of cases and often include focal nocturnal seizures reminiscent of idiopathic focal epilepsy. Electrical abnormalities can persist for months or years.

The syndrome seems to be frequently, although not consistently, associated with behavioural disturbances and/or cognitive deterioration. The mechanism of language dysfunction remains unclear but is likely to be a consequence of interictal epileptic activity rather than epileptic seizures. The interictal paroxysmal activity eventually disappears leading to some recovery of cognitive function.

Morikawa et al. (1985) found identifiable brain pathology in 20–30% of cases, and Gaggero et al. (1995) demonstrated areas of reduced blood flow by SPECT corresponding to the most actively discharging brain areas in four of their ten cases. Guerrini et al. (1998c) reported the association of ESES and unilateral focal polymicrogyria, and similar cases have subsequently been observed (e.g. Caraballo et al. 1999). These observations suggest ESES is heterogeneous and caused by multifocal pathological abnormalities. Another organic cause is hydrocephalus, which may be related to thalamic injury (Guzzetta et al. 2005).

The pathophysiological mechanisms underlying this condition are still incompletely understood; recent data suggest that the abnormal epileptic EEG activity occurring during sleep might cause the typical clinical symptoms by interfering with sleep-related physiological functions, and possibly neuropsychological processes mediating higher cortical functions such as learning and memory consolidation (Tassinari et al. 2009; Bölsterli et al. 2011; Bölsterli Heinzel et al. 2014).

Treatment is often disappointing and controlled trials are lacking. Veggioleti et al. (2012) suggested a treatment algorithm based upon a review of the literature (mainly case reports or rather small retrospective studies). Treatment options include some antiepileptic drugs (valproic acid, ethosuximide, levetiracetam, and benzodiazepines), corticosteroids, immunoglobulins, the ketogenic diet, and surgery (multiple subpial transections). Some investigators claim satisfactory results with sulthiame (Gross-Selbeck 1995; Lerman-Sagie and corticosteroids). Some investigators claim satisfactory results with sulthiame (Gross-Selbeck 1995; Lerman-Sagie and corticosteroids). Some investigators claim satisfactory results with sulthiame (Gross-Selbeck 1995; Lerman-Sagie and corticosteroids).

LANDAU–KLEFFNER SYNDROME

Landau–Kleffner syndrome (LKS), a condition also called ‘epileptic aphasia’ presents a paroxysmal sleep EEG activity similar to ES. This syndrome is defined as acquired aphasia that is often but not always predominantly receptive in type in conjunction with intense paroxysmal EEG activity that is more intense in sleep. Awake tracings show uni- or bilateral spike foci often over the temporal lobes (Hirsch et al. 1990; 2006b; Beaumanoir 1992; Maquet et al. 1995). There may be a correlation between the intensity of paroxysmal activity, especially during sleep, and language deterioration. In such cases, there is a rapid or progressive loss of language abilities that often involves mainly verbal auditory discrimination. Approximately 80% of children have seizures that are typically focal but not severe. Atypical absences may occur and are frequently repetitive. In most cases, both the epilepsy and EEG abnormalities disappear before age 15 years (Dulac et al. 1983; Rossi et al. 1999; Hommet et al. 2000).

The outlook for language is poor and most patients continue to experience language difficulties as adults. The severity of the language impairment is variable ranging from almost no verbal ability to mild or moderate deficits in speech communication (Bishop 1985; Deonna et al. 1989).

Similar EEG activity involving other brain areas may be responsible for disturbance of other functions. Hirsch et al. (1995) reported apraxia associated with continuous parietal EEG paroxysms and suggested a similar mechanism to LKS. Neville and Boyd (1995) suggested that epilepsy may manifest as a gait disorder that responds to corticosteroid treatment.

LKS is highly heterogeneous (Deonna et al. 1977; Hirsch et al. 1990; Maquet et al. 1995; Van Bogaert 2013; Deonna and Roulet-Perez 2016). Some children have predominant disturbances in expressive language or complex patterns of language disturbance. Others do not exhibit the pattern of continuous spike–wave discharges during sleep, and occasionally patients have severe persisting epilepsy.

The mechanism of the syndrome is unclear. PET studies yield heterogeneous results (Maquet et al. 1990; Rintahaka et al. 1995; De Tiège et al. 2004; Luat et al. 2005). Magnetoencephalographic spikes originated in the left auditory area in one study (Paetau et al. 1992), and interictal discharges may be responsible for the aphasia.

Both LKS and ESES are examples of epileptic encephalopathy, illustrating the effects of ‘subclinical’ electrographic
discharges on brain function, and confirming that epilepsy is not limited to seizures and has more pervasive effects. Indeed, some cases of LKS also manifest more diffuse dysfunction, for example, involving the frontal lobes (Roulet et al. 1991; Hirsch et al. 1995). Transient deficits in localised brain functions such as the anterior opercular syndrome (Roulet et al. 1989; Boulloche et al. 1990) have also been linked to intense, localised, paroxysmal EEG activity.

Treatment of the condition is disappointing. Anticonvulsant agents usually fail to abolish the paroxysmal activity or improve language competence, although some success has been reported with the drugs used in ESES (Veggiotti et al. 2012; van den Munckhof et al. 2015). Corticosteroids or ACTH treatment is an accepted practice but must be continued for 1 year or more (Lerman et al. 1991; Hirsch et al. 1995). There are no controlled clinical trials investigating therapeutic options for LKS. Only open-label data are available. Early diagnosis and initiation of prompt medical treatment appear to be important to achieving better long-term prognosis. Several antiepileptic drugs are reportedly beneficial, including valproic acid, diazepam, ethosuximide, clonazepam and clonazepam. Reports on the efficacy of lamotrigine, sulthiame, felbamate, nicardipine, vigabatrin, levetiracetam, vagal nerve stimulation and the ketogenic diet are limited. Carbamazepine and possibly phenobarbitone and phenytoin occasionally exacerbate the syndrome (Mikati and Shamseddine 2005). Only anecdotal reports are available and the relationship between treatment and language improvement, although generally accepted, remain unproved. The same applies to surgical treatment by multiple temporal transections (Morrell et al. 1989; Devinsky et al. 1994; Morrell et al. 1995; Robinson et al. 2001).

**DIFFERENTIAL DIAGNOSIS FROM PAROXYSMAL DISORDERS OTHER THAN EPILEPSY**

Epilepsy is the most important of the neurological disorders of childhood characterised by paroxysmal manifestations, but a host of other paroxysmal conditions can occur in children. Indeed, the diagnosis of epilepsy is often made incorrectly in the presence of paroxysmal events (Stroink et al. 2003; Xu et al. 2016). An incorrect diagnosis of epilepsy was made in 20–30% of children referred to one epilepsy clinic (Jeavons 1983), in 27 of 124 children (22%) reported by Desai and Talwar (1992), and in 10–20% of children according to Merrick et al. (1991). Such figures reflect a common experience (Aicardi 2003) and remain similar despite recent developments and increased awareness in the field. The misdiagnosis rate of 5% for the diagnosis of epilepsy (Van Donselaar et al. 2006) should be considered an absolute minimum, as the authors acknowledge. A misdiagnosis rate of at least 23% in a British population-based study (Scheepers et al. 2003) may reflect general practitioners and paediatricians without special training in epilepsy playing a central role in diagnosis and treatment. More specialised physicians do better. Neurologists (error rate 5.6%) do better than non-specialists (error rate 18.9%) in another hospital-based UK study (Leach et al. 2005).

Diagnostic inaccuracy is especially common for a first seizure. One-quarter of children were incorrectly diagnosed as having a seizure while the diagnosis of epilepsy was missed in over one-third of children in a study involving 127 children seen in a tertiary care First Seizure Clinic (Hamiwka et al. 2007).

Because an incorrect label of epilepsy all too often has profound consequences on a child’s life, such misdiagnoses must be avoided. So, ideally, all patients suspected of having epilepsy should have an assessment by a child neurologist, but this is not possible in many countries due to available resources (Van Donselaar et al. 2006).

The section below reviews the most common nonepileptic paroxysmal conditions that cause faints and other turns. Paroxysmal events as a manifestation of narcolepsy-cataplexy; shuddering; benign nonepileptic infantile spasms or gratification phenomena are treated in other sections of this book.

**ANOXIC SEIZURES**

So-called anoxic seizures are due to cortical hypoxic failure of energy metabolism because of anoxia or hypoxia. They may occur in many circumstances: bradycardia of less than 40 beats per minute, tachycardia of more than 150 beats per minute, asystole of more than 4 seconds, systolic pressure less than 50mmHg or venous O₂ pressure less than 20mmHg.

Cortical hypoxia results in loss of consciousness and of postural tone. When severe, liberation of tonogenic brainstem centres from corticoreticular inhibition causes decoricate rigidity and/or opisthotonus. Increasing degrees of cortical hypoxia produce slowing of frequency of the dominant cortical rhythms, followed by complete flattening of the EEG tracing, which corresponds to the tonic phase. With correction of hypoxia, slow waves reappear and may be synchronous with a few jerks of the limbs before resumption of normal EEG activity (Gastaut 1974; Stephenson 1990). Anoxic seizures can be due to several different mechanisms (Table 16.15), several of which may be operative in the same patient or even in the same attack (Stephenson 1990, 2013).

**REFLEX SYNCOPES AND FAINTS**

Syncope refers to a sudden loss of consciousness and postural tone associated with diminished energy substrates to the brain
usually through a decrease in cerebral perfusion by oxygenated blood, due to reduction in cerebral blood flow or to a drop of the oxygen content, or to a combination of both. Low perfusion is usually the consequence of a cardio-inhibitory mechanism mediated through the vagus nerve or of a vaso-depressor mechanism with variable vagal accompaniment (vasovagal or neuro-cardiogenic syncope). It may rarely result from primary cardiac events. In faints, the loss of consciousness is generally preceded by sensations of light-headedness, and the loss of tone is progressive with the patient slowly slumping to the ground. The loss of posture is occasionally abrupt with a sudden fall. In such cases the tip of the tongue may be cut, though true tongue biting with lateral laceration is unusual (Stephenson 1990; Lempert et al. 1994). Urinary incontinence is not uncommon and does not indicate an epileptic mechanism.

The diagnosis of syncope rests essentially on the circumstances of occurrence which include emotional stimuli or stress, standing posture, especially in a confined atmosphere, or minor pain. In some individuals faints are regularly provoked by the same stimulus such as getting into or out of a bath (Stephenson 1990; Patel et al. 1994), combing one’s hair (Lewis and Frank 1993) or stretching (Pelekanos et al. 1990). Some triggers are so specific as to allow a clinical diagnosis without any investigations; these include venipuncture, ear piercing, and hair grooming, whereas if domestic bathing of an infant is the trigger one may say with confidence that the diagnosis is not syncope (Nechay and Stephenson 2008). During the attack, the patient becomes pale, the eyes may deviate vertically and the pulse may slow.

It is prudent to obtain a 12-lead electrocardiogram (ECG) if the history is not typical, but an EEG is not required. One should bear in mind that 2% of typically developing children may have discharges such as rolandic sharp waves and this ‘abnormality’ may lead to diagnostic confusion. Ocular compression during EEG is rarely justified except in exceptional circumstances (Stephenson 2008).

In some cases, a true epileptic attack can be induced by the hypoxia resulting from a syncope (Aicardi et al. 1988; Battaglia et al. 1989; Stephenson 1990). Such instances have been termed anoxic–epileptic seizures (Stephenson 1990; Horrocks et al. 2005) and may be of long duration resulting in episodes of status epilepticus (Battaglia et al. 1989).

Alternatively, cardiac arrhythmias can occasionally result from an epileptic discharge involving cardioregulatory efferents. Such a phenomenon (epileptic–anoxic seizure) may play a role in sudden death of patients with epilepsy (Oppenheimer et al. 1990; Stephenson 1990; Stephenson et al. 2004). The epileptic nature of such episodes may be difficult to diagnose. Home videos are of substantial help for a more accurate diagnosis.

Many syncopes have an abrupt onset; clonic movements occur in approximately 50% of cases and incontinence in 10% (Stephenson 1990). Syncopes can occur in the sitting and even in the supine position, may be preceded by hallucinatory phenomena or evidence postictal confusion, thus rendering distinction from an epileptic seizure difficult. Vasovagal syncopes are mostly a benign phenomenon although they generate considerable anxiety. Reassurance is usually sufficient, but treatment with atropine may be justified for frequent syncopes.

Vasovagal syncopes are often familial in nature (Camfield and Camfield 1990; Cooper et al. 1994) but do not follow Mendelian rules of inheritance.

Syncopes may occur electively in febrile children and such accidents are apt to be mistaken for febrile convulsions. The oculocardiac reflex produces a lasting slowing of the heart rate and may induce a seizure identical to the patient’s usual attack. This mechanism is not universally accepted, as a strong oculocardiac reflex does not exclude the possibility of a febrile convolution.

Niaprazine, an antihistaminic drug is associated with fainting and loss of consciousness. The loss of consciousness is associated with hypotonia and pallor, is of brief duration and occurs within 30 minutes of absorption in most cases (Bodiou and Bavoux 1988). Severe cases are rare (Auduy 1988).

BREATH-HOLDING SPELLS

Breath-holding spells occur in about 4% of all children below the age of 5 years. There are two major forms, the cyanotic and the pallid types (Lombroso and Lerman 1967). The mechanisms of the two forms are different, and most ‘pallid breath-holding attacks’, such as occur when a child bumps her/his head and almost immediately loses consciousness, are best regarded as reflex hypoxic syncope precipitated by painful stimuli or emotion (Stephenson 1990; Breningstall 1996).

Cyanotic breath-holding episodes are provoked by fright, pain, anger or frustration. The child cries vigorously then holds her/his breath in expiration. This results in cyanosis eventually culminating in loss of consciousness and loss of muscle tone. The latter may be followed by brief body stiffening before respiration resumes and the attack ends. Polygraphic recordings have shown a sequence of slowing of the EEG tracing with bradycardia such as one would expect in the overshoot phase of a Valsalva manoeuvre. Despite their frightening appearance, breath-holding spasms are harmless (Gordon 1987). The mechanism of cyanotic breath-holding spells is still imperfectly known (DiMario and Burleson 1993). Oxygen desaturation and reduction of cerebral blood flow because of increased intrathoracic pressure with decreased venous return play a role. However, cyanosis develops with surprising rapidity and an intrapulmonary right-to-left shunt seems likely as a result of imperfect matching of ventilation to perfusion (Breningstall 1996). Gastaut (1974) distinguished between breath-holding spells and sobbing spasms or sobbing syncope in which the child would ‘sob intensely and intractably for a long period of time (1–3 minutes)’ before losing consciousness. Exceptional cases of breath-holding episodes resulting in death have been associated with severe underlying conditions (Southall et al. 1990). Such exceptions do not modify the benign prognosis of the condition.

Pallid breath-holding episodes may exist in isolation or alternate with the cyanotic form in the same child. They accounted for 19% of cases in the study by Lombroso and Lerman (1967). In this type, which is often precipitated by pain, especially from trivial head trauma, the child loses consciousness following a minimum of crying or no crying at all. Pallor is marked and stiffening is the rule. In many such patients, the attack is associated with a period of asystole (cardio-inhibitory syncope) that can also be induced by compression of the eyeballs (Lombroso and Lerman 1967; Stephenson 1980). Urinary incontinence is common. The mechanism is reflex cardio-inhibition resulting in cardiac standstill with a consequent hypoxic attack. The tonic attack on EEG is associated with flattening of the record that follows a run of slow waves. A few clonic jerks are not infrequently observed following the tonic attack (Fig. 16.23).

Pallid breath-holding episodes are more frequently mistaken for epilepsy than the cyanotic forms. The diagnosis rests as much on the fact that all episodes are precipitated by an adequate stimulus as on the seizure description, which

Figure 16.23 Anoxic seizure induced by pressure on the eyeballs. Ocular pressure was applied at the first horizontal arrow, resulting in cardiac asystole with appearance, after a few seconds, of slow waves on the EEG. The patient turned pale and had two clonic jerks. Later, the EEG flattened while the boy became mildly cyanosed and a tonic spasm occurred (second horizontal arrow). Following resumption of cardiac contractions, slow waves reappeared on the EEG and a further clonic jerk was observed. (Courtesy Professor H Gastaut, Hôpital de la Timone, Marseille.)
may be difficult to distinguish by history from an epileptic seizure. Indeed, they may be responsible for anoxic–epileptic seizures (Stephenson 1990; Stephenson et al. 2004; Horrocks et al. 2005). The outlook for this form is also favourable, and explanation and reassurance that the episodes produce no harm and will cease is often followed by a marked diminution of their frequency. Rarely is psychiatric help needed, and no drug treatment is necessary or effective (Gordon 1987). Exceptionally, cardiac pacing has been needed (Wilson et al. 2005).

**UNUSUAL TYPES OF REFLEX SYNCOPE**

Self-induced reflex syncope are rare but may pose difficult diagnostic problems. Such syncope are seen in patients with psychosis and cognitive deficiency (Gastaut et al. 1987) and are usually mistaken for absences or drop attacks. Affected children stop breathing and inflate their chest or abdomen, producing a Valsalva manoeuvre. After a few seconds, they turn pale, exhibit a vacant look and a loss of tone that may be limited to the neck or involve the lower limbs with resultant fall. A similar phenomenon is frequently seen in girls with Rett syndrome where it alternates with hyperventilation periods, and rarely occurs in intellectually typical children with behavioural disturbances. The diagnosis rests on a peculiar polygraphic sequence (Gastaut et al. 1987; Aicardi et al. 1988). Video with audio may be sufficient for diagnosis, if attention is paid to the lack of breathing sounds during the ‘breath-hold’. EEG/ECG will document the typical changes if an episode is recorded, with ECG showing a combination of tachycardia and reduction of QRS amplitude by about 50% followed by – after about 10 seconds – rebound bradycardia, and a burst of EEG slow activity.

Management is difficult and no evidence base exists for any particular treatment. Fenfluramine, naltrexone, and the use of a wrestler’s belt have been reported to be effective, at least in the short term (Stephenson 2013).

**ANOXIC SEIZURES DUE TO RESPIRATORY OBSTRUCTION**

These symptoms are infrequent in children, although accidental suffocation or strangulation may occur. Induction of anoxic seizures by an adult, usually the mother, is a relatively common form of Munchausen by proxy or Meadow syndrome (Rosenberg 2003; Galvin et al. 2005). The diagnosis may be challenging if the mother presses the infant’s face into her breast. The constant presence of the mother at the onset of each episode is an essential clue, with a final diagnosis established by polygraphic recording (Stephenson et al. 2004) or covert EEG–video monitoring, which, however, raises ethical and legal problems (Bauer 2004).

**SYNCOPEs OF CARDIAC ORIGIN**

Syncope of cardiac origin are much rarer than reflex vasovagal or cardio-inhibitory attacks. They represented only 6% of 108 syncope studies by McHarg et al. (1997). It is important to recognise them as they may be due to dangerous conditions causing sudden death; preventive treatment and monitoring are, therefore, essential.

Cardiac disorders responsible for syncope include valvular disorders such as aortic stenosis, which can produce syncope on effort; postoperative conduction blocks; cardiomyopathies sometimes associated with myopathies; and intrinsic disturbances of cardiac rhythm such as Wolf–Parkinson–White syndrome, congenital atrioventricular block and the prolonged Q-T interval syndrome. These syndromes result from channelopathies involving specific sodium or potassium channels and include several distinct syndromes (long and short Q-T syndromes, Brugada syndrome, Ward–Romano syndrome, Jervell–Lang–Nielson syndrome). Long Q-T syndromes (LQTS) (Crotti et al. 2008) are by far the most common of the cardiac conduction disorders that may present as ‘seizures’.

Molecular genetic studies have shown that at least seven different long Q-T syndromes exist including: potassium channel mutations (LQT2) on chromosome 7q35–q36, sodium channel protein mutation on chromosome 3 (LQT3), ras-1 protein gene mutations on chromosome 11p (Towbin 1995; Sarkozy and Brugada 2005; Wolpert et al. 2005). They are genetically transmitted, which has an impact on diagnosis, counselling and treatment, and may be recessive or dominant (Avanzini et al. 2004). Associated features, for example, deafness in the recessive Jervell–Lang–Nielson syndrome, may be present. All these syndromes can mimic epilepsy (Gordon 1994; Pacia et al. 1994) and can result in sudden death (Goldenberg et al. 2005).

Occurrence of episodes during sleep or exercise may be a hint to the correct diagnosis. Episodes can also be precipitated by emotion or stress. Such circumstances as well as a family history of sudden death or ‘epilepsy’, or a personal history of chest pains, palpitations or a surgically repaired heart defect require full cardiac investigation. The corrected Q-Tc interval is prolonged in most cases, although occasional cases of cardiac syncope with a normal Q-T have been reported, so the ECG should be systematically recorded with the EEG in patients with unexplained loss of consciousness (Bricker et al. 1984). Prolonged ECG recording and effort test may be indicated in selected cases (Noussiaen et al. 1989), especially when a history of familial syncope or sudden death is present. In some cases, a pacemaker should be inserted as sudden death is possible.

Acute episodes of hyperpnoea and cyanosis are a common feature of congenital cyanotic cardiomyopathies. They may result in loss of consciousness and may be followed by hemiplegia of vascular origin. Severe apnoea may also be a feature of the syndrome of alternating hemiplegia (Bourgeois et al. 1993; Andermann et al. 1995).
**EPISODES OF APNOEA OR BRADYCARDIA IN YOUNG INFANTS**

**NEAR-MISS SUDDEN INFANT DEATH SYNDROME**

Study of the sudden infant death syndrome (SIDS) is beyond the scope of this book. However, some near-miss SIDS cases may be easily mistaken for epileptic events, the more so as they can be followed by neurological sequelae and episodes of status epilepticus (Constantinou et al. 1989). Indeed, the true sequence of events may be impossible to establish in some cases. Less severe episodes may manifest as briefer episodes of apnoea, with hypo- or hypertonia and a change of colour that may be wrongly interpreted as epileptic phenomena. Such events may occur in the first few days of life in apparently healthy infants (Grylack and Williams 1996).

The most common cause of seizure-related death in children with epilepsy is sudden unexpected death in epilepsy (SUDEP). SUDEP is relatively uncommon in childhood, but the risk increases if epilepsy persists into adulthood. Although the direct cause of SUDEP remains unknown, death most often follows a generalised convulsive seizure, and the risk of SUDEP is strongly related to drug-resistant epilepsy and frequent generalised tonic–clonic seizures. The most effective SUDEP prevention strategy is to reduce the frequency of seizures (Donner et al. 2017). Screening for infants at risk of sudden death has been investigated extensively. Most studies report no precise correlation between polygraphic recordings and the later occurrence of sudden death (Reerink et al. 1995), so that indications for use of electronic monitors in the home remain unclear. In preterm infants, episodes of marked desaturation can occur without apnoea and remain undetectable by monitoring (Poets et al. 1995). The 2016 updated edition of the Cochrane Review (Maguire et al. 2016) on treatments for the prevention of SUDEP found very low-quality evidence of a preventive effect for nocturnal supervision against SUDEP concluding that further research is required to identify the effectiveness of other current interventions; for example, seizure detection devices, safety pillows, selective serotonin reuptake inhibitors, early surgical evaluation, educational programmes, and opiate and adenosine antagonists in preventing SUDEP in people with epilepsy.

Physicians and other health care professionals have a critical role in supporting families that lose a child to epilepsy. Comprehensive reviews provide health care providers with information needed to discuss the risk of death in children with epilepsy and support families following a loss (Donner et al. 2017; Shankar et al. 2017).

The awake apnoea syndrome consists of apnoeic–bradycardic episodes and may be causally related to the presence of gastro-oesophageal reflux (Pedley 1983; Spitzer et al. 1984; See et al. 1989; Page and Jeffery 2000) or to oesophageal spasm (Fontan et al. 1984). The episodes resemble syncope and are often preceded by restlessness and an apprehensive look and accompanied by opisthotonus, so the misdiagnosis of epilepsy is not rare. Such episodes may respond to the treatment of gastro-oesophageal reflux, although this is debated (Brand et al. 2005).

Other causes of apnoea in neonates and infants appear in Table 16.16.

**ALTERNATING HEMIPLEGIA OF CHILDHOOD (AHC)**

Alternating hemiplegia of childhood (AHC) was initially described as a variant of hemiplegic migraine. However, the condition is so different from classic migraine that it should be regarded as a specific disorder (Bourgeois et al. 1993). The disease certainly goes undiagnosed in many cases.

The onset of the disorder is almost always in the first year and usually in the first 6 months of life (Panagiotakaki et al. 2010); a few late-onset cases are on record (Mikati et al. 2000). Paroxysmal manifestations appear first, sometimes even in the neonatal period (Aicardi 2002). They consist of episodes of hemiplegia that are never isolated but variously combined with tonic seizures ocular motor manifestations and automatic phenomena. The clinical findings of 30 ‘historical’ cases, examined by Jean Aicardi and published in the third edition of this book, are listed in Table 16.17. Localised or generalised tonic and dystonic seizures and episodes of nystagmus often precede the hemiplegias by weeks to months.

In an effort to elucidate the natural history of AHC, a European Network for Research on Alternating Hemiplegia collected the data on a large cohort of 157 patients (Panagiotakaki et al. 2010). At inclusion, patients were aged from 9 months to 52 years. The median age at diagnosis was 20 months. All patients experienced hemiplegic episodes; 86.5% reported episodes of bilateral weakness, 88% dystonic episodes, 53% epileptic seizures, 72% developed chorea and/or dystonia and 92% intellectual disability. When data over the course of the illness were examined for the whole cohort, the severity of symptoms did not appear to change, with the exception of abnormal ocular movements and hypotonia that regressed, but did not disappear into adulthood (from 86% to 36% and 76% to 36%, respectively). No statistically significant correlation between a history of severe paroxysmal hemiplegic/dystonic episodes and a worse neurological outcome was identified. Seven patients had died, some of whom experienced severe plegic episodes or epileptic seizures at the time of death. History of severe plegic/dystonic episodes was not found to be an aggravating factor for deceased patients. Based on the above observation the authors concluded that the natural history of AHC is highly variable and unpredictable for individual patients.

The frequency of episodes is usually high, with instances of hemiplegia occurring several times a month and lasting from a few minutes to several days. A characteristic feature in most cases is the occurrence of episodes in which the

<sup>a</sup>Gastrointestinal reflux remains a deleted cause of apnoea.

<sup>b</sup>Exclusion diagnosis.

<sup>c</sup>Apnoea, pallor, cyanosis, impression of imminent death. About half the cases are due to known disorders (respiratory, digestive, neurological or cardiac); the remaining cases are idiopathic and may be related to the sudden infant death syndrome and to sudden unexpected death in epilepsy patients (SUDEP).
hemiplegia shifts from one side to the other, with a period of bilateral paralysis associated with mutism, difficulties in swallowing and drooling (Krägeloh and Aicardi 1980). Severe quadriplegic attacks with amimia, malaise and decreased consciousness are often observed (Fusco and Vigevano 1995). Frightening, possibly life-threatening, episodes of apnoea occur in some patients. A very characteristic feature is the disappearance of all symptoms on falling asleep. In prolonged episodes the child is normal on waking up but all symptoms return within 10–20 minutes. Parents often take advantage of this short period to feed the child.

A benign form has been reported by Andermann et al. (1994). In their two patients, the episodes occurred during sleep. A case associated with paroxysmal dystonia is on record (Kemp et al. 1995).

Nonparoxysmal manifestations are present in all patients after a course of a few months or years and run a progressive course. They include intellectual disability of variable degree, choreoathetosis and dystonia, ataxia and sometimes pyramidal tract signs.

The clinical picture of the classic form is so characteristic that there are few differential diagnoses. Initially, however, the occurrence of unilateral tonic seizures followed by hemiplegia makes the diagnosis of focal epileptic seizures difficult to avoid for physicians not familiar with the disease. In about half the patients, true seizures may occur with or without temporal relationship to the hemiplegias. The differential diagnosis is discussed by Andermann et al. (1995), and the main causes of paroxysmal hemiplegia are listed in Table 16.18.

The cases of cutis marmorata congenita with recurrent alternating hemiplegia described by Baxter et al. (1993) can closely simulate the disorder.

All laboratory investigations and neuroradiological studies including MRI have been negative. Transient muscle mitochondrial abnormalities have been reported (Kemp et al. 1995) but are inconstant (Kyriakides and Drousiotou 1994). SPECT has shown variable changes in perfusion, depending probably on the timing of examination (Andermann et al. 1995). Ictal EEGs show only a moderate slowing on the affected side.

Dominant transmission has been reported in a family with affected members with typical but less severe symptoms and a later onset up to 3 years of age (Mikati et al. 1992), and two pairs of affected monozygotic twins and a few cases of apparently recessive transmission are also on record, but the vast majority of cases are sporadic. Two cases have been attributed to mutation in the second gene of familial hemiplegic migraine, ATP1A2 (Bassi et al. 2004; Swoboda et al. 2004). However, no mutations in this gene were found by Kors et al. (2004) or in several unpublished cases. Given the difficulty of separating such cases from hemplegic migraine, this attribution remains uncertain.

In 2012, mutations in the ATP1A3 gene (MIM 182350), located at 19q13.2 [hg19], were identified (Heinzen et al. 2012; Rosewich et al. 2012; Ishii et al. 2013) as the primary cause of AHC (AHC2, MIM 614820).

AR, autosomal recessive; AD, autosomal dominant; S, sporadic, XR, X-linked recessive.
Mutations in \(\text{ATP1A3}\) are found in approximately 75% of cases and the disease is transmitted as an autosomal dominant trait. The mutations are usually de novo, but some have been found to be transmitted to offspring. The \(\text{ATP1A3}\) gene (23 exons, open reading frame [ORF] contains 3042 base-pairs) encodes the sodium-potassium (Na+/K+) ATPase \(\alpha\) 3 subunit (1014 amino acids). Mutations in the \(\text{ATP1A3}\) gene, are also found in patients with dystonia 12 (rapid onset dystonia parkinsonism; RDP MIM 128235) and CAPOS (cerebellar ataxia, areflexia, pes cavus, optic atrophy and sensorineural hearing loss, MIM 601338) syndrome (Heinzen et al. 2014).

The outcome is variable; some children may reach a normal or borderline intellectual level but most have moderate or severe intellectual disability and almost all have a chronic movement disorder (Aicardi 2002; Panagiotakaki et al. 2012, 2015).

Following the discovery that mutations in the gene \(\text{ATP1A3}\) were prevalent in patients with AHC, clinical data from an international cohort of 155 AHC patients (84 females, 71 males; between 3 months and 52 years), allowed study of the spectrum of different mutations within the \(\text{ATP1A3}\) gene and the correlations with the phenotypes (Panagiotakaki et al. 2015). In total, 34 different \(\text{ATP1A3}\) mutations were detected in 85% (132/155) patients, seven of which were novel. In general, mutations were found to cluster into five different regions.

The most frequent mutations included: p.Asp801Asn (43%; 57/132), p.Glu815Lys (16%; 22/132), and p.Gly947Arg (11%; 15/132). Of these, p.Glu815Lys was associated with a severe phenotype, with more severe intellectual and motor disability. The mutation p.Asp801Asn appeared to confer a milder phenotypic expression, and p.Gly947Arg appeared to correlate with the most favourable prognosis, compared to the other two frequent mutations. Overall, the comparison of the clinical profiles suggested a gradient of severity between the three major mutations with differences in intellectual \((P=0.029)\) and motor \((P=0.039)\) disabilities being statistically significant. For patients with epilepsy, age at onset of seizures was earlier for patients with either p.Glu815Lys or p.Gly947Arg mutation, compared to those with p.Asp801Asn mutation \((P=0.001)\). With regards to the five mutation clusters, some clusters appeared to correlate with certain clinical phenotypes. No statistically significant clinical correlation was found between patients with and without \(\text{ATP1A3}\) mutations (Panagiotakaki et al. 2015).

Treatment with the calcium entry blocker flunarizine (Casaer et al. 1987; Silver and Andermann 1993; Andermann et al. 1995) reduces the frequency and duration of episodes in about half the cases. Other agents, including the NMDA receptor antagonist memantine, which has been found effective in a few patients (Korinthenberg 1996), and chloral hydrate or niaprazine, which if given at the onset of an attack may abort it (Veneselli and Biancheri 1997), are of uncertain efficacy. Treatment with topiramate was reported effective in a few children (Di Rosa et al. 2006; Jiang et al. 2006).

**PAROXYSMAL DISTURBANCES OF CONSCIOUSNESS**

The recurrence of variable degrees of disturbed consciousness from coma and stupor to lethargy and confusion is a common and difficult diagnostic problem. Most of the conditions that give rise to such problems are described in other chapters. Table 16.19 gives a list of responsible disorders to help diagnostic orientation. In most disorders, the diagnosis is suggested by a history of previous similar events and/or by a family history of similar cases. Metabolic disorders are particularly apt to present with recurrent disturbances of consciousness, often associated with vomiting and precipitated by infections and fasting. The possibility of drug toxicity should always be considered in such cases. A syndrome of idiopathic recurrent stupor (Tinuper et al. 1994; Lugaresi et al. 1998) in adolescents and young adults has been attributed to the accumulation of an endogenous ligand of benzodiazepine receptors, endodzepine-4, and may respond to flumazenil, which blocks benzodiazepine receptors. This syndrome has also been reported in children (Soriani et al. 1997).

The diagnosis demands exclusion of covert administration of exogenous benzodiazepines (Granot et al. 2004). However, a number of synthetic benzodiazepines are difficult to detect by conventional methods thus casting doubt on the very concept of endodzepine stupor (Cortelli et al. 2005). Associated phenomena may include hypothermia in Shapiro syndrome (Sheth et al. 1994) or, rarely, hyperthermia in the so-called reverse Shapiro syndrome (Hirayama et al. 1994).

**ACUTE PSYCHIATRIC MANIFESTATIONS**

Acute psychiatric manifestations represent the second most common cause of epilepsy misdiagnosis. In most cases the resemblance to epileptic seizures is only superficial, and episodes of anxiety, acute phobic episodes, instances of epigastric or laryngeal sensation of pressure, fugues and recurrent episodes of feelings of de-realisation often do not raise major diagnostic problems. However, panic attacks are sometimes mistaken for epilepsy (Genton et al. 1995). Hallucinations due to schizophrenia, or to schizophrenia-like states due to substance abuse, and acute confusional episodes may be difficult to distinguish from some types of nonconvulsive status epilepticus. Recurrent episodes of abnormal paroxysmal behaviour may be due to intermittently manifesting metabolic diseases such as hyperammonaemia or hypoglycaemia, and metabolic screening is indicated when these diagnoses are considered.

**Munchausen syndrome by proxy** may also be regarded as a cause of psychogenic seizures and can cause great diagnostic difficulties. The mothers, most often the offenders, may invent a story of seizures and, sometimes, tell it with great sophistication (Meadow 1984, 1991) or even teach the child that he or
aggression and be associated with reduced consciousness and postictal sleep. However, the episodes may occur following only slight provocations, and aggression is clearly directed, which differs from what is seen in patients with complex partial seizures fighting against restraint.

**PSYCHOGENIC NONEPILEPTIC SEIZURES (PSEUDOSEIZURES)**

The terms to describe such manifestations have changed over the years. The term ‘pseudoseizures’ is nowadays perceived as pejorative by many patients and has been progressively replaced by psychogenic nonepileptic seizures (PNES). Dickinson and Looper (2012) reviewed the history and terminology of PNES. The majority of published studies of PNES involve studies with small sample sizes and retrospective analysis of data. In a thorough 2007 Cochrane review of PNES non-drug treatment approaches, only three studies were deemed sufficiently rigorous (Brooks et al. 2007).

Some forms of hysterical attacks, psychic or psychogenic seizures, can be very difficult to distinguish from true epileptic seizures (Holmes et al. 1980). They are frequent in adolescents and may occur in children as early as 4 years of age (Kramer et al. 1995). They can occur even during apparent sleep (Harden et al. 2003) and in children with neurodevelopmental impairment (Neill 1990). ‘Pseudoseizures’ are commonly observed in children who also have epileptic seizures and are one important cause of apparent ‘intractability’ of epilepsy. They may also occur in children who have never had epileptic seizures (Holmes et al. 1980; Lesser 1996).

PNES can mimic any type of seizures, especially generalised ones, but unilateral or focal seizures may be seen and even EEG may not be sufficient for differential diagnosis from epileptic seizures as organic frontal seizures may not have an EEG expression. Motor signs can be subtle as trembling, intermittent stiffening or hyperventilation, head shaking, eye fluttering and oromotor activity, or more impressive as generalised violent, thrashing and uncoordinated movements, generalised stiffening, kicking, head or body turning from side to side, pelvic thrusting, generalised tremor, complex motor activity, and focal motor activity (for a review see Lortie 2013). The unique motor sign clearly associated with PNES is eye closure with active opposition to opening. Chung et al. (2006) reviewed 938 ictal events from 221 patients. They found that ictal eye closure had a sensitivity of 96.2% and a specificity of 98.1% for PNES.

Most PNES differ from true seizures by the nature of movements, which are not typical clonic jerks but rather semi-purposeful activity, by their violent and theatrical expression and by a nonstereotyped pattern. In one series of 21 children (Wyllie et al. 1990), 10 had episodes of unresponsive, generalised limb jerking and thrashing movements, and six had episodes of staring and unresponsiveness. Most children were responsive immediately after the paroxysm.
The average age of 43 patients studied by Lancman et al. (1994b) was 12.4 years at onset of seizures and 15 years when the diagnosis was made. Twenty-one of them received antiepileptic agents, and most episodes consisted of violent uncoordinated movements and generalised trembling, although a few patients had only staring seizures. The average duration of episodes was 5.6 minutes, although Bhatia and Sapra (2005) observed that their patients tended to have long episodes lasting 10–35 minutes. Induction of seizures by suggestion (Lancman et al. 1994a) may be helpful. However, the personality of the parents and/or patient and the way they describe the episodes may give rise to serious difficulties.

Ninety-four of 416 paediatric patients monitored during a 3-year period (23%) were found to have had nonepileptic events (Kurluay et al. 2010). Thirty-eight per cent were diagnosed with psychogenic nonepileptic seizures, of which 72% were adolescents. In children younger than 5 years of age, behavioural events and parasomnias were the most common mimickers of epilepsy. Globally, girls are more often diagnosed with PNES than boys (Irwin et al. 2000; Paalnisis and Paolicchi 2003).

Video alone, including home video, may have a high specificity and sensitivity in selected patients when reviewed by experienced observers (respectively 94% and 93% in a recent study) (Chen et al. 2008). However, the onset of the seizure is generally missed in home videos. Caregivers should also be instructed to capture limb and face movements in order to obtain useful information (Widdess-Walsh et al. 2012). When PNES are suspected they should be investigated with prolonged video-EEG to avoid unnecessary treatment (Lortie 2013).

Some true epileptic seizures, particularly of frontal lobe origin, may suggest hysteria or simulation. Weinstock et al. (2003) reported on five children with ‘hyperkinetic’ episodes mimicking frontal lobe seizures, which are particularly difficult to identify. A nonparoxysmal EEG is an important argument but certainly does not exclude the diagnosis as movement artefacts may render the EEG uninterpretable and normal tracings occur occasionally in ‘organic’ frontal seizures. Close video-EEG observation of the patients and tests of provocation may be necessary to firmly establish the diagnosis (Wyllie et al. 1990). Conversely, recording of typical EEG discharges concomitant to clinical events excludes the diagnosis of PNES.

Pseudo-status epilepticus is relatively frequent in adult patients and can be seen also in children (Tuxhorn and Fischbach 2002). Recognition of such cases is essential as the diagnosis of epilepsy often results in prolonged and increasingly heavier drug therapy, with negative effects.

Pseudoseizures masquerading as absences have been observed in 18 children with hyperventilation syndrome by North et al. (1990). The EEG of these patients showed bursts of slow-wave activity without spikes, corresponding to apparently impaired awareness and responsiveness. A similar EEG change associated with altered responsiveness can be observed during hyperventilation in typically developing children (Epstein et al. 1994).

Once the diagnosis of pseudoseizures is established, drug treatment should be rapidly discontinued. Some form of psychiatric treatment seems beneficial, at least in the short term (Holmes et al. 1980). The short-term outcome was favourable in 16 of the 21 children in the series of Wyllie et al., but only ten of 22 children followed-up for 40 months or more by Lancman et al. (1994b) were seizure-free at last visit. Gudmunsson et al. (2001) found that 14 of 17 children and adolescents with PNES were symptom-free after an average duration of treatment of 1.5 years and could resume school. A firm diagnosis is critical so that a shift away from antiepileptic medication and toward psychiatric therapy becomes possible.

THE HYPERVENTILATION SYNDROME

Hyperventilation syndrome is relatively common, especially in adolescent girls. The term implies that ventilatory effort is greater than necessitated by metabolic demands. Patients complain variably of chest pain, light-headedness and dyspnoea. Pseudo-absence spells and syncope may suggest the diagnosis of epilepsy. The diagnosis rests on a high index of suspicion and the presence of the typical symptoms. Rebreathing in a plastic or paper bag enables control of the symptoms of an impending attack and has both diagnostic and therapeutic value. Underlying family problems should be looked for, but the outlook is somewhat guarded as many children show chronic anxiety as adults (Herman et al. 1981; Oren et al. 1987).

SEIZURES OF TOXIC ORIGIN

Episodes of sudden loss of consciousness, often with convulsions or other neurological phenomena, should always raise the suspicion of toxicity. Predominantly motor manifestations may occur following use of an increasing number of drugs. Such seizures are often dystonic with recurrent episodes of stiffness, neck hyperextension and opisthotonus. Oculogyric crises are frequent. Any recurrent attack with extrapyramidal manifestation should suggest drug intoxication although this possibility may be denied by the parents or custodians. The drugs most commonly causing symptoms include psychotropic agents such as phenothiazines and butyrophenones (Pranzatelli 1996) and metoclopramide (Leopold 1984), but a vast number of agents produce similar symptoms (Elzinga-Huttenga et al. 2006) and a review of these is beyond the scope of this book. The important point is that any acute neurological or psychiatric manifestation in a child or adolescent should immediately suggest such a possibility and makes a thorough investigation imperative, regardless of the denegations of parents or relatives. A familial susceptibility to drugs may exist. Consciousness is preserved in many cases and this does not rule out intoxication that can produce other neurological manifestations with intact vigilance. Urine examination for the commonly responsible drugs should
be performed, and more specialised research may be required in doubtful cases.

Most acute drug reactions are self-limited. Treatment with intravenous benzotropine or diphenhydramine is useful to control rapidly severe dystonic–dyskinetic attacks, although some cases may be resistant to high doses (Leopold 1984).

### TETANY

Tetany is a manifestation of peripheral nerve hyperexcitability. The term is often used to designate convulsions due to hypocalcaemia in the newborn infant. In older infants and children, tetany proper is characterised by episodes of tonic muscular spasms and paraesthesias affecting the distal territory of nerves, often precipitated by hyperventilation or limb ischaemia. The clinical manifestations of classic tetany do not appear before 3 months of age. Carpopedal spasm is the most striking manifestation – it appears abruptly and affects the fingers primarily. The spasm is characterised by fingers flexed at the proximal joint and extended at the distal joints, with the thumbs strongly adducted and opposed. The feet may be similarly involved. Consciousness is preserved. Laryngospasm is common and may occur simultaneously with carpopedal spasm or independently. The vocal cords are adducted so that inspiration becomes noisy, and complete interruption of respiration rarely occur.

Between spasms, signs of latent tetany may be present but the Chvostek sign is not characteristic as it occurs in some typically developing children. Nerve hyperexcitability is expressed electrophysiologically by repetitive electromyograph (EMG) activity (multiplets) elicited by cuff-ischaemia of the arm, but is present also in 20–30% of healthy individuals (Eisinger 1987).

Tetany is usually due to hypocalcaemia and/or hypomagnesaemia but may also occur in normocalcaemic states. In such cases, tetany appears to be the consequence of a decrease in the level of ionised calcium with a normal level of total calcium. Decreased ionisation of calcium can be caused by alkalosis from hyperventilation or repeated vomiting as in pyloric stenosis.

Vitamin D deficiency is now a rare cause of tetany. Postoperative hypoparathyroidism and pseudohypo-parathyroidism are more frequently causal (Wilson and Hall 2002). Hypomagnesaemia with secondary hypocalcaemia is more rare (Visudhipan et al. 2005). Calcification of the basal ganglia can be found in patients with hypo-parathyroidism and pseudohyoparathyroidism, headaches and extrapyramidal signs. Additionally, patients with pseudohyoparathyroidism are obese, below average height, with a moon-shaped facies and short metacarpals. Intellectual disability, cataracts, enamel defect and decreased olfaction and auditory acuity are additional features (Ellie et al. 1989). In all types, epileptic seizures can occur at any age and are, in fact, more commonly observed than the muscle spasms of classic tetany.

The treatment of tetany consists of parenteral administration of calcium salts and vitamin D, and occasionally of magnesium salts.

### INVESTIGATIONS IN PATIENTS WITH EPILEPSY

Epileptic seizures are transient clinical events. Consequently, the identification of an attack as epileptic mainly depends upon reports from the patient and/or other witnesses. History taking is by far the most important ‘investigation’ for the diagnosis of epilepsy; if medical errors, in terms of both diagnosis and treatment choices, are to be avoided. The mainstay of the diagnosis is a good eyewitness account of the episode, but this information may not be available, may be incomplete, misleading or rather vague, and may not correspond to the definition of the various epileptic seizures or syndromes. The results of the additional investigations including EEG may also be uninformative, difficult to interpret, or contradictory.

A detailed description and updates of ancillary investigations are beyond the scope of this section. The reader is referred to the specialised literature on EEG (Daly and Pedley 1990; Blume and Kalbara 1995; Mizrahi et al. 2004; Kaminska et al. 2005; Crespel et al. 2006; Shcomer and Lopes Da Silva 2012), structural and functional neuroimaging (Kuzniecky and Jackson 2005; Gaillard et al. 2009; Chugani 2010; Gaillard et al. 2011; So and Ryvlin 2015; Gaillard and Oluigbo 2016) and neuropathology (Blümcke et al. 2015). Genetic and metabolic screening were treated in the corresponding chapters of this book. Presurgical evaluation strategies, both general and per aetiology can be found in Arzimanoglou et al. (2016).

The first step, following a first paroxysmal event reported by the patient or their family, is to obtain a precise description and formulate a hypothesis about the epileptic or nonepileptic nature of the event. History taking usually requires more than one session because new memories and questions may arise after the first questioning. The family needs to be informed about the importance of focal clinical signs if present, and about other elements that can provide clues to diagnosis and treatment. The parents should be encouraged to record a home video, an invaluable source of information. A detailed description of the clinical paroxysmal events, performed in a rigorous and comprehensive manner, is mandatory.

The accuracy of the diagnosis of epilepsy varies from a misdiagnosis rate of 5% in a prospective childhood epilepsy study in which the diagnosis was made by a panel of three experienced paediatric neurologists (Stroink et al. 2003) to at least 23% in a UK population-based study (Scheepers...
Epilepsy and Other Seizure Disorders

Chapter 16

**Electroencephalography**

An EEG is systematically recorded in children with a first epileptic seizure. However, it is of no value in cases presenting with simple febrile convulsions and in many cases of sporadic seizures. In general, an EEG, like any other investigation, should be required only when some sort of first hypothesis has been formulated. It may identify specific interictal or ictal abnormalities that are associated with an increased epileptogenic potential or a seizure disorder. The request for an EEG should be accompanied by a detailed description of the paroxysmal event and related clinical findings to maximise interpretation of the recording. It is also essential that the recording technique is standardised and that an experienced paediatric electroencephalographer interprets the recording, as the EEG profoundly changes with age, both in terms of background and type of abnormalities. The reader is referred to the specialised EEG literature for details (Daly and Pedley 1990; Blume and Kalbasa 1995; Mizrahi et al. 2004; Kaminska et al. 2005; Crespel et al. 2006).

The EEG is indicated as an emergency investigation only in cases of: suspected neonatal seizures, infantile spasms, nonconvulsive status epilepticus, coma of undetermined aetiology, confusional state or neurological signs suggesting a localised brain insult. In all other cases it is preferable to defer the investigation. Following a first unprovoked seizure the quantity of expected information from the standard EEG is generally too low to affect treatment recommendations in most patients (Gilbert and Buncher 2000).

In patients with previously diagnosed epilepsy, systematic repetition of the EEG at each presentation to an emergency department is unwarranted (Arzimanoglou et al. 2004), unless seizure semiology has changed.

EEG information should always be interpreted in conjunction with the clinical history (Koutroumanidis et al. 2017a,b). A normal EEG, even if repeated, does not exclude the diagnosis of epilepsy, nor does an abnormal or even a paroxysmal tracing establish it. The diagnostic yield of the interictal EEG can be increased if the conditions and techniques of recording are based upon a syndromic diagnostic hypothesis (e.g. sleep deprivation EEG when suspecting juvenile myoclonic epilepsy).

**Routine Electroencephalogram**

The ‘routine’ EEG of infants and young children should systematically include a sleep record. Standard activation procedures such as hyperventilation and photic stimulation should be included, and eventually adapted to the diagnostic hypothesis (e.g. investigating the spectrum of photosensitivity when suspecting a stimulus-sensitive epilepsy or reaction to low-frequency photic stimulation when suspecting a progressive myoclonic epilepsy).

In occasional cases, the EEG tracings may suggest an aetiology (e.g. the presence of a slow-wave focus may indicate...
a focal lesion; localised near-continuous EEG discharges may suggest focal cortical dysplasia). The lateralising and localising value of the EEG has been extensively discussed. Although a consistently focal EEG focus is of considerable value, diffuse paroxysmal EEG abnormalities are not rare in children with focal lesions, especially cortical malformations and developmental tumours (Kahane et al. 2005), and should not contra-indicate the possibility of surgery.

The prognostic significance of the EEG may be clearly established. Slow spike–wave complexes or multifocal spikes with abnormally slow background indicate the likelihood of an unfavourable course. Likewise, an abnormal EEG before discontinuing therapy may be associated with a high recurrence rate (Shinnar et al. 1990, 1994).

In general, however, the EEG is not an essential guide to therapy. The presence of EEG paroxysms is not in itself an indication for drug treatment nor a necessary contra-indication to its discontinuation. In rolandic epilepsy, for example, the EEG may normalise several months or years after cessation of seizures. The greater or lesser amount of paroxysmal EEG activity is rarely, if ever, an indication for stepping up or reducing therapy, except possibly in the case of some epileptic encephalopathies in which there are arguments (but no certainty) for trying to suppress or diminish the EEG epileptic activity. Clinical expertise of the treating physician is essential in interpreting EEG findings.

OTHER ELECTROENCEPHALOGRAM TECHNIQUES

In addition to hyperventilation, intermittent photic stimulation and brief sleep, which are routinely employed, prolonged sleep studies are of great interest under certain circumstances. All-night sleep records are particularly useful in such epilepsy syndromes as the Landau–Kleffner syndrome, and atypical partial benign epilepsy, or when continuous spike–waves of slow sleep are suspected. Sleep EEG is essential for recording nocturnal seizures, for example, in frontal lobe epilepsy. Nap recordings may be sufficient in many cases and should be privileged in children (Peraita-Adrados et al. 2001). Prolonged monitoring is also of value for the surveillance of neonates with seizures and in cases of encephalopathies with EEG-clinical dissociation.

Ambulatory EEG monitoring is a useful technique in cases in which the clinical history and sleep EEG are not sufficient to establish or rule out the diagnosis of epilepsy, and in which seizures are frequent enough to make their occurrence likely during a 24- or 48-hour period. Distinction between true and nonepileptic seizures is one of the best indications for this technique. It also facilitates sleep recording in older children who may not easily fall asleep in the laboratory. However, this technique is much less used nowadays, as ambulatory recording in childhood is prone to artefact and lead disconnection, and lacks video correlation. For these reasons it has been replaced by in-hospital video-EEG monitoring.

Video-EEG recordings (either of short duration conducted in an out-patient monitoring facility or of longer duration during hospitalisation) has become an essential tool for diagnosis and treatment. Its main indication is the recording of ictal phenomena for differential diagnosis, localisation and better syndromic diagnosis. Interictal activity can also be recorded for a longer duration and correlated to behavioural status. Digital EEG acquisition and storage in a format for subsequent re-montaging and filtering have improved the speed and accuracy of ictal recordings and replaced paper recording.

Telemetric EEG monitoring combined with neuropsychological tests has shown that isolated discharges or even single spikes may produce transient cognitive dysfunction (Arts et al. 1988). Their presence does not however require systematic treatment. Indications to treat with AEDs, the choice of the drug to be prescribed and the duration of treatment trial should be evaluated on a case-by-case basis and in collaboration with a paediatric epileptologist (Arzimanoglou et al. 2004).

Video-EEG monitoring of both ictal and interictal activity is essential in the pre-operative evaluation for epilepsy surgery. However, video-EEG monitoring must be interpreted with the assistance of experienced personnel (medical and paramedics) who can test patients during seizures looking for signs and symptoms of localising value such as a transient aphasia, limb dystonia, visual field or memory defects. Other EEG techniques, discussion of which are beyond the scope of this book, include semi-invasive (sphenoidal or ethmoidal electrodes, foramen ovale electrodes) and invasive techniques (extradural, subdural or depth electrode recordings).

NEUROIMAGING IN EPILEPSY

STRUCTURAL NEUROIMAGING

Although abnormalities on neuroimaging are observed in up to one-third of children with a first seizure, most do not influence immediate treatment or management decisions such as the need for hospitalisation or further investigations. Hirtz et al. (2000) reported that imaging results significantly contributed to further clinical management in only 2% of patients. In the majority of these cases imaging had been performed because the seizure was focal or there were specific clinical findings. Thus, there is insufficient evidence to support a recommendation at the level of guidelines for the use of routine neuroimaging; that is, imaging performed for a first non-febrile seizure in a child.

Factors to be considered for non-urgent neuroimaging study include age of the child, need for sedation, EEG results, history of head trauma, and other clinical factors including family history of epilepsy. MRI should be seriously considered in any child with a significant cognitive or motor impairment of unknown aetiology, unexplained abnormalities
Infants (<2 years) in addition to those 24 months and older

- Axial, coronal, sagittal (or 3D) T2
- 3D T1 and FLAIR less useful
- If clear abnormality with MRI then proceed to surgical planning (5)
- Source localisation (3D EEG, MEG or fMRI – EEG), FDG-PET, ictal/interictal subtraction SPECT generally equivalent. As a general rule follow institutional availability and expertise – if negative move to next modality (e.g. FDG-PET – if negative then SPECT then MEG). Recognise strengths and limitations of each modality (Jayakar et al. 2014)

The diagnosis of hippocampal sclerosis by MRI rests on unilateral decreased size of the Ammon horn, increased T2 signal and loss of the internal structure of the hippocampal architecture (Jackson et al. 1990; Cendes et al. 1993a, b) (Fig. 16.24). Hippocampal sclerosis is highly correlated with focal seizures of temporal lobe origin (Raymond et al. 1994; Cendes et al. 1995; Cendes 2005). A careful search for additional anomalies is indicated in cases of hippocampal sclerosis, especially with a view to detection of dual pathology (e.g. coexistence of cortical dysplasia).

It is our practice not to recommend neuroimaging studies for children with classic idiopathic generalised epilepsies (absence epilepsy, JME) or for children with typical Rolandic epilepsy. Contrariwise, imaging is obligatory for children with all other types of seizures or for any patient with atypical epilepsy. In children with non-idiopathic focal epilepsy that resists AED treatment, we repeat the MRI investigation using high-resolution techniques, preferably after a full revision of the electroclinical presentation of the seizures. Informing the neuroradiologist about the suspected topography of the epileptogenic zone is mandatory.

**FUNCTIONAL NEUROIMAGING AND OTHER TECHNIQUES OF INVESTIGATION**

Functional imaging studies using radiotracers, PET and SPECT, are performed to identify or confirm the ictal focus in the pre-operative evaluation for surgery. The goal of these investigations is to identify eloquent cortical regions and fibre tracts to be spared during epilepsy surgery, and to investigate the pathophysiology of focal and generalised seizure disorders (for detailed reviews see Duncan 1997; Gaillard 2006).

PET allows for the measurement of regional variations in glucose metabolism using $^{18}$FDG (fluoro-deoxyglucose), to map cerebral metabolism by means of $^{15}$O-labelled water; $^{11}$C-flumazenil is utilised to quantify benzodiazepines receptors. The basic aspects and limitations of the technique, the radiopharmaceuticals in epilepsy, the sensitivity of different types of PET investigations, and the practical utility of PET imaging in the presurgical assessment of focal epilepsies has been reviewed (Mauguire and Ryvlin 2004; Jayakar...
et al. 2014; Gaillard and Oluigbo 2016). Because of its limited temporal resolution, PET does not allow ictal studies but can evaluate interictal glucose metabolism. A correlation has been shown to exist between primary epileptic regions and hypometabolic areas (Chugani et al. 1987; Theodore et al. 1992).

In children with infantile spasms and normal MRI, PET may reveal regional metabolic abnormalities that identify the seizure-onset zone (Chugani et al. 1988). In some children, however, metabolic abnormalities at the onset of infantile spasms resolve with time and thus may represent a functional state that is potentially reversible (Itomi et al. 2002). In children with tuberous sclerosis, the PET tracer $[^{11}C]$methyl-L-tryptophan (AMT) is claimed to be selectively taken up by epileptogenic tubers (Chugani et al. 1998). If proven, this observation might allow differentiation from non-epileptogenic tubers in the interictal state and facilitate candidate selection (Kagawa et al. 2005). $[^{11}C]$AMT uptake is also enhanced in focal cortical dysplasia (Fedi et al. 2003; Juhasz et al. 2003). PET studies in Lennox–Gastaut and Landau–Kleffner syndromes reveal mixed results (for a review see Gaillard 2006).

SPECT is based on regional blood flow and has a lower spatial resolution than PET. The radiopharmaceutical 99mTc-HMPAO permits the study of ictal events when injected during a seizure as it is immediately taken up by active cells, with scanning performed 4–6 hours after injection (Harvey et al. 1993a, b; Newton et al. 1995). Interictal SPECT gives results generally similar to those of PET, for example, decreased localised uptake in the region of origin of seizures, although its accuracy is not uniform as time of injection may vary among centres (Cross et al. 1997).

Ictal SPECT compared with an interictal investigation demonstrated regional hyperperfusion in 67–90% of patients (Gaillard 2006) that in a majority of patients correlated with the ictal focus. Such a correlation has been validated with simultaneous intracranial EEG (Spanaki et al. 1999). Seizure localisation using ictal SPECT was also reported in children with intractable epilepsy (Harvey et al. 1993a, b; Cross et al. 1995). False localisation is reported in 3–4% of studies, most probably because of seizure propagation, particularly following late injection times. Subtraction techniques with MRI co-registration improve postictal SPECT localisation of seizure foci (O’Brien et al. 2004). The main technical limitation of this technique derives from the fact that in order for an ictal SPECT study to be useful, the ligand must be injected during the first 10 seconds of seizure onset, which demands a constant surveillance during video-EEG investigations.

**Functional magnetic resonance imaging (fMRI)** is based on oxygenated haemoglobin giving a different magnetic resonance signal than deoxyhaemoglobin, with increased blood flow to actively discharging neurons resulting in an increased

---

**Figure 16.24** MRI scans of both hippocampi of a patient with mesial temporal sclerosis showing details that can be obtained with high-resolution techniques. (Top) Right hippocampus (arrow) is of almost normal size but internal structure cannot be made out. (Bottom) Increased T2 signal in external part of right hippocampus (arrow). (Courtesy Dr G Jackson, Melbourne, Australia.)
signal. The resulting increased oxyhaemoglobin/deoxyhaemoglobin ratio (Morris et al. 1994; Detre et al. 1995), permits localisation of areas of active brain regardless of whether the activity is normal, for example, voluntary movements, or abnormal, such as epileptic. Functional MRI may have a dual role: (1) to localise epileptic foci by identifying regional blood flow changes that accompany partial seizures; and (2) to map the brain areas such as the motor or language areas that must be respected surgically. Several studies indicate that fMRI language paradigms reliably identify hemispheric dominance for language, including bilateral and right-hemisphere language representation in adults and in children 5 years of age and older (for reviews see Gaillard 2006; Pelletier et al. 2007). This technique is replacing more invasive methods such as intracarotid injection of amytal to determine language laterisation (Wada testing) or other essential functions (Pelletier et al. 2007).

Other techniques in clinical practice include magnetoencephalography (MEG), as well as various computerised methods of signal interpretation and EEG topographic studies (e.g. dipole models). MEG registers magnetic brain activity with a high spatio-temporal resolution. It co-registers magnetic spike sources with anatomic MRI, to produce magnetic source images to determine the locus of epileptiform activity. Since distortion of magnetic fields by the skin, skull and CSF is negligible, the technique, while still expensive, offers an almost undistorted view of brain activity with a horizontal dipole and assists in focus localisation and presurgical functional mapping (Rampp and Stefan 2007; Murakami et al. 2016; Bagić and Burgess 2016; Bagić et al. 2017). MEG spike clusters are corroborated by intraoperative invasive monitoring studies revealing good correlation in the majority of cases.

Another important role of MEG relates to mapping critical cortex for speech, motor, sensory, visual and auditory function. When linked to standard neuronavigation devices, MEG brain mapping assists the neurosurgeon in nonlesional cases. As paradigms for brain mapping improve and as MEG software upgrades become more sensitive to analysing all types of spike sources, MEG might play an increasingly important role in paediatric neurosurgery, especially for the child with intractable epilepsy (Grondin et al. 2006).

Equivalent dipole modelling, or electrical source imaging, is another relatively novel technique for the spatio-temporal analysis of scalp voltage fields. Based on EEG recorded data, this technique provides accurate interpretation of radial dipole models and can lead to a better characterisation of their location and propagation. Importantly, this technique can be employed at minimal cost making it attractive for epilepsy surgery centres with more limited resource modern techniques of 3-D MRI reconstruction and realistic head models have both improved localisation accuracy and provided a means of displaying results in an image of the individual's brain (Ebersole and Hawes-Ebersole 2007).

The Task Force for Paediatric Epilepsy Surgery of the ILAE published an update on the diagnostic tests utilisation in evaluation for respective epilepsy surgery (Jayakar et al. 2014) that also provides clues for the more global use of the above tools.

TREATMENT OF EPILEPTIC SEIZURES AND EPILEPSY SYNDROMES

The management of epilepsy is not limited to the prescription of drugs. Particularly complicated cases require considerable time, competences, and technical and human resources. In many ‘ordinary’ cases it still requires careful attention, and specialist neurological advice should be sought in most, if not all, cases before starting treatment. The impact of epilepsy on the life of the child and the family group is considerable, and the education and support of parents, counselling and help with educational problems, and management of behavioural difficulties may be even more important than drug therapy of seizures.

EDUCATION OF PARENTS AND CHILDREN

Because the impact of the diagnosis of epilepsy is not only – or not even essentially – concerned with the rational aspects but has also to take into account misconceptions and prejudices traditionally associated with seizure disorders, a personalised, yet full, explanation should be given to the patient and family. The misconception that epilepsy is a disease ‘in its own right’ should be dispelled, and the concept of epileptic seizures as symptoms of brain dysfunction should be discussed thoroughly. Preconceived entrenched ideas, for example, that all epilepsies are life-long or related to psychiatric disorders, should be discussed and dispelled, as should the frequently expressed fear that brain tumours or other serious brain disorders are a common cause (Brett 1997; Arzimanoglou et al. 2004). A full set of information cannot be given in one session, and repeated interviews are required. Families need time to build and verbalise their concerns. Similarly, the treating physician often needs time to establish a definite diagnosis of the type of epilepsy and its underlying aetiology, a prerequisite for an optimal response to treatment and accurate prognosis.

A full explanation of the aims of therapy, its shortcomings and potential risks of discontinuation. This is essential for the establishment of a confident relationship between patient and physician (Aicardi and Taylor 1998).

It is extremely important to provide a clear understanding of permitted activities and what restrictions are warranted. Restrictions should be limited to a reasonable minimum, with the knowledge that some risks are unavoidable. Swimming is possible with adequate one-to-one supervision.
The use of a bicycle (except on safe roads), and especially of a motorbike, is one of the most difficult problems and can be solved only individually and often imperfectly. Sports such as tennis, football or basketball or gymnastics should be encouraged. Scuba diving and water cave diving should not be permitted.

**DRUG TREATMENT**

**GENERAL PRINCIPLES**

Drug treatment is the therapy of choice for the vast majority of children with seizure disorders. The main drugs currently available are shown in Table 16.20 and primary pharmacokinetic data is given in Table 16.21.

A number of wide-spectrum AEDs have been developed during the last 25 years, including lamotrigine, levetiracetam, topiramate, felbamate, zonisamide and rufinamide. Perampanel is also a promising wide spectrum agent. Others, such as oxcarbazepine, eslicarbazepine, gabapentine, vigabatrin and pregabalin are excellent alternatives for the control of focal seizures. Controlled data in young children are usually lacking, and the drugs are often used out of licence. Data from clinical trials in adults, extrapolated to predict benefits in paediatric patients, often result in fewer or smaller trials being required to obtain a new drug license for children (Wadsworth et al. 2016; Pellock et al. 2017a).

A systematic review of 30 adjunctive therapy focal onset seizures trials supported the extrapolation of efficacy results in adults to predict a similar adjunctive treatment response in 2- to 18-year-old children with focal seizures (Pellock et al. 2012). Effect measures were consistent between adults and children for gabapentin, lamotrigine, levetiracetam, oxcarbazepine and topiramate. Placebo-subtracted median per cent seizure reduction between baseline and treatment periods (ranging from 7.0% to 58.6% in adults and from 10.5% to 31.2% in children) was significant for 40 out of 46 and six out of eight treatment groups studied. The ≥50% responder rates (2.0–43.0% in adults and 3.0–26.0% in children) was significant for 40 out of 46 and six out of eight treatment groups (Pellock et al. 2012).

Unconventional agents such as ACTH and corticosteroids are extremely potent drugs for the treatment not only of infantile spasms but also of other types of resistant epilepsy, especially when cognitive and/or major behavioural disturbances appear. They deserve a full trial (2–4 weeks or more) in such cases.

The mode of action of AEDs is beyond the scope of this book (for reviews see Levy et al. 2002; Wyllie et al. 2006, 2011; Pellock et al. 2017b) and still imperfectly known. Steps from absorption through entry and distribution into the brain constitute the pharmacokinetics of a drug. Considerable knowledge has accumulated over the past two decades about the pharmacokinetics of AEDs, especially in children (Dodson and Pellock 1993; Kearns et al. 2003; Booth and Evans 2004). Later steps with resulting changes in neuronal excitability constitute the pharmacodynamic phase of drug action. Initial pharmacokinetic steps (from absorption to brain entry) are reflected in the blood levels of a drug (Landmark et al. 2016). It has been shown that the blood levels of AEDs are more closely related to brain levels than to the dosage ingested, which is the rationale for their determination. However, blood levels are only one link in the chain of processes that take place between ingestion of a drug and its therapeutic and other effects, and their relationship to brain levels and to levels at the receptors are not necessarily close. Such discrepancies are frequent with sodium valproate and can also occur with carbamazepine (Suzuki et al. 1991, 1994).

**INSTIGATION OF TREATMENT**

Initiating antiepileptic drug treatment is an important clinical decision that requires a firm diagnosis of epilepsy. Consequently, drug therapy should not be initiated for children with paroxysmal events of uncertain origin (Arzimanoglou et al. 2004), or in patients with a single seizure (unless it is of a type allowing a firm diagnosis of an epilepsy syndrome) or for those with epileptic EEG abnormalities without clear-cut clinical manifestations or consequences (Hirtz et al. 2000; Arts et al. 2004; Beghi 2007). Likewise, preventive drug treatment for patients with potentially epileptogenic brain lesions is of unproven value and best avoided as it may result in years of useless drug therapy (Shinnar and Berg 1996).

The problem posed by children with interictal EEG discharges and non-seizure behaviours or cognitive decline is challenging. EEG paroxysms may play a role in some cases (Nicolai et al. 2006), especially if prolonged. Treatment is clearly indicated for some syndromes of severe cognitive decline such as ESES or the LKS (see Encephalopathy with Status Epilepticus During Slow Sleep (ESES) and Landau–Kleffner Syndrome sections), even though there is only anecdotal evidence of efficacy. As these syndromes are typically treatment-resistant, assessing their responsiveness to therapy may prove difficult. Most clinicians are disinclined to treat children with learning difficulties or attention deficit based solely on interictal EEG anomalies. Treatment decisions should, therefore, be evaluated on an individual basis by an experienced child neurologist with competences in both epilepsy and neurophysiology.

Children with two or more seizures or those with a first seizure predictive of chronic epilepsy are candidates for drug treatment. Treatment for patients with infrequent seizures, seizures that are clinically restricted or that occur at socially ‘convenient’ times may not require immediate therapy. The decision to initiate treatment also depends heavily on lifestyle preferences if seizures are relatively rare (Beghi 2007). The decision has to be taken in concertation with the family by a child neurologist specialised in epilepsy.

</table>

Lack of controlled studies for the use of AEDs in children often obliges the use of off-licence drugs. This table does not take into account local legal authorisations for the use of AEDs.

- Oral administration unless otherwise noted (i.v. = intravenously; i.m. = intramuscularly).
- Slow release preparation available.
- May aggravate myoclonic and absence seizures.
- Progressive increase in dose especially important.
- Oral, liquid and i.v. preparations available.
- For refractory cases only.
- For acute treatment of status.

ACTH, adrenocorticotropic hormone; ESES, electrical status epilepticus in sleep.

</table>

*Tmax = time to peak plasma level after administration of single dose.

Half-life may exceed 100 hours in the first 2 weeks of life.

Half-life in patients receiving the drug as monotherapy, before development of induction.

Half-life in patients receiving the drug chronically, when auto-induction has developed, or receiving other inducing agents.

PEMA = phenylethylmalonamide.

Not significant as the drug binds irreversibly to glutamate-transaminase thus increasing brain GABA level, therefore the important half-life is that of restoration of enzyme level.
CHOICE OF DRUG(S)

The choice of drug(s) depends preferably on the epilepsy syndrome or, if this is not yet identified, on the type of seizure(s) experienced by the patient (Arzimanoglou 2002; Wheless et al. 2007; Wilmshurst et al. 2015a, b; Pellock et al. 2017b). Table 16.22 indicates an order of preference for the usual AEDs in the most frequent types of childhood epilepsy.

Any choice is of necessity arbitrary, in part because neither efficacy nor adverse drug effects are fully predictable (Arzimanoglou et al. 2004). Selection of the first drug is often dependent on toxicity, adverse effects and ease of administration as the effectiveness of several different drugs is often comparable. This does not apply to absence seizures and many myoclonic seizures for which mostly sodium valproate, ethosuximide, levetiracetam and the benzodiazepines are indicated. Comparative studies both in adults (Mattson et al. 1992; Richens et al. 1994) and in children (Verity et al. 1995; de Silva et al. 1996) have failed to show significant differences in the efficacy of conventional drugs (phenobarbitone, phenytoin, carbamazepine, sodium valproate) used as monotherapy for focal or generalised convulsive seizures. These results do not exclude the possibility of some agents being more effective in subsets of patients or individual cases.

Some agents are more efficacious in generalised epilepsy or control both focal and generalised seizures (sodium valproate, lamotrigine, levetiracetam, topiramate, zonisamide) while others are indicated for focal seizures only (carbamazepine, gabapentin, oxcarbazepine, vigabatrin). Some agents may aggravate rather than improve certain forms of epilepsy (e.g. carbamazepine for genetic [idiopathic] generalised epilepsies or syndromes with predominantly myoclonic seizures or typical absences; lamotrigine in some cases of young children with Dravet syndrome). However, while this applies for the initial choice of drugs, in resistant cases with tonic–clonic seizures applying too strict rules may be counterproductive.

In many instances the likelihood of adverse effects is critical for drug selection. Major adverse effects are rare (see Adverse Effects of Antiepileptic Drugs section), but even relatively mild effects may significantly impact quality of life. Thus, given the choice between carbamazepine, phenobarbitone and phenytoin, carbamazepine is often preferred in childhood due to its ease of administration and lack of effect on cognition (phenobarbitone), or gingival hyperplasia and hirsutism (phenytoin). New generation AEDs have better short- and long-term tolerability than older antiepileptic agents and are preferred as a first choice.

MONOTHERAPY VERSUS POLYThERAPY

Single drug administration is associated with fewer and less confusing side effects than multiple agents and diminishes drug interactions. Therefore, treatment should almost always be started with a single agent. Seventy to 90% of newly diagnosed, common forms of epilepsy are controlled with monotherapy (Forsythe and Sills 1984; Brodie 1990; Kwan and Brodie 2000a, b, 2001).

Drug combinations should be considered after single drugs in correct dosages have failed to control seizures for a substantial period. However, sequential monotherapy should precede the use of multiple therapy as the value of adding a second drug is often uncertain. Approximately 10–15% of patients so treated have improved seizure control, but a few patients may deteriorate and there is a likelihood of increasing side effects.

Combinations of more than two drugs are rarely indicated (Aicardi and Shorvon 1998; Arzimanoglou et al. 2004). No consensus exists on the number of monotherapy trials that should be attempted before combination therapy is introduced, but at least two appropriate AEDs at the maximally tolerated dose should be tried. Evidence from open clinical trials in adolescents and adults (Kwan and Brodie 2000b, 2001) has shown that full control of seizures is only rarely obtained from a third drug when the first two have failed. This probably applies to children as well. However, the occurrence of two types of seizures in the same patient (e.g. LGS or Dravet syndrome) that require different therapy (Aird et al. 1984; Perucca and Levy 2002) sometimes justifies the early introduction of combination therapy. Even in such cases, however, the use of some modern drugs with a large spectrum of action (e.g. valproate, lamotrigine, levetiracetam, topiramate) may obviate the need for polytherapy.

MODE OF ADMINISTRATION

In principle, the use of more than two doses per day is to be avoided except in cases of very resistant epilepsy treated with drugs of short half-life. Some drugs, for example, phenobarbitone, vigabatrin or lamotrigine, may be given in a single evening dose in older children and adolescents. Sodium valproate can also be used as a single dose in adolescents (Covanis and Jevons 1980).

Gradually increasing or decreasing drug dosage on drug initiation or withdrawal is essential. The first or successive drug should be introduced at low dosage and titrated gradually until control is obtained or the limit of tolerance reached. This is especially important with lamotrigine as the frequency of allergic hypersensitivity rashes increases with rapid introduction. Slow withdrawal is also important for barbiturates, vigabatrin and felbamate, whose rapid discontinuation may induce status epilepticus. However, in the common epilepsies of childhood, withdrawal over 4–8 weeks did not seem to be associated with a higher recurrence rate (Dooley et al. 1996).

When a first drug has failed and another is introduced, the first agent should be withdrawn progressively. It should be remembered that achievement of a stable drug level requires approximately four plasma half-lives. The time to achieve stable levels may be much longer as the dose is usually gradually increased and as phenomena of induction progressively modifies (usually shortens) the apparent drug half-life.

*Lack of controlled studies for the use of AEDs in children often obliges the use of off-licence drugs. This table does not take into account local legal authorisations for the use of AEDs.
The treating physician must be convinced that in everyday clinical practice a rapid titration of an AED is only exceptionally indicated. The families also need to be informed about the expected delays in achieving stable, and hopefully efficacious, drug levels. Two of the most frequently observed medical errors include overly rapid substitution of a newly prescribed AED or too early instigation of adjunctive treatment.

**MONITORING OF ANTISEIZURE DRUG THERAPY**

Regular clinical supervision of children on antiepileptic drug therapy is essential. Special attention should be given to side effects including diplopia or vertigo that may be considered normal phenomena by the family or the patient. Digestive disturbances, drowsiness or language expression disturbances should also be considered carefully. However, most adverse events are transitory and early discontinuation of a drug should be avoided in most cases, provided that the patient is informed beforehand and titration is slow. A moderate leukopenia and elevation of transaminases are common and do not herald the appearance of hepatic failure or pancytopenia.

In evaluating the efficacy of any drug regimen, clinical judgement based on seizure recurrences is fundamental. It is relatively easy in patients with frequent, regularly repeated seizures (e.g. in absence epilepsy) but it becomes long and difficult in patients with rare seizures or irregular seizures that cluster. This difficulty must not lead one to forget that the end-point of treatment is the control of seizures, not obligatorily a normal EEG or a so-called therapeutic blood level.

Monitoring the blood levels of AEDs is not routinely indicated and is rather useless in children with epilepsies that are well controlled on regular or low-dosage and well-tolerated monotherapy. Many patients are seizure-free with blood levels well below the published ranges, and modification of dosage to obtain ‘therapeutic’ levels is ineffective (Woo et al. 1988) and increases the risk of side effects. Likewise, discontinuation of a drug because its level is ‘subtherapeutic’ can result in seizure relapse (Richens 1982). Conversely, in resistant cases, the dose should be pushed to the limit of clinical tolerance, regardless of blood levels.

Blood level determinations may be useful to check patients’ compliance and to confirm suspected toxicity in infants or in children with intellectual disability, in whom recognition of a side effect may be difficult. Detection of blood interactions in patients taking multiple agents is less frequently required. Phenytoin therapy has a low therapeutic ratio (i.e. the margin of safety) which may lead to ‘breakthrough’ seizures in previously well-controlled children (Aicardi 1994). Blood levels are unhelpful with some drugs (vigabatrin, levetiracetam, lamotrigine, topiramate) and of dubious value with others, for example, sodium valproate, whose levels are poorly correlated to clinical effects.

Interpretation of blood levels is not always straightforward, especially in cases of interactions (Levy et al. 2002; Landmark et al. 2016); for drugs with variable protein binding that results in a change in levels of free, unbound, drug, and for those with active metabolites, such as carbamazepine, as the rate of formation of the metabolite is not constant and blood levels are not measured routinely.

When blood level determination is requested, should always consider the dose, time of administration and time of blood sample collection.

**ADVERSE EFFECTS OF ANTIPELLEPTIC DRUGS**

Adverse effects of antiepileptic drugs are common (Table 16.23) and extensive reviews are available (Levy et al. 2002; Kothare and Kaleya et al. 2007; Perucca and Gilliam 2012). The most common adverse effects are transient and occur at the beginning of treatment. These include digestive disturbances, drowsiness and dizziness. All antiepileptic agents may – albeit rarely – produce adverse effects that seriously hamper the patient’s activities. These effects range from acute intoxication with disturbances of consciousness (Larrieu et al. 1985; Zaret and Cohen 1986; Weaver et al. 1988; Meador 1994, 2001; Martin et al. 1999) or, exceptionally, death (Stone and Lange 1986; Murphy et al. 1987; Leestma et al. 1997) to subtle chronic toxicity with protean manifestations (McLeod et al. 1978; Dravet et al. 1980; Joyce and Gunderson 1980; Karas et al. 1982; McLachlan 1987; Pellock 1987; Appleton et al. 1990; Weig and Pollack 1993; Gerber et al. 2000; Pellock 2017b), and to apparently minor but sometimes psychologically and socially disabling effects such as acne, excessive weight gain (Egger and Brett 1981; Dinesen et al. 1984; DeToledo et al. 1997) or weight loss (Potter et al. 1997).

Allergic or idiosyncratic reactions are also common, and these may rarely be responsible for fatalities (Gilhus and Matte 1986; Browne et al. 1988; Kaufman et al. 1997; Schienger et al. 1998; Fernández-Calvo et al. 2000).

Based on the underlying mechanisms, idiosyncratic reactions can be differentiated as follows:

1. Immune-mediated hypersensitivity reactions, which range from benign skin rashes to serious conditions such as drug-related rash with eosinophilia and systemic symptoms.
2. Reactions involving unusual nonimmune-mediated individual susceptibility, often related to abnormal production or defective detoxification of reactive cytotoxic metabolites (as in valproate-induced liver toxicity).
3. Off-target pharmacology, whereby a drug interacts directly with a system other than that for which it is intended, an example being some types of AED-induced dyskinesias.

Although no AED is free from the potential of inducing idiosyncratic reactions, the magnitude of risk and the most

common manifestations vary between drugs, a consideration that impacts on treatment choices (Zaccara et al. 2007).

### Antiepileptic Drugs and Cognition

The cognitive effects of anticonvulsants (Meador 1994, 2001; Alden Rampley 2001; Boshuisen et al. 2015) must also be carefully monitored, and no drug is completely exempt from unfavourable cognitive or behavioural effects. Some agents (e.g., phenobarbitone, topiramate) are more prone to adverse effects than others (e.g., sodium valproate, carbamazepine, lamotrigine, gabapentin, levetiracetam).

The relative effects of the newer AEDs are not fully determined. No cognitive effects were found with lamotrigine (Smith et al. 1993), and several studies using quality-of-life measures reported a beneficial effect of lamotrigine on patient perception of psychological well-being (Smith et al. 1993; Brodie et al. 1995). In 25 healthy adults participating in a double-blind randomised crossover design study, lamotrigine produced significantly fewer cognitive and behavioural effects than carbamazepine (Meador 2001). Psychomotor slowing, language problems and memory disturbance are reported with topiramate (Martin et al. 1999; Bootsma et al. 2006). Word-finding difficulty in both children and adults is unique to topiramate (Meador 2001; Brandt et al. 2015).

Witt et al. (2015) demonstrated greater adverse effects of a higher drug load on cognition, especially executive functions. We share the conclusion of the authors that ‘simply counting the number of drugs may be sufficient as a rough estimate of the risk of side effects’. Despite available data it is unfortunately still common to see children, particularly with severe epileptic encephalopathies, treated with four or more irrationally associated AEDs. This practice may intensify the consequences of the underlying pathology and rarely leads to a clinically meaningful reduction of seizure frequency.

Neuropsychological testing is helpful to identify cognitive adverse effects that severely impair quality of life. Cognitive screening can be achieved by easy-to-use scales such as EpiTrack, a 15-minute tool to detect and track cognitive side effects of AEDs and adverse effects of seizures (Lutz and Helmstaedter 2005). A junior version of EpiTrack is a valid and reliable screening tool for assessing executive function in children and adolescents (Helmstaedter et al. 2010).

### Antiepileptic Drugs and Pregnancy Related Issues

Teratogenicity must be considered with long-term treatment for female adolescents with epilepsy (Morrell 2002; Tettenborn et al. 2002). AEDs are among the most common teratogenic drugs and induce both anatomical (malformations) and behavioural (cognitive/behavioural) changes in the offspring (Meador and Loring 2016). Treating epilepsy during pregnancy requires a balance between maternal and fetal risks associated with uncontrolled seizures against the potential teratogenic effects of AEDs. A rational approach requires knowledge of these risks, an understanding of the effects of pregnancy on seizure control and AED disposition (Battino and Tomson 2007). Older AEDs (benzodiazepines, phenytoin, phenobarbitone and valproate) carry a risk of major fetal malformations, including cleft lip and palate and cardiac defects.

The International Registry of Antiepileptic Drugs and Pregnancy (EURAP), prospectively epilepsy and pregnancy registry prospectively monitored pregnancies exposed to monotherapy with different doses of four common drugs: carbamazepine, lamotrigine, valproic acid, and phenobarbital (Tomson et al. 2011). Pregnancies were excluded if they ended in spontaneous abortions, had chromosomal or genetic abnormalities, involved treatment changes in the first trimester or other situations that could affect fetal outcome. The authors assessed rates of major congenital malformations in 1402 pregnancies exposed to carbamazepine 1280 to lamotrigine 1010 to valproic acid, and 217 to phenobarbital. An increase in malformation rates with increasing dose at the time of conception was recorded for all drugs. Multivariable analysis including ten covariates in addition to treatment with AEDs showed that the risk of malformations was greater with a parental history of major congenital malformations (odds ratio 4.4, 95% confidence intervals 2.06–9.23).
The lowest malformation rates occurred with less than 300mg per day lamotrigine [2.0% (17 events), 95% confidence intervals 1.19–3.24] and less than 400mg per day carbamazepine [3.4% (five events), 95% confidence intervals 1.11–7.71]. Compared with lamotrigine monotherapy at doses less than 300mg per day, risks of malformation were significantly higher with valproic acid and phenobarbital at all investigated doses, and with carbamazepine at doses greater than 400mg per day (Tomson et al. 2011).

The UK Epilepsy and Pregnancy Register (Morrow et al. 2006) showed that only 4.2% of live births to women with epilepsy had a major congenital malformation (MCM). The MCM rate for multi-drug exposure was greater than for monotherapy. Multi-drug regimens containing valproate had significantly more MCMs. Carbamazepine monotherapy was associated with the lowest risk of MCM (Morrow et al. 2006).

The risk of malformations is generally regarded as highest in fetuses exposed to multiple AEDs in higher doses.

The majority of patients with epilepsy maintain seizure control during pregnancy. Seizure control and AED treatment were recorded prospectively in 3806 pregnancies of 3451 women with epilepsy taking part in EURAP (Battino et al. 2013); 66.6% remained seizure-free throughout pregnancy. Generalised tonic–clonic seizures occurred in 15.2% and women with idiopathic generalised epilepsy were more likely to remain seizure-free (73.6%) than women with localisation-related epilepsy (59.5%; P<0.0001). Worsening of seizure control from the first to second or third trimesters occurred in 15.8% of pregnancies. The AED dose was increased during pregnancy in 26.0% and a second AED added to the initial monotherapy in 2.6% of pregnancies. Seizures were more likely to occur in the first trimester in pregnancies with a greater drug load (35%; increased dose and/or addition of another AED) than in pregnancies without an increase (15.3%) (P<0.0001). Pregnancies exposed to lamotrigine were less likely to be seizure-free, 58.2% (P<0.0001), had more generalised tonic–clonic seizure (GTCS) (21.1%; P<0.0001) and were more likely to require an increase in drug load, 47.7% (P<0.0001). The authors concluded that a more proactive approach to adjusting the dose of AEDs in pregnancy should be considered, in particular in pregnancies with seizures in the first trimester and exposure to lamotrigine (Battino et al. 2013).

Congenital malformations associated with AEDs are generated in the first trimester of pregnancy and neural tube defects are complete by day 28 after conception. Pre-conception counselling is thus essential. Modifications of the ongoing treatment should take place before conception to allow optimal therapy with the lowest possible dose, preferably of monotherapy. The type(s) of seizures must be taken into account. For example, if generalised tonic–clonic seizures in a patient with JME are well controlled with an average dose of lamotrigine but some myoclonic jerks persist, not adding other medication, at least until the end of the first trimester, is preferable.

**ANTIEPILEPTIC DRUGS AND A PARADOXICAL INCREASE IN SEIZURE FREQUENCY**

In some cases, AEDs cause a paradoxical increase in seizure frequency (Guerrini et al. 1998a, 2002c; Perucca et al. 1998). Carbamazepine, vigabatrin or gabapentin are contra-indicated in patients with absence epilepsy or juvenile myoclonic epilepsy (Shorvon et al. 1978; Callahan and Noetzel 1992) and should be used with caution in patients with a mixed seizure disorders, particularly a combination of atonic, tonic–clonic, myoclonic and atypical absence seizures with generalised EEG discharges (Perucca et al. 1998). Aggravation of seizures is reported with lamotrigine in young children with Dravet syndrome (Guerrini et al. 1998b). The aggravation of absence or myoclonic seizures with phenytoin has also been reported, but the overall number of cases is lower than that recorded with carbamazepine.

In view of the problems associated with chronic treatment with AEDs much depends on cooperation between patient and his or her family and their understanding of the problems posed by the disorder. The nature of the problem should be explained in simple terms, and the need for prolonged supervision should be emphasised. Treatment is a reasonable compromise between when initiating anticonvulsant medication that modifying the dosage to find the best dose for the individual child is often necessary, and that different or additional medications may be required if the first drug fails to control seizures. This may help parents to accept later changes with less anxiety and fewer doubts about the competence of their physician.

**NON-DRUG MEDICAL TREATMENTS**

**KETOSCINIC DIET**

The ketogenic diet has long been in use for the treatment of children with severe epilepsies (Freeman et al. 2007). Although the mechanism of action of the diet is poorly understood (Boison 2017), a high serum concentration of ketone bodies is required for its effectiveness. Various modifications of ketogenic diets utilise either medium-chain triglycerides or conventional 4:1 or 3:1 ratios. Although unpalatable, the diet’s taste and appearance can be made acceptable (Freeman et al. 1994).

Side effects include diarrhoea, growth failure and, in some children, renal stones and severe acidosis. These may be life threatening, and fatalities have occurred, especially with the co-administration of acetazolamide (Prasad et al. 1996). This drug should therefore be discontinued two weeks before
starting the diet. Elevated levels of cholesterol are occasionally observed, and long-term effects are poorly documented. The short-term beneficial effect of the diet is indisputable for several types of seizures including myoclonic seizures (Caraballo et al. 2006), the LGS (Schwartz et al. 1989a, b) and some resistant focal or generalised seizures (Kossoff et al. 2006). The 2016 Cochrane review (Martin et al. 2016) identified seven randomised controlled trials that generated eight publications (Bergqvist et al. 2005; Kossoff et al. 2007; Seo et al. 2007; Neal et al. 2008, 2009; Raju et al. 2011; El-Rashidy et al. 2013; Sharma et al. 2013). All applied intention-to-treat analysis with varied randomisation methods. The seven studies recruited 427 children and adolescents and no adults. A meta-analysis could not be conducted due to the heterogeneity of the studies. Reported rates of seizure-freedom were as high as 55% in a 4:1 ketogenic diet group after 3 months and seizure reduction reached 85% in a 4:1 ketogenic diet group after 3 months.

Adverse effects occurred in all studies and for all ketogenic diet variations, including short-term gastrointestinal-related disturbances, to longer-term cardiovascular complications. Attrition rates were reported with all ketogenic diets and across all studies due to lack of observed efficacy and dietary tolerance.

At the initiative of The Charlie Foundation, a panel comprised of 26 paediatric epileptologists and dietitians from nine countries with expertise in the ketogenic diet published a set of clinically useful recommendations (Kossoff et al. 2009). Based on available data the panel agreed on a list of syndromes and conditions in which the ketogenic diet is beneficial including glucose transporter protein 1 (GLUT-1) deficiency, pyruvate dehydrogenase deficiency (PDHD), myoclonic-astatic epilepsy, tuberous sclerosis complex, Rett syndrome, Dravet syndrome, epileptic infantile spasms, selected mitochondrial disorders, glycogenosis Type V, Landau–Kleffner syndrome, Lafora body disease and subacute sclerosing panencephalitis. The authors also listed a set of disorders with an absolute contraindication to the use of ketogenic diet including carnitine deficiency (primary), carnitine palmitoyl transferase (CPT) I or II deficiency, carnitine translocase deficiency, several \( b \)-oxidation defects, pyruvate carboxylase deficiency and porphyria (Kossoff et al. 2009).

Education of parents is all important and a team approach is essential for optimal results (Kossoff et al. 2007). Consideration should be given to discontinue the ketogenic diet after 3 months if unsuccessful, and 2 years if completely successful, but longer diet durations are necessary for GLUT-1 and PDHD and may be perfectly appropriate based on individual responses for intractable epilepsy. During discontinuation, the group recommended a gradual wean over 2–3 months, unless an urgent discontinuation of the diet is indicated.

For a long time, the ketogenic diet was not recommended for use in infancy (under the age of 2 years) because it is a crucial period in development and the perceived high risk of nutritional inadequacies. For a consensus statement regarding guidelines for the clinical management of the ketogenic diet in infants see Van der Louw et al. (2016).

**SURGICAL TREATMENT OF EPILEPSY**

Although approximately 70% of patients respond satisfactorily to drugs, resistant cases especially in children are not rare. A sizeable number of these can potentially be controlled by surgical treatment, as shown by experience in adults. Paediatric surgical data are also encouraging and no different from the adult surgical outcome data (Lindsay et al. 1979; Gilliam et al. 1997; Wylee et al. 1998; Mathern et al. 1999; Bittar et al. 2002; Schmidt et al. 2004). Successful surgical therapy is particularly desirable for children and deserves to be considered more liberally and earlier than is now customary (Engel 1996; Aicardi 1997; Arzimanoglou et al. 2004; Cross et al. 2006, 2016). It would constitute a definitive treatment, not only preventing the possible harmful consequences on the brain of repeated seizures and the psychosocial problems resulting from interference of epilepsy with everyday life and education, but also by permitting the use of smaller dosages for AEDs or even their discontinuation (Aicardi 1997). In spite of these potential advantages, the utilisation of epilepsy surgery in children remains underutilised (Lachhwani 2005; Arzimanoglou et al. 2016c). Although epilepsy surgery programmes have been launched in most major paediatric centres, the interval between onset of the disease and surgery is still extremely long, often more than 15 or 20 years. Unfortunately, such delays occur even for well-defined epilepsy syndromes such as mesiotemporal epilepsy (Berg et al. 2003). In one randomised controlled trial, Wiebe et al. (2001) compared surgical versus medical treatment for temporal lobe epilepsy in adults, showing that seizure control and quality of life were significantly better with surgery than with medical treatment.

Multiple historical features suggest a low likelihood of seizure remission. Most are recognisable early in the course of treatment and the threshold for referring children for further evaluation should be low (Table 16.24). Childhood-onset epilepsy differs significantly from adult-onset cases as several aetiologies and syndromes are unique to the paediatric population. For many, the aetiology only becomes clear as the epilepsy evolves, thus the history obtained by the clinician must include a detailed description of seizure onset, such that idiopathic epilepsies of childhood which ultimately remit or those of symptomatic genetic origin (i.e., \( SCN1A \) mutations) which are unlikely to benefit from surgical therapy are correctly identified. At the same time, there are several paediatric epilepsy syndromes and aetiologies in which surgical therapy is especially efficacious and should be considered early in the course of treatment. Lastly, infants and young children differ in that catastrophic epilepsy presentations may require more urgent surgical evaluation to prevent epileptic encephalopathy and loss of neurodevelopmental status.

The most obvious and probably still strongest barriers to surgery are cultural and psychological (Jetté et al. 2016;
Kwon et al. (2016). Information on surgical options are under-appreciated by general practitioners and even neurologists and child neurologists. The decision-making processes are usually highly complex and require a multidisciplinary approach involving input from several specialties and specialised diagnostic procedures (Arzimanoglou et al. 2016c). Lack of knowledge, concern or outright fear regarding surgery may also lead to protracted delay. A rollercoaster course characterised by remission and exacerbation may also render it difficult to know if the epilepsy is truly drug resistant (Berg et al. 2006). Additional confounding factors include the poorly known natural history of many childhood epilepsies, varied aetiologies, and the fact that studies may bundle together lesional and non-lesional lesions. Given the lack of class 1 or 2 evidence for imaging techniques (MRI, PET, SPECT, fMRI, MEG) that has resulted from the development of new and powerful neuroimaging techniques (MRI, PET, SPECT, fMRI, MEG) that facilitate precise definition of the type and operability of epileptogenic lesions. Given the lack of class 1 or 2 evidence for the relative utility of each modality, recommendations were issued by a consensus of the Paediatric Epilepsy Surgery Task Force of the ILAE Commissions of Pediatrics and Diagnostics (Jayakar et al. 2014). The recommendations limit over or underutilisation while retaining substantial flexibility in the use of the tests.

Another major step that facilitated early access to surgery has resulted from the development of new and powerful neuroimaging techniques (MRI, PET, SPECT, fMRI, MEG) that facilitate precise definition of the type and operability of epileptogenic lesions. Given the lack of class 1 or 2 evidence for the relative utility of each modality, recommendations were issued by a consensus of the Paediatric Epilepsy Surgery Task Force of the ILAE Commissions of Pediatrics and Diagnostics (Jayakar et al. 2014). The recommendations limit over or underutilisation while retaining substantial flexibility in the use of the tests.

Further development of video-EEG techniques and intracranial electrodes and employment of neurosurgical tools and techniques (Jayakar et al. 2016; Tassi et al. 2016), also contributed to the change of views regarding epilepsy surgery in children. For example, epilepsies formerly considered generalised may indeed be due to localised lesions which may be amenable to surgery. This applies, for example, to many cases of epileptic infantile spasms and possibly to other syndromes with diffuse or multifocal features (Madhavan et al. 2007). Epilepsy surgery may be successful for selected children and adolescents with a congenital or early-acquired brain lesion, despite abundant generalised or bilateral epileptiform discharges on EEG (Wyllie et al. 2007).

*For a detailed description of surgical treatment of the epilepsies per aetiology refer to Arzimanoglou et al. (2016).*
INDICATIONS, CONTRAINDICATIONS AND TYPES OF AVAILABLE SURGICAL TREATMENT

Most surgical techniques are intended to remove the epileptogenic tissue responsible for initiation and spread of the seizure discharge. Criteria for surgical removal of epileptogenic tissue include a severity sufficient to interfere with everyday life, cognitive deterioration related to active epilepsy, clinical and other evidence pointing to a localised brain area, and the possibility of removing epileptogenic tissue without unacceptable functional sequelae.

Several procedures are utilised to treat epilepsy. These can be schematically grouped into two major categories:

1. Excisional surgery that removes the cortical neuronal pool responsible for generation of the seizures; and
2. Palliative or functional surgery, which aims to interrupt or limit the propagation of seizure discharges, thus limiting their clinical manifestations and consequences.

Excisional surgery includes a wide spectrum of procedures including small cortical resections to hemispherectomy. Palliative surgery (Polkey 2003a) is mostly represented by callosotomy, whether of the anterior half or two-thirds of this structure or complete (Jalilian et al. 2010).

Other palliative techniques include vagus nerve stimulation (VNS), which requires placement of a stimulator under the skin. In this technique, an electrode is wrapped around the left vagus nerve, so that adjustable pulsed stimuli can be applied. In children, the results are encouraging with reduced seizure frequency, particularly in the epileptic encephalopathies (Polkey 2003a, b; Alexopoulos et al. 2006; Benifla et al. 2006; Panebianco et al. 2015; Lagae et al. 2016), but controlled studies are still lacking. Adverse effects associated with implantation and stimulation are primarily hoarseness, cough, dyspnoea, pain, paraesthesia, nausea and headache, with hoarseness and dyspnoea more likely to occur with high than low stimulation.

The long-term impact of VNS was discussed in a retrospective multicentre study of 347 children aged 6 months to 17.9 years at the time of implant (Orosz et al. 2014). The results indicated that at 6, 12, and 24 months after implantation, 32.5%, 37.6%, and 43.8%, respectively, of patients evidenced favourable results for all secondary predominant seizure type. Responder rates were higher in children and adults, belong to the syndromic category of focal structural (non-idiopathic epilepsies) (Kahane et al. 2005). However, while some syndromes are amenable to surgical intervention, others are unlikely to respond favourably (Table 16.25). The requirements for resective surgery in children with focal epilepsy vary with the type of resection considered. Three basic requirements apply to almost all cases: (1) the epileptogenic area must be clearly localised to a restricted brain region; (2) no other independent epileptogenic area exists in those areas that are not included in the planned resection, and (3) any possible deficit resulting from resection must be acceptable (Arzimanoglou et al. 2004).

Completeness of resection of the epileptogenic area is the major condition for a satisfactory surgical result. The choice of procedure depends upon the location and extent of the ictal onset zone, its relationship with adjacent functional brain areas and convergent data that confirms the surgical target. Epilepsy surgery mandates a multidisciplinary approach that

Chapter 16 Epilepsy and Other Seizure Disorders

The clinical expression of epilepsy may be misleading in children as generalised seizures may have a focal onset. The surgical spectrum in early-onset epilepsy now includes not only other focal epilepsies but also more complex secondarily generalised types. Developmental lesions that cause infantile epilepsy are often poorly localised, involve extensive brain areas and require extensive operations (e.g. hemispherotomy). Surgery is also performed in progressive conditions such as Rasmussen encephalitis (Bien et al. 2005), Sturge–Weber syndrome (Arzimanoglou et al. 2000; Bourgeois et al. 2007) or tuberous sclerosis (Jansen et al. 2007).

PRESURGICAL EVALUATION OF CHILDREN

Presurgical evaluation has the same bases in children as it does in adults. Detailed consideration of the existing methods is beyond the scope of this book, and the reader is referred to the extensive literature available (e.g. Lüders and Comair 2001; Kahane et al. 2005; Arzimanoglou et al. 2016c).

The presurgical assessment of a patient is a stepwise process. Detailed history taking and precise definition of the clinical seizure pattern (in terms of both symptoms and sequence of events) are indispensable. The importance of the EEG has been repeatedly emphasised. In some lesional cases interictal EEG and high-quality structural neuroimaging may prove sufficient for localisation. More often in both lesional and MRI-negative cases, video-EEG recording is essential. Congruence among the results of the clinical history and the definition of seizure pattern, the neuropsychological evaluation and neuroradiology, scalp EEG (interictal and ictal), and, in selected cases, other supporting tests (e.g. ictal or interictal SPECT and PET, functional MRI) should be sought as any discordance in the results of the various investigation methods considerably decreases the chances of a good outcome. Intracranial EEG recording remains the criterion standard for the localisation and definition of the extent of the epileptogenic zone, particularly for MRI-negative cases or when the limits of the lesion cannot be clearly identified by structural neuroimaging. The method of intracranial study (grids, strips, stereotactically implanted depth electrodes) depends on the pre-operative hypothesis and experience of the epilepsy surgery team.

EEG recording, functional imaging and ictal semiology are analysed to evaluate children with MRI-negative focal epilepsy. All of these factors are influenced by maturation, and the potential for significant changes over time must always be considered. This is especially evident in infants whose symptomatic focal epilepsy is more likely to propagate to motor pathways leading to apparent electro-clinically generalised epileptic seizures (Duchowny 1987). Surgically remediable cases of MRI-negative infantile spasms have been reported, and a high frequency of infantile spasms tuberous sclerosis complex evolves into focal epilepsy (Riikonen and Simell 1990).

Systematically, all available data must be reviewed and analysed by an experienced multidisciplinary group.

MRI-Negative Patients

The importance of MRI in the pre-operative evaluation for epilepsy surgery cannot be overestimated. Utilising high-resolution epilepsy protocols and expert interpretation, MRI detects structural lesions in up to 85% of MRI-negative patients (van Oortzien et al. 2002). The presence of a focal lesion helps define the epileptogenic zone and guides placement of intracranial electrodes. In a recent review of current practice worldwide (Harvey et al. 2008), MRI was performed in 99.5% of paediatric epilepsy surgical candidates.

In contrast, the inability to detect a focal lesion on MRI presents significant challenges to the successful localisation of the epileptogenic zone. Histopathological analysis of tissue removed in MRI-negative cases often reveals microscopic abnormalities. The incidence of MRI-negative cases in the ILAE taskforce series was 17% (Harvey et al. 2008), although meta-analysis of patients of all ages reveals a considerably higher incidence of magnetic resonance negativity in the paediatric population (31% in children versus 21% in adults) (Telléz-Zenteno et al. 2010). Referral bias is undoubtedly important as centres with experience in invasive EEG recording techniques have an incidence of MRI-negative cases that is over 50% (Paolicchi et al. 2000).

All children with refractory MRI-negative focal epilepsy should first undergo video/EEG recording with ictal capture. If a focal region of epileptogenesis is identified, MRI re-investigation with a focus on a specific region of interest should be performed. Ideally, the epileptogenic region should be convergent with the semiotically suspect anatomical region of seizure onset. Particular attention must be given to focal electrographic features at seizure onset as these are highly relevant to the identification of the zone of seizure origin.

The role of functional imaging in paediatric cases is well established. Ictal SPECT and PET are both sensitive and specific tools to delineate temporal and extratemporal seizure-onset zones (Gaillard et al. 1995; Lawson et al. 2000; Kaminiska et al. 2003; Juhasz and Chugani 2003). Functional imaging is not always required in MRI-negative patients, but is helpful when there is a lack of clinical and electrophysiological convergence. In contrast, functional imaging is virtually obligatory in divergent and MRI-negative cases. Although ictal SPECT is considered superior for localising extratemporal foci and PET superior for temporal foci, a comparison of both modalities in paediatric temporal lobe epilepsy reveals diagnostic accuracy in the range of 80–90% for both (Lee et al. 2005).

More recently, MEG has been employed successfully in MRI-negative cases. In a cohort of 22 children with subtle
or nonfocal MRI findings, RamachandranNair et al. (2007) identified 17 (77%) with good surgical outcome and eight (36%) who became seizure-free. Postoperative seizure-freedom correlated with the presence of MEG clusters within the resection margin whereas bilateral MEG dipole clusters or scattered dipoles correlated with seizure persistence. Seizure-freedom was greater when there was complete concordance between MEG and EEG localisation. Multiple seizure types predicted poor postoperative outcome.

The use of multiple modalities to define the epileptogenic zone in MRI-negative paediatric refractory focal seizures is widely regarded as state-of-the-art (Kurian et al. 2007; Seo et al. 2007; Jayakar et al. 2008; Dorward et al. 2011). The choice of modality depends on local institutional protocols and resources, and there is only limited data to support the superiority of a single approach.

In a study of 14 children undergoing comprehensive multimodal investigations for intractable MRI-negative focal epilepsy, SISCOM (subtraction fctal SPECT co-registered to MRI) and MEG showed better concordance with intracranial EEG data than PET (Seo et al. 2007). However, PET and SPECT data do not guarantee a seizure-free outcome (Dorward et al. 2011). It is difficult to draw definitive conclusions when the number of patients is limited.

The existing evidence indicates that favourable outcomes are indeed possible and that rates of seizure-freedom are comparable to adults. Low-grade focal cortical dysplasia is the underlying pathology in the majority of candidates, but a seizure-free outcome is pathology-independent as it is determined by the ability to completely excise the physiological and anatomical seizure-onset zone. This goal is achievable in many children with a multimodal approach. The number of children with refractory focal epilepsy who are MRI-negative but are not referred for surgical consideration is unknown.

OUTCOME OF SURGICAL THERAPY

Complete resection of the epileptogenic zone as a predictor of seizure-free outcome is singularly important and has been characterised by complete resection of the anatomical lesion by MRI and complete resection of the epileptogenic zone as defined by intracranial recordings. Krsek et al. (2009) found that 70% of patients became seizure-free following complete resection of the epileptogenic zone as defined by both anatomical and physiological resection, while only 22% of patients with incomplete resection achieved seizure-freedom. However, complete resection of the epileptogenic zone by EEG or MRI when complete resection by both modalities is not possible may also achieve seizure-freedom (Perry et al. 2010).

In a retrospective review of incomplete resections in children characterised by both EEG and MRI completeness, 40% achieved seizure-freedom, with those incomplete by both MRI and EEG least likely to become seizure-free (24%) compared to over 50% incomplete by one modality (Perry et al. 2010). These findings confirm that complete resection of EEG and MRI abnormalities is the best predictor of a seizure-free outcome, but a seizure-free outcome is still attainable with complete resection by at least one modality. The contribution of each modality to the concept of complete resection is debated, with some data suggesting an advantage to complete EEG resection over complete MRI resection (Perry et al. 2010).

Several other variables contribute to seizure-freedom to a lesser degree, many ultimately related to the ability to achieve complete resection. Among pre-operative variables, unifocal lesions on pre-operative MRI have more favourable outcome (Cossu et al. 2008; Perry et al. 2010). Widespread lesions on MRI may limit the ability to achieve complete resection. Other pre-operative variables such as age of seizure onset and duration of epilepsy prior to surgery do not impact outcome (Kral et al. 2003; Cossu et al. 2008; Krsek et al. 2009). Patient specific substrate may indirectly influence outcome in some cases. For example, a full scale IQ of less than 70 has been associated with poor postsurgical outcome as have psychiatric comorbidities in patients undergoing temporal lobectomy (Guarnieri et al. 2009; Kanner et al. 2009). Both suggest more widespread cerebral involvement that compromises the likelihood of a complete resection.

Of the operative variables, temporal lobe resection has repeatedly demonstrated better outcome (Wyllie, et al. 1998; Alexandre et al. 2006; Cossu et al. 2008), up to 70% at 5 years in some case series (Benifla et al. 2008). This finding may be related to less common overlap of the epileptogenic zone with eloquent cortex, as occurs commonly in extratemporal locations. Unilobar resections more commonly result in seizure-free outcome than multilobar procedures (Wyllie, et al. 1998; Cossu et al. 2008; Perry et al. 2010), a finding also likely related to completeness of resection.

Finally, histopathological variables may contribute to seizure-free outcome. Several series have demonstrated more favourable outcome when the aetiology of epilepsy is related to tumour versus cortical dysplasias (Wyllie et al. 1998; Cossu et al. 2008). Hamiwka et al. reported 72% seizure-free rates at 10 years in patients with developmental tumours versus 32% for cortical dysplasia. These findings likely reflect completeness of resection, as tumours are typically well circumscribed. Among patients with FCD, those with Type IIa/b more often achieve postsurgical seizure-freedom compared to those with Type Ia/b and mild malformation of cortical development (Krsek et al. 2009). Type II FCD is more easily detected by MRI, while lower grade FCD is more often diffuse and poorly localised.

PALLIATIVE EPILEPSY SURGERY

The primary surgical goal seizure-freedom for intractable epilepsy is not always achievable and seizure reduction is an alternative benefit in some candidates. Palliative procedures
may eliminate one of several seizure types. For example, eliminating atonic seizures reduces the risk of injury (e.g. fractures, lacerations). Similarly, eliminating complex partial seizures in temporal lobe epilepsy with continued aura without loss of consciousness may be tolerable and beneficial. Reducing the likelihood of status epilepticus or seizure clusters is also positive.

Corpus callosotomy is an effective treatment to reduce or eliminate atonic seizures. Other generalised seizure types such as myoclonic, absence, and tonic–clonic seizures are less likely to respond. Callosotomy disrupts the major trans-callosal pathway linked to rapid propagation of ictal discharges between the cerebral hemispheres. Partial callosal disconnection (anterior two-thirds) is often sufficient to achieve this goal while complete corpus callosotomy increases risk for the disconnection syndrome (Jalilian et al. 2010).

Multifocal cortical malformations or multifocal ictal onset zones may also benefit from palliative procedures. Patients with tuberous sclerosis complex exemplify this clinical scenario. The pre-operative evaluation must identify the epileptogenic tuber and epileptogenic potential of surrounding tubers. Outcome is generally favourable when the MRI, EEG and SPECT findings are convergent. In cases with multifocal ictal onset, resection of the region associated with the most debilitating seizure type or most frequent onset can prove beneficial (Radhakrishnan et al. 2008). In a recent review of Lennox–Gastaut cases undergoing excisional procedures, 74% experienced seizure-freedom or significant reduction of seizures at 33 months follow-up (Lee et al. 2010). The majority (85%) had cerebral lesions on MRI, although nonlesional patients also experienced benefit from surgical treatment.

Another commonly encountered indication for palliative surgery is the presence of ictal onset which encroaches upon eloquent cortex. As complete resection of the epileptogenic zone would result in unacceptable disability, sparing of eloquent cortex may result in significant improvement. When both the MRI defined lesion and EEG defined epileptogenic zone cannot be completely resected, the likelihood seizure-freedom is low. However, if at least one modality can be completely resected, seizure-freedom occurs in a clinically significant proportion of patients (Perry et al. 2010). This underscores the importance of including patients for epilepsy surgery in whom the pre-operative evaluation suggests the procedure may be incomplete.

Multiple subpial transections (MST) have been utilised for seizures arising within functional cortex. As functional cortical units are arranged radially while epileptogenic activity spreads horizontally a transverse cortical incision should theoretically disrupt horizontal spread while preserving radial functionality. When performed in conjunction with focal cortical resections MSTs can result in seizure reduction nearing 60%. However, when used alone, seizure-freedom rates are much more disappointing (Beniffa et al. 2006).

### Antiepileptic Drugs Following Surgery

Discontinuation of AED treatment should be considered in all children with postoperative seizure-freedom but should follow assessment of risks and consequences of seizure recurrence (Braun and Schmidt 2014; Braun et al. 2016). Seizure recurrence following postoperative AED withdrawal is between 15% and 30%, with children being less at risk than adults.

There is no proof that AED withdrawal itself negatively affects long-term seizure outcomes in seizure-free patients under AED treatment or after epilepsy surgery. AED discontinuation only unveils the natural history of the epilepsy and the completeness of resection after epilepsy surgery (Boshuisen et al. 2012, 2014). This was convincingly demonstrated by an observational retrospective study (TimeToStop) of 766 children under age 18 years from 15 European centres. Withdrawal practices were quite different between centres with a median interval from surgery to start of AED reduction of 12.5 months (95% confidence intervals 11.9–13.2) and time to complete withdrawal 28.8 months (95% confidence intervals 27.4–30.2), respectively. Ninety-five children had seizure recurrence during or after AED withdrawal (Boshuisen et al. 2012).

Data from neuropsychological assessments were available for 301 children and were analysed separately. Start of AED withdrawal, number of AEDs reduced, and complete AED withdrawal were associated with improved postoperative IQ scores and gain in IQ, independent of other determinants of cognitive outcome (Boshuisen et al. 2015).

### Prognosis of Epilepsy

The prognosis of epilepsy syndromes varies according to aetiology, associated manifestations, and patient age. Therefore, studies that do not specify specific populations are of limited value. They may only indicate overall prognosis assuming that referral patterns are not overly selective or biased.

However, a brief overview of some prognostic aspects of the epilepsies of children in general (the risk of recurrence after a first seizure, the risk of relapse after discontinuation of drug therapy, the problem of intractable epilepsy, the social and educational outcome of epilepsy, the risk of sudden death in adolescents and young adults) can provide a useful framework for studying the needs of the community, individuals and their families. Studies of global prognosis of childhood epilepsy reveal that certain factors (e.g. frequency of seizures, presence or absence of neurological or cognitive deficits, type of seizure, duration of seizures) have a strong correlation with...
the outcome of epilepsy. These factors have predictive value, not only for unclassified cases of epilepsy but also for some well-defined syndromes.

A state-of-the-art workshop (Arts et al. 2013), focussed on data from cohort studies, trials and studies on treatment, current knowledge on outcome of childhood epilepsy in general and of specific types and syndromes. The workshop also identified areas of unknown knowledge and future research topics.

**RISK OF RECURRENCE AFTER A FIRST UNPROVOKED SEIZURE**

Recurrence rates after a first generalised tonic–clonic seizures vary between 25% and 54% (Annegers et al. 1986; Boullooche et al. 1989; Shinnar et al. 1990, 1996, 2000; Berg et al. 1998; Haut et al. 2007). Most occur within one year. These results suggest that treatment of a first seizure (First Seizure Trial Group 1993; Beghi 2007), is not indicated as half the children will remain seizure-free. Risk factors for recurrence include an neurodevelopmental delay, young age (<4 years), family history of epilepsy, and an abnormal EEG (Shinnar et al. 1994). The recurrence risk is 25% at 24 months after an idiopathic first seizure and a normal EEG, 34% when the EEG was abnormal but non-epileptiform, and 54% with epileptiform abnormalities. Early age at onset (<2 years) is strongly associated with medically resistant epilepsies primarily due to cases of epileptic encephalopathy. When these are excluded, the recurrence rate for infants is the same as for older children (Camfield et al. 1993).

These figures apply only to cases of isolated seizures or epilepsies. The risk of recurrence is much higher when neurological signs or intellectual disability are present. In a longitudinal study of 246 children, Sillanpää (1993) found that 5-year terminal remission after 35 years was 80% in idiopathic epilepsy, 69% in cryptogenic epilepsy, and only 56% in symptomatic cases. While 77% of patients with normal neurological and intellectual status attained a 5-year terminal remission, this decreased to 50% for patients with intellectual disabilities, 46% with cerebral palsy, and 29% when both intellectual disability and cerebral palsy were present. Even a minor neurological abnormality significantly decreased the probability of remission. However, in a large population of both children and adults with newly diagnosed epilepsy, Cockerell et al. (1997) found a 3-year remission rate of 86% and 5-year remission rate of 68% at 9-year follow-up.

In a study aimed at defining the prospects of newly diagnosed childhood epilepsy, assessing the dynamics of its course, identifying relevant variables and developing models to assess the individual prognosis, Arts et al. (2004) evaluated 453 children with newly diagnosed epilepsy followed for 5 years to define the course of newly diagnosed childhood epilepsy, assess its dynamics and identify relevant variables and developing models. Terminal remission at 5 years (TR5) was compared with terminal remission at 2 years (TR2) and with the longest remission during follow-up. Variables defined at intake and at 6 months of follow-up were analysed for prognostic power. Three-hundred and forty-five children (76%) had a TR5 more than 1 year, 290 (64%) more than 2 years and 65 (14%) had no seizures during the entire follow-up. Of 108 children (24%) with TR5 <1 year, 27 had intractable seizures at 5 years.

Medication was commenced in 388 children (86%). AEDs were withdrawn in 227 (59%). A TR5 more than 1 year was achieved by 46% on one AED, 19% on two AEDs, and 9% on all additional AED regimes. Almost 60% of the children treated with a second or additional AED regime had a TR5 more than 1 year. Variables predicting outcome at study onset were aetiology, history of febrile seizures and age. When onset and 6-month variables were combined, sex, aetiology, post-ictal signs, history of febrile seizures and terminal remission at 6 months were all significant. The course of the epilepsy was persistently favourable in 51%, persistently poor in 17%, improving in 25% and deteriorating in 6%. Intractability was, in part, only a temporary phenomenon. The outcome at 5 years in children with newly diagnosed epilepsy was favourable in 76% with 64% off medication. Almost a third of the children had a fluctuating course; improvement was clearly more common than deterioration.

To provide evidence as to whether different patterns of evolution of drug resistance and remission exist, Sillanpää and Schmidt (2006a) performed a prospective, long-term population-based study of 144 patients, followed on average for 37.0 years (SD 7.1, median 40.0, range 11–42) after a first seizure before the age of 16 years. Nearly half of childhood-onset epilepsy entered terminal remission without relapse, and one-fifth did so after relapse. One-third had a poor long-term outcome with persistent seizures after remission or without remission. These studies are useful for understanding the natural history of the epilepsies, but the samples are relatively small. Larger subject pools are required to define different aetiologies. Relapse rates are also likely to vary considerably among populations with varied epilepsy aetiologies.

**RISK OF RELAPSE AFTER DISCONTINUATION OF TREATMENT**

The risk of relapse is relatively small in children who are seizure-free for 2 or 3 years on therapy (Bouma et al. 1987; Arts et al. 1988; Ehnhardt and Forsythe 1989; Aldenkamp et al. 1993; Shinnar et al. 1994). Figures vary between 12% and 42%, suggesting that discontinuation of therapy after 2 years is probably possible for most common seizure types. Dooley et al. (1996) found that the recurrence rate was no higher with discontinuation of treatment 1 year after the last seizure compared to 2 years, and Tennison et al. (1994) found no difference in recurrence rate between a 6-week and a 9-month weaning period. Similar results were obtained in a prospective study by the Medical Research Council (1991).
The long-term outcome for seizure relapse after planned discontinuation of AEDs in seizure-free patients was evaluated in the longitudinal population-based study of 148 patients from the onset of their epilepsy at average follow-up of 37 years (Sillanpää and Schmidt 2006b). AEDs were completely discontinued in 90 patients. Seizure relapse after AED discontinuation occurred in 33 (37%) at average follow-up of 32 years. Among eight of the 33 patients who restarted AEDs, two achieved 5-year terminal remission, but only 10–19 years after restarting treatment. The remaining six patients never achieved long remission, and two of six never entered a 5-year remission. Factors associated with failure to achieve remission were symptomatic aetiology and localisation-related epilepsy.

DRUG-RESISTANT (INTRACTABLE) EPILEPSY

Drug-resistant epilepsy is defined as epilepsy with uncontrolled seizures despite 'relevant' therapy (Juel-Jensen 1968). This definition is highly imprecise as the definition of adequate therapy is variably appreciated, and the level of control of epilepsy and the assessment of adverse effects are highly individualised. Some patients are inadequately treated rather than being drug resistant, and it is therefore essential to look for factors associated with apparent intractability such as an unrecognised neurological disorder, precipitating factors and treatment irregularities. Misdiagnosis of the epilepsy type results in the selection of an inappropriate drug – for example, ethosuximide for focal seizures, carbamazepine for myoclonic seizures – or failure to recognise that the seizures are not epileptic and caused by psychogenic or cardio-circulatory disturbances (Aicardi and Shorvon 1998). Differential diagnosis is discussed later in this chapter.

Even 'true' drug resistance falls along a continuum rather than being all-or-nothing. Partial control may be possible and beneficial, although optimal quality of life is best achieved by complete seizure control (Birbeck et al. 2002; Spencer et al. 2007).

The concept of 'drug resistance' cannot be defined in any one way. Individual studies use different definitions, creating difficulties for comparisons of results across studies. In a prospective cohort of 613 children in Connecticut with newly diagnosed epilepsy (1993–7), six different published definitions or indicators for intractability were applied and compared (Berg and Kelly 2006). All definitions were assessed at various times within the first 5 years after diagnosis, with the exact timing reflecting how their use in initial reports. Depending on the definition used, the epilepsy in 9–24% of children was considered drug resistant. All definitions were strongly associated with remission status at last follow-up and with longer-term outcome. The authors concluded that no single preferred definition of intractable epilepsy exists and that consideration should be given to whether a single or different definitions are required. We would add that 'drug resistance' should not be confounded with 'prognosis'.

Approximately 20–30% of epilepsy is resistant to drug therapy. Intractable epilepsies include many 'catastrophic epilepsies' or 'epileptic encephalopathies', including the Lennox–Gastaut and Dravet syndromes, and cases of focal seizures that are usually lesional in origin. The molecular and cellular mechanisms underlying drug resistance are unknown (Sisodiya 2005; Remy and Beck 2006).

The natural evolution of focal non-idiopathic (structural) epilepsy is variable and it often difficult to decide how many trials of mono- and polytherapy should be considered. Clearly when other therapeutic options – especially resective surgery – are available and have a good prospect of success, medical therapy should probably not be prolonged for more than some months or even less with deterioration. However, drug regimens will be tried for much longer periods for epilepsy resistant to medical therapy and not amenable to surgery.

Predictors of drug resistance include infantile spasms, remote symptomatic epilepsy, a history of status epilepticus, neonatal seizures and microcephaly (Berg et al. 1996). To determine prospectively when in the course of epilepsy intractability becomes apparent, Berg et al. (2006) analysed the data from a prospective cohort of 613 children followed for a median of 9.7 years. Epilepsy syndromes were grouped into focal, idiopathic, catastrophic and other. Drug resistance was defined in both a stringent (two drugs failed, and one seizure/month, on average, for 18 months) and less rigorous way (failure of two drugs). Delayed intractability was defined as 3 or more years after epilepsy diagnosis. Eighty-three children (13.8%) met the stringent definition and 142 (23.2%) met the two-drug definition.

Intractability depended on syndrome \( (P<0.0001) \): 26 children (31.3%) meeting the stringent definition and 39 (27.5%) meeting the two-drug definition had delayed intractability. Intractability was delayed more often in focal than in catastrophic epilepsy (stringent: 46.2% versus 14.3%, \( P=0.003 \); two-drug: 40.3% versus 2.2%, \( P=0.0001 \)). Early remission preceded delayed intractability in 65.4–74.3% of cases. After becoming intractable, 20.5% subsequently entered remission and 13.3% were seizure-free at last contact. These findings help explain why surgically treatable epilepsies may take 20 years or longer before referral to surgery.

To improve patient care and facilitate clinical research, the ILAE appointed a Task Force to formulate a consensus definition of drug-resistant epilepsy (Kwan et al. 2010). The aim was to provide a general scheme to categorise response to each therapeutic intervention, including a minimum dataset of knowledge about necessary intervention and a core definition of drug-resistant epilepsy. A set of essential criteria based on response to trials of antiepileptic drugs was employed. Issues related to frequency and severity of seizures were deliberately excluded from the definition as not critical to the concept of drug resistance and subject to individual interpretation. The Task Force also stated that complete seizure-freedom is the only relevant outcome consistently associated with improved
quality of life. ’Duration of active epilepsy’ was also excluded, since it is more related to overall prognosis.

The number of AEDs was considered instrumental, primarily to avoid undue delays, which however were frequent, in identifying drug-resistant epilepsy and refer to an epilepsy specialist. Drug-resistant epilepsy was defined as failure of adequate trials of two tolerated, appropriately chosen and managed antiepileptic drug schedules (whether as monotherapies or in combination) to achieve sustained seizure-freedom.

We consider this definition to be a clinically meaningful consensus, underscoring the fact that early recognition of a given epilepsy as ‘difficult-to-treat’, rather than being a conclusion should be interpreted as the starting point for a multidisciplinary expertise. The definition is applicable to all types of epilepsies, either ‘benign’ or related to aetiologies favouring an increased seizure frequency.

EDUCATIONAL, LEARNING AND BEHAVIOUR PROBLEMS

Although the majority of children with epilepsy do not have learning difficulties or behavioural issues, one-fifth to one-third may be symptomatic from underlying CNS lesions (Sillanpää 1992, 2004; Beghi et al. 2006). Conversely, 20% of children with intellectual disability have epilepsy, and one-third also have cerebral palsy (Forsgren et al. 1990).

Various educational and behavioural difficulties may occur in children with epilepsy who are cognitively intact. The prevalence of psychiatric disorders is several times higher in children with epilepsy than in the general population (Freilinger et al. 2006; Austin and Caplan 2007), and emotional regulation disorders are common but often recognised (Plioplys 2003; Caplan et al. 2005; Reilly et al. 2015). The cause of these associations is unclear as they are not explained by differences in sex, age, presence of physical disability or low intelligence.

School underachievement is significantly more common in children with epilepsy (Seidenberg et al. 1986; Arts et al. 2004; Hermann and Seidenberg 2007). This is likely to be due in part to limited intellectual abilities in some patients. Bourgeois et al. (1983), Rodin et al. (1986) and Aldenkamp et al. (1990) have shown that some children with epileptic seizures may develop intellectual difficulties as a consequence of seizures, their treatment and socio-educational factors. However, many patients with epilepsy, even when well controlled were overqualified for their jobs (Olsson and Campenhausen 1992) suggesting low self-esteem or low parental expectations (Levin et al. 1988; Collings 1990).

Sillanpää (1990) showed that professional underachievement was also common in adult patients with epilepsy starting in childhood, even with a normal IQ. Loiseau et al. (1983) have shown that children with absence epilepsy have poorer social and professional achievement, than would be expected from their IQ scores or the benignity of their epilepsy. In contrast children with benign partial epilepsy have a completely normal prognosis. The reasons for such differences are poorly understood.

Considerable attention has been given to the contribution of subclinical EEG discharges to interference with learning or cognitive processes involving attention, concentration or specialised tasks (Arts et al. 1988; Kasteleijn-Nolst Trenité et al. 1988, 1990; Aldenkamp et al. 1992; Arzimanoglou et al. 2005; Deonna and Roulet-Perez 2005; Koop et al. 2005). However, important subclinical discharges may be, their relationship to all of the behavioural and learning difficulties of many children with epilepsy is complex. Feelings of inadequacy and specialised neuropsychological deficits correlate with aggressive behaviour, poorer school performance, fewer friends and fewer interests (Hermann 1982; Viberg et al. 1987; Fastenau 2011). Prospective studies, involving a large sample of children with newly diagnosed epilepsies and a long-term follow-up are lacking. Careful assessment and remedial help may be needed on an individual basis. In an overwhelming majority of children with epilepsy, regular schooling is possible, and special schools for patients with epilepsy are rarely – if ever – justified for patients without other neurodevelopmental problems.

SOCIAL AND EDUCATIONAL OUTCOME

The educational level of persons with epilepsy is much lower than the general population. In a long-term study of adults with childhood-onset epilepsy, Sillanpää (1992) found that approximately one-third of 176 patients received less than primary education and 37% only primary education. Only 18% went to secondary school and 9% graduated; 3% had a university degree. The proportion of patients with a driving licence (61%), of those married or having a stable relationship (65%), of those having children (49.5%) were all significantly lower compared to controls. The proportion who were unemployed (9.1%) was higher. Patients with active epilepsy did significantly less well than those who had been in remission for 5 years or more.

Another study from Finland (Koponen et al. 2007) explored social functioning and psychological well-being in a population-based cohort of epilepsy patients compared to matched controls identified through the National Registry of Social Insurance Institution. The age at onset of epilepsy was significantly associated with the level of further education, and the level of seizure control with employment status. Patients with epilepsy and a lower level of basic education had a significantly lower level of further education, employment, and fewer social relations. Some differences in psychological well-being were also seen in those who had passed a matriculation examination when compared to matched controls.

The most important conclusion of the study was that in young adults with well-controlled epilepsy social functioning and successful basic education is comparable to healthy peers. This suggests that social and educational support during the time of basic education may be crucial to favourable
intellectual, functional, and social development later in life. Both professional and informal support is needed in addition to conventional treatment of epilepsy.

All the above figures reflect, in part, the presence of complicating factors such as neurological impairment, learning difficulties and intellectual disability. However, even patients without complicating factors do less well than the general population in terms of professional and social adjustment (Loiseau et al. 1983). This is probably due, in part, to school absenteeism, low expectations from parents and teachers, rejection by peers, and practical problems (e.g., lack of driving licence). Many of these factors reflect prejudice and poor understanding by the public and the patients themselves about their condition. This situation could be improved by better awareness.

**RISK OF DEATH IN YOUNG PEOPLE WITH EPILEPSY**

Mortality rates are increased in people with epilepsy (Nilsson et al. 1997; Shackleton et al. 1999). A review of published series (Shackleton et al. 2002) showed that the mortality risk in patients with epilepsy is dependent on specific patient cohorts. Considerable unexplained variance remains among different source populations. Hence no uniform summary estimate for the elevated mortality is possible.

In a series devoted exclusively to childhood epilepsy, mortality during the first 10 years after onset was 5.7%, and another 2.9% died between 11 and 12 years after seizure onset (Kurokawa et al. 1982). Trevathan et al. (1997) reported that 4% of their epileptic population died before 11 years of age. An Australian study found a mortality rate of three per 1000 individuals, compared with 0.23 per 1000 in control children (Harvey et al. 1993c). Mortality was found to be higher in those epilepsies with onset before age 1 year in symptomatic epilepsy and infantile spasms than epilepsies with grand mal seizures.

Excess mortality is also present in population-based studies. In a review of the literature, Harvey et al. (1993c) found the mean estimate of death in epileptic children younger than 15 years was approximately five per 1000 children. Children with secondary epilepsy accounted for 94% of all deaths.

In a prospective community cohort of 613 children (Berg et al. 2004), symptomatic aetiology and epileptic encephalopathy were independently associated with mortality. The overall standardised mortality ratio for the cohort was 7.54. In children with symptomatic epilepsy, the standardised mortality ratio was 33.46 (95% confidence intervals, 18.53–60.43) and 0.43 (95% confidence intervals, 0.36–5.73) in non-symptomatic epilepsy. These results suggest that children with epilepsy have an increased risk of death and that most deaths occur in children with severe underlying conditions and are not directly related to the occurrence of seizures.

The overall mortality among patients of all ages is two to three times the general population (O’Donoghue and Sander 1997). Although the causes of death are quite variable, sudden unexpected death, accidents and suicide deserve special consideration.

Sudden unexpected death in epilepsy refers to sudden, unexpected, witnessed or unwitnessed, nontraumatic and nondrowning death in patients with epilepsy, with or without evidence for a seizure and excluding documented status epilepticus, in which postmortem examination does not reveal a toxicological or anatomical cause of death (Nashef et al. 1997). The cause of SUDEP is most likely heterogeneous with regard to both mechanisms and circumstances. A unified definition and classification (Nashef et al. 2012; Ryvlin et al. 2013) found that the most important risk factor is the occurrence and frequency of generalised tonic–clonic seizure (GTCS), which triggers the majority of witnessed episodes. Therefore, preventing SUDEP must minimise the risk of GTCS with optimal medical management and patient education. Another hypothetical strategy to prevent SUDEP is to reduce the risk of GTCS-induced postictal respiratory distress. This might be achieved by using a lattice pillow, providing nocturnal supervision, reinforcing interictal serotoninergic tone, and lowering opiate- or adenosine-induced postictal brainstem depression (Ryvlin et al. 2013). However, as recognised by the authors and by a recent Cochrane review (Maguire et al. 2016), very low-quality evidence of a preventive effect for nocturnal supervision against SUDEP is currently available. Further research is required to identify the effectiveness of other current interventions, for example seizure detection devices, safety pillows, SSRIs, early surgical evaluation, educational programmes, and opiate and adenosine antagonists.

SUDEP mainly occurs in adolescents and young adults and constitutes a significant cause of mortality in this age group. The rate is around one per 1000 patients per year (Nashef et al. 1995) so the issue clearly warrants continued investigation. A retrospective study from Australia (Opeskin et al. 2000) examined 15751 autopsy records covering a 6-year period; 357 cases had epilepsy, 50 of which (14%) were classified as SUDEPs. The SUDEP rate was approximately one per 3000 individuals with epilepsy per year. This study suggested the following positive associations: young age, tonic–clonic seizures, seizure frequency greater than ten per year, duration of epilepsy more than 10 years, intellectual disability, psychiatric disease and alcohol abuse. The role of factors such as AED compliance, psychotropic drug prescription and
recent unusually stressful life events was less clear. These observations support the hypothesis that seizures are the mechanism of many cases of SUDEP. The associations observed were largely in agreement with previous studies.

The mechanisms of sudden death in epilepsy are obscure. Asphyxia and cardiac dysrhythmias are likely factors. However, impressive apnoeic seizures with major cyanosis do not necessarily suggest a poor prognosis. Hewertson et al. (1994) reported a benign outcome in four of six infants and children with such events. Ryvlin et al. (2006b) discussed the pathophysiology and potential prevention of SUDEP. According to the authors, ictal arrhythmias may represent a more prevalent cause of SUDEP than previously recognised. There are no specific recommendations regarding the most appropriate therapeutic strategies to prevent SUDEP apart from the supervision at night of patients with refractory convulsive epilepsy (Langan et al. 2005).

The question of whether to discuss the risk of SUDEP, and when to discuss it, with patients with epilepsy is a major unresolved issue. Similar to other issues related to epilepsy treatment and care, the discussion of SUDEP should be considered on an individual basis (Shankar et al. 2017). It should take into account the wishes of the patient to discuss SUDEP and the possibility of specific protective measures (e.g. night surveillance for drug-resistant cases, arguments in favour of better compliance).

Headache Disorders in Children

Kenneth J Mack

Headache is a common childhood complaint. Headaches can be divided into the primary headache disorders, such as migraine, and the secondary headache disorders, which are due to an underlying disorder.

PRIMARY HEADACHE DISORDERS

MIGRAINE

Migraines are severe, often bilateral, throbbing headaches frequently located in the temples or frontal head regions. Migraine occurs in 2–5% of preschool children, 10% of school-aged children and 20–30% of adolescent girls (Abu-Arafeh and Russell 1994; Aromaa et al. 1998). Approximately 20% of migraine patients experience their first attack when younger than 5 years of age (Bille 1997).

Symptoms of migraine vary with the age of the child. In preschool children, migraine often consists of episodes involving an ill, pale appearance, abdominal pain, vomiting and the need to sleep. Pain may be expressed by irritability, crying, rocking or seeking a dark room in which to sleep. Five to ten-year-old patients with migraine tend to experience bilateral frontal, temporal or retro-orbital headache with associated nausea, abdominal cramping, vomiting, photophobia, phonophobia and a need to sleep. Parents may describe these children as pale with dark circles under the eyes. Older children tend to present with a unilateral, temporal headache and the location and intensity of pain often change within or between episodes.

Migraine can occur with or without aura. Only 10–20% of children with migraine experience an aura, often for the first time after the age of 8 years. The aura usually precedes the headache by less than 60 minutes and lasts for 5–20 minutes. The aura may present without headache. Children often are unaware of or unable to describe their aura. The visual aura is the most common form in children, consisting of blurred vision, fortification spectra (zigzag lines), scotomata (field defects), scintillations, black dots, kaleidoscopic patterns of various colours, micropsia, macropsia (distortion of size) and metamorphopsia (‘Alice in Wonderland’ syndrome). Visual auras often are reported as moving or changing shapes; other auras include attention loss, confusion, amnesia, agitation, aphasia, ataxia, dizziness, vertigo, paresthesia or hemiparesis. Aura symptoms vary widely within and between episodes.

The headaches can last 60 minutes to 48 hours, but usually last less than 4 hours. Some young patients report short headaches lasting 10–20 minutes. The severity of childhood headache often is milder than adult migraines. The headache phase can be associated with cold extremities, nausea, anorexia, vomiting, diarrhea or constipation, dizziness, chills, excessive sweating, ataxia, numbness, photophobia, phonophobia, memory loss or confusion. Often the patient cannot concentrate or function effectively during or immediately after episodes. Relief typically is associated with sleep. After the headache phase, the patient may feel either elated and energised or more typically exhausted and lethargic. This stage of migraine may last from hours to days (Gladstein et al. 1993).

Migraine is associated with a variety of comorbid conditions. Psychiatric symptoms such as depression, panic episodes, anxiety disorders or phobia may be present. Epilepsy and migraine often occur within the same individual, although most patients with migraines do not have seizures. Migraineurs are more prone to motion sickness than patients without migraine. Intermittent vertigo is found frequently in patients with migraine. There is a higher cardiovascular reactivity to postural changes in patients with migraine and this may result in dizziness. Migraines are also associated with sleep disturbances and ice-cream headache in some patients (Raskin and Knittle 1976; Kuritzky et al. 1981; Schoenen et al. 1998; Dodick et al. 2003; Maizels and Burchette 2004; Pellock 2004).

Types of Migraine

Status migrainosus is a severe form of migraine in which the headache attack is continuous for longer than 72 hours. Patients usually have a pre-existing migraine history. In those who vomit, rehydration is often the necessary first step. One often effective treatment can be intravenous fluids, an anti-emetic, and dihydroergotamine (DHE) (Linder 1994).

Familial hemiplegic migraine is an autosomal-dominant form of migraine with aura. Patients have a prolonged
hemiplegia that can be accompanied by numbness, aphasia and confusion. The hemiplegia may precede, accompany or follow the headache and symptoms may last from hours to days. The headache usually is contralateral to the hemiparesis. Some familial hemiplegic migraine is associated with cerebellar ataxia. Other types of severe familial hemiplegic migraine may present with coma, fever and meningismus. Some forms of familial hemiplegic migraine respond to acetazolamide or calcium channel blockers. Structural lesions, vasculitis, cerebral haemorrhage, brain tumour, mitochondrial myopathy, encephalopathy, alternating hemiplegia and lactic acidosis need to be considered in the differential diagnosis. Mutations in the **CACNA1A**, **ATP1A2**, **SCN1A** and **PRRT2** genes have been found to cause familial hemiplegic migraine. The chance of finding a genetic mutation in such patients is increased when there is a positive family history and when the child presents with symptoms before the age of 16 (de Vries et al. 2007).

**Basilar-type migraine** is a subtype of migraine with aura and is observed mostly in adolescent and young adult females. Headache pain may be located in the occipital area. Basilar-type migraine is characterised by disturbances in function believed to originate from the brainstem, occipital cortex and cerebellum. The occipital headache must have at least two of the following aura symptoms: dysarthria, vertigo, tinnitus, hyperacusia, diplopia, bi-field visual symptoms, ataxia, decreased level of consciousness or bilateral paresthesias. A history of typical migraine exists in many families. Some patients experience basilar migraine episodes intermingled with typical migraine episodes (Brenner et al. 2007).

**Benign paroxysmal vertigo of childhood** is a condition characterised by brief episodes of vertigo, disequilibrium and nausea, usually found in children aged 2–6 years. The patient may have nystagmus within but not between the episodes. The child does not have hearing loss, tinnitus or loss of consciousness. Symptoms usually last only a few minutes. These children often develop a more common form of migraine as they mature. Brain magnetic resonance imaging (MRI) can be obtained to exclude posterior fossa abnormalities, especially if abnormalities in the neurological examination are found between episodes (Abu-Arafeh and Russell 1995).

**Acute confusional migraine** is characterised by transient episodes of amnesia, acute confusion, agitation, lethargy and dysphasia. This form of migraine is often precipitated by minor head trauma. The child may have a receptive or expressive aphasia, and the confusional state may either precede or follow the headache. Some children also experience recurrent episodes of confusion. The patient usually recovers within hours. The child may not have a history of headache but usually develops typical migraine episodes when older. It is important to exclude hypoglycaemia, intoxications, encephalitis, structural lesions and seizures (Shaabat 1996).

Migraine-associated **cyclic vomiting syndrome** is characterised by recurrent periods of intense vomiting separated by symptom-free intervals. Many patients with cyclic vomiting have regular or cyclic patterns of illness. Symptoms usually have a rapid onset at night or in the early morning and last 6–48 hours. Associated symptoms include abdominal pain, nausea, retching, anorexia, pallor, lethargy, photophobia, phonophobia and headache. The headache may not appear until the child is older. Migraine-associated cyclic vomiting syndrome usually begins when the patient is a toddler and resolves in adolescence or early adulthood; it rarely begins in adulthood. More females than males are affected by cyclic vomiting. Usually a family history of migraines in the parents or siblings is present. These children often experience severe fluid and electrolyte disturbances that require intravenous fluid therapy. Migraine-associated cyclic vomiting syndrome is a diagnosis of exclusion. Other causes of cyclic vomiting include gastrointestinal disorders (malrotation), neoplasms, urinary tract disorders, metabolic, endocrine and mitochondrial disorders (Andersen et al. 1997; Rashed et al. 1999).

In **abdominal migraine**, the patient may suffer from recurrent bouts of generalised abdominal pain with nausea and vomiting, but often with no headache present. The episodes are often relieved by sleep and later the child awakens feeling better. Abdominal migraine may alternate with typical migraine and can lead to typical migraine as the child matures. These children respond to migraine prophylactic medication (Dignan et al. 2001; Russell et al. 2002).

**Paroxysmal torticollis of infancy** is an uncommon disorder characterised by repeated episodes of head tilting associated with nausea, vomiting and headache. Episodes usually occur in infants and may last from minutes to days. Posterior fossa abnormalities should be considered in the differential diagnosis. As with hemiplegic migraine, recent data has linked these symptoms to mutations in the **CACNA1A** gene in some patients (Abu-Arafeh and Russell 1995; Drigo et al. 2000; Giffen et al. 2002).

**Acephalic migraine of childhood** (migraine sine hemiconitia) is characterised by a migraine aura without headache, usually visual auras and a female predominance. A family history of migraine is frequent.

**Migraine aura** occurs in about one-third of adult and adolescent patients and can consist of blurred vision, fortification spectra (zigzag lines), scotomata (field defects), scintillations, black dots, kaleidoscopic patterns of various colours, micropsia, macropsia (distortion of size) and metamorphopsia (‘Alice in Wonderland’ syndrome). Visual auras often are reported as moving or changing shapes; other auras include attention loss, confusion, amnesia, agitation, aphasia, ataxia, dizziness, vertigo, paresthesia or hemiparesis. Aura symptoms vary widely within and between episodes. In contrast, **retinal migraine** is an uncommon condition where there are repeated episodes of monocular (as opposed to hemifield or binocular) visual disturbance, including scintillations, scotomata or blindness, associated with migraine headache (Lendvai et al. 1999).

**Ophthalmoplegic migraine** is a poorly understood inflammatory disorder, rather than a primary headache disorder. Patients present with an ophthalmoplegia, typically a unilateral IIIrd nerve palsy and headache. During an attack, MRI studies may demonstrate inflammation of the third cranial nerve,
Evaluation and Diagnosis of Migraine

No specific diagnostic tests for migraine exist and the diagnosis is made through the history, physical examination and clinical judgment. The child with migraine should have a normal general physical examination and a normal detailed neurological examination. Only a small percentage of headache patients require further laboratory and radiologic studies. An imaging study should be considered in patients with a history of seizures, recent head trauma, significant change in the headache, or evidence of focal neurological deficits or papilloedema upon physical examination. No absolute rules exist in the evaluation of the headache patient; the decision to perform a neuroimaging study ultimately is based on clinical judgment. Electroencephalography (EEG) is not useful in the routine evaluation of headache patients. It should be considered in patients with an atypical migraine aura, episodic loss of consciousness or symptoms suggestive of a seizure disorder. Lumbar puncture is indicated if meningitis, encephalitis, subarachnoid haemorrhage or high-low pressure syndromes are considered. Patients in whom elevated intracranial pressure is suggested or with focal neurological deficits should undergo a neuroimaging study prior to a lumbar puncture (Lewis et al. 2002).

Treatment and Prognosis of Migraine

The treatment of migraine headaches should emphasise identification of environmental trigger factors, pain control at the time of the headache and preventive medication. The treatment of children with mild, infrequent episodes consists primarily of rest, trigger avoidance and analgesics. The patient and parents benefit from a simple explanation of the headache pain and reassurance that it is not caused by a brain tumour or other life-threatening condition. A regular bedtime, regular meal schedules and avoidance of overloading the child’s schedule with activities are important. Helping the child recognise migraine triggers is helpful but often difficult. It is important that the patient has realistic expectations; identifying and avoiding triggers reduces the frequency of migraine headache but does not eliminate headaches.

Psychological triggers include stress, anxiety, worry, depression and bereavement (Antrila et al. 2004). Emphasising to the patient and family that migraine is not an imagined or psychological illness is important. Stress is not the sole cause of the headaches, although it makes migraines more difficult to manage. Physiological triggers include fever or illness, missing a meal, fatigue and sleep deprivation. Environmental triggers of migraine include fluorescent light, bright light, flickering light, fatigue, barometric pressure changes, high altitude, strong odours, computer screens or rapid temperature changes. Some patients report that complex visual patterns like stripes, checks or zigzag lines may trigger migraines. Physical exertion can trigger childhood migraine. Some migraineurs report that they are more likely to get a headache after participating in sports or being extremely active. Minor head trauma (e.g. being hit in the head with a ball, falling on one’s head) also may result in a migraine attack. Travel or motion may cause migraine, particularly in young children (Jan 1998).

At the time of the headache, advise the child to lie down in a cool, dark, quiet room and fall asleep. Sleep is the most potent antimigraine treatment. Some patients find that ice or pressure on the affected area of pain can alleviate pain temporarily. Nonsteroidal anti-inflammatory agents are effective if taken at an appropriate dosage during the aura or early headache phase. Gastric stasis occurs in migraine patients and causes delay in absorption of oral medications. Occasionally, carbonated beverages may improve absorption. Nonpharmacological treatment modalities such as self-relaxation, biofeedback and self-hypnosis may be reasonable alternatives to pharmacological treatment in managing childhood migraine, particularly in adolescents (Lewis 2004).

Prophylactic or preventive medications are taken on a daily basis to reduce the frequency or severity of headaches and associated symptoms. A good response to prophylactic medications is often considered a 50% reduction in the frequency or severity of episodes. Consider the use of prophylactic drugs for children with frequent (>2 per week), prolonged and disabling migraine episodes that do not adequately respond to other treatments. Often, several weeks are necessary before therapeutic gains are observed with prophylactic medications. Possible preventive medications include amitriptyline, propranolol, gabapentin, valproate, topiramate, flunarizine, verapamil and riboflavin (Hershey et al. 2000; Silberstein et al. 2012). Unfortunately, there is limited high-quality evidence for the best preventive treatment of migraine in childhood. In part, it is difficult to demonstrate efficacy of a single approach because of the traditionally high placebo response rates in children, which approach 50–70% in some studies. This was evidenced in a recent high-quality randomised controlled trial study that compared placebo to topiramate to amitriptyline. In that study the placebo response rate approached 60% and topiramate and amitriptyline failed to exceed that rate of success (Powers et al. 2017). Still, the best available evidence supports the use topiramate and cognitive behavioural therapy in the treatment of migraine.

Migraines may change in frequency as children move into adulthood. In one of the few longitudinal studies of childhood migraine patients, children with migraine were followed for 40 years (Bille 1997). The average age at onset of the migraines was 6 years. During puberty or young adulthood, 62% of the children were migraine-free for at least 2 years; approximately 33% of these children regained regular episodes after an average of six migraine-free years and a surprising 60% of the original 73 children still had migraines after 30 years; 22% of the participants never had a migraine-free year. Of those patients who became parents, 52% have at least one child in their present or previous families who developed recurrent migraineous headache.
**CHRONIC DAILY HEADACHE DISORDER**

Chronic daily headache is a disorder where the diagnosis is based on the presence of headache for greater than or equal to 15 headache days in 1 month, over a period of three consecutive months, and with no underlying organic pathology. The headaches last for more than 4 hours per day. This headache disorder tends to affect adolescents and adults, but can occur before puberty. It can occur in up to 4% of young women and up to 2% of young men, with similar prevalence rates seen in studies from Asia, Europe and the United States (Kavuk et al. 2003).

Silberstein and others (1996) have defined four different categories of chronic daily headache based upon symptoms. These include transformed or chronic migraine, chronic tension type headache, new daily persistent headache and hemicrania continua. Many adolescents with chronic daily headache have a past history of episodic migraine. The transformation to a chronic migraine may occur over a period of weeks to months, or it may occur abruptly over a matter of hours (Mack 2004). Approximately a quarter of adolescents with chronic daily headache will have no significant past headache history and an infection such as mononucleosis or a minor head injury may incite a new, daily persistent headache (Mack 2004). A smaller number of patients will have a history of tension type headaches prior to their chronic daily headache.

Most commonly, the youngster with chronic daily headache will complain of at least two types of headaches. Prominent are severe intermittent headaches that are migrainelike. They tend to be panencephalic or frontal in location. The severe headaches will be described as throbbing, severe, crushing, knife-like or hatchet-like. They are often associated with nausea during the most severe times and the patient will frequently have photophobia, phonophobia and osmophobia. For this more severe headache pain, sleep will sometimes help, but they will still have persistent headache when they awaken. The frequency of these severe headaches will vary with the individual. The severe episodes typically occur multiple times a week.

In addition to these severe intermittent headaches, the patient with chronic daily headache will often complain of a continuous headache that is present 24 hours a day, 7 days a week. This continuous headache may wax and wane in severity, often being worse either in the morning or at the end of the school day. The characteristics of the all-the-time headache pain are similar to the episodes of severe headaches, only much less intense. Some patients may also describe this all-the-time headache as having features of a tension type headache, with the pain being band-like or crushing rather than throbbing.

Headache is not the only symptom in chronic daily headache; it is really a multi-symptom complex. Sleep is disrupted in at least two-thirds of the patients who have chronic daily headache. Typically, the headache syndrome will not resolve until the sleep is improved (Dodick et al. 2003).

Many chronic daily headache patients also complain of dizziness which is associated with feeling weak, unsteady and with blurry, or loss of, vision. This is often positional and may involve syncope or near syncope several minutes after standing. There is typically no vertigo, except during severe headache episodes. The dizziness is particularly prominent in the morning. A difference in blood pressure or pulse rate between sitting and standing may be noted and the patient often experiences mild symptoms of this dizziness if stood up for several minutes in the office. One may see either a significant tachycardia with standing (postural orthostatic tachycardia syndrome) and/or a decrease in the systolic blood pressure with standing (Raskin and Knittle 1976; Johnson et al. 2010).

Mood problems and anxiety also frequently coexist with chronic daily headache. The mood problems may precede or follow the onset of the headache. Both the symptoms of headache and mood need to be addressed. If there are significant problems with mood and anxiety, it is difficult to control the headaches until these symptoms are improved. Other frequent comorbid symptoms include non-specific abdominal pain, back pain, neck pain and diffuse muscle and joint pain and often no additional organic aetiology is found to explain these additional pain symptoms. There are important environmental factors that play a role in these headaches. There is an interesting seasonal variability in the degree of chronic daily headache symptoms. Most patients will do better in the summertime and frequently have a worsening of their headaches at the start of the school year and school absence can be a significant problem (Sartory et al. 1998).

In addition to the preventive treatments listed above for migraine, there are other therapies that should be considered in chronic migraine. Onabotulinumtoxin type A has been shown in randomised controlled trials in adults to be effective in reducing headache levels and migraine days. There are retrospective studies in adolescents that have shown similar effectiveness to what is seen in adult populations (Ahmed et al. 2010). The Cefaly antimigraine device is a neurostimulatory device that is placed on the forehead, similar to a tiara, and used for 20 minutes each day to decrease the headache burden (Schoenen et al. 2013). It seems to be best tolerated by patients without alldynia. In some patients with chronic post-traumatic headaches or neuralgia, selective trigger point injections with a local anaesthetic can be useful in decreasing pain.

The next generation of medications that will be developed for migraine and chronic migraine will affect CGRP, a neurotransmitter associated with pain (Schuster and Rapoport 2016). There are several approaches being developed in parallel by at least five pharmaceutical companies and the end products will have the potential for either abortive or preventive use.

**Evaluation of Chronic Daily Headache**

Neuroimaging studies will be normal in the overwhelming majority of chronic daily headache patients. Occasionally in these patients, white matter abnormalities, arachnoid cysts or pineal cysts will be seen that are generally believed to be of no clinical significance in relation to the chronic daily
headache. If a patient has had a significant history of head
or neck trauma, particularly at the onset of the chronic daily
headache, then magnetic resonance angiogram (MRA) of the
neck should also be considered to rule out a possible carotid dis-
section. When pseudotumour cerebri is a strong consideration,
then an magnetic resonance venography (MRV) should also
be considered since sinus thrombosis can cause elevated intra-
cranial pressure. Serum studies to consider include evaluation
of the thyroid, sedimentation rate and antinuclear antibodies
(ANA). Many patients will transition from a headache-free
period or episodic migraines to chronic migraines during an
infection so consideration should be given to serology for
Epstein–Barr virus, West Nile virus and other viral or bacterial
infections (Lewis et al. 2002; Mack and Gladstein 2008).

**Treatment and Prognosis of Chronic Daily Headache**

Chronic daily headache is difficult to control and it typically
takes weeks to months to effect a change in headache control.
The cornerstones of therapy are education, preventive medi-
cations and attention to environmental trigger factors. It is
difficult for many families to comprehend that the head pain
can persist for such a long time, that there are no abnormali-
ties showing up on diagnostic testing and that the medications
they are prescribed are not immediately effective. It is thus
useful to spend adequate time with the patient and family dis-
cussing the role of medications, when not to use pain relievers,
the role of non-medication approaches (such as biofeedback
or physical therapy), and what the family should expect in
the short and long term. After 1 month of an effective ther-
apy, a reasonable expectation would be to have less frequent
severe headache episodes, and a decrease in the intensity of
the all-the-time, 24/7 headache. It is rare to see complete res-
olution of the headaches after a short period of time. Once a
trend toward improvement is seen, the dose of medication is
adjusted for optimal control of the headaches, and the patient
is continued on the preventive for at least 6 months of good
(but rarely complete) symptom control. It is not unusual to
make frequent adjustments in management initially, and it
may take months before matching up the right preventive
medication or the right therapeutic approach with the indi-
vidual patient (Galli et al. 2004).

Preventive medications are traditionally used in episodic
migraines to reduce the frequency of the migraine headaches.
However, in chronic daily headache, a reasonable therapeutic
goal would be to make the severe intermittent headaches less
frequent, and to make the all-the-time headache less intense.
The most published experience of preventives in chronic
migraine or chronic daily headache is the use of medicines
that work on the serotonergic system or the anticonvulsants.
Unfortunately, there have been few prospective randomised
controlled studies in children to give us guidance as to what
is the most effective or safe medication to use in chronic daily
headache (Lewis et al. 2004).

Studies in adults and children have shown that tricy-
cyclic antidepressants, such as amitriptyline, are helpful in
chronic daily headache. Consideration needs to be given to
following electrocardiogram (ECG) changes, as this drug
may prolong the QT interval. Weight gain is a significant
concern in adolescents with these medicines, and it affects
some children more than others. Amitriptyline can also be
helpful for sleep onset. Other tricyclics, such as nortripsy-
tine or protriptyline, may cause less sedation (Hershey et al.
2000).

Other serotonergic agents such as the selective serotonin
reuptake inhibitors (SSRIs) have also shown to be effective in
some adults with chronic headache. The SSRIs seem to be less
effective than the tricyclics for pain control, although they are
more helpful in children for their positive effects on mood. In
select patients, the use of an SSRI can be very useful (Saper
et al. 1994).

Studies in headache patients have shown anticonvulsants
are also useful. Valproate, topiramate and gabapentin have
been used. Choice of rational pharmacotherapy to treat the
patient’s other problems is ideal. Antidepressants can
address underlying mood disorders as well as sleep problems.
Beta-blockers can make depression worse; however, they may
be helpful for patients with a postural orthostatic tachycardia
syndrome. Calcium channel blockers are useful for patients
who also have hypertension, but cause constipation and
orthostatic hypotension. If the patient needs to lose weight,
topiramate is a good choice, although this may result in cog-
nitive clouding. The use of botulinum toxin shows promise as
well (Mack and Gladstein 2008).

**Hemicrania continua** is a rare headache syndrome, occur-
ing in approximately one percent of chronic daily headache
patients. It is a persistent unilateral headache pain. The pain
may be characterised by a stabbing sensation and may be asso-
ciated with autonomic changes. It is important to recognise
this entity since these patients may respond to daily doses of
indomethacin to ameliorate this condition.

Pain control at the time of the headache is a very difficult
problem for patients. Analgesics that are typically effective
for episodic migraine headaches are not very effective for chronic
migraine or chronic daily headaches. Most patients report that
pain relievers are not effective for the all-the-time, 24/7 head-
ache. It is reasonable to discourage patients from trying to use
analgesics to treat the all-the-time headache, since this may
result in analgesic overuse and a potential analgesic rebound
headache. Combating rebound from those substances is part
of the treatment. Medications implicated in this overuse syn-
drome include most over the counter analgesics and decon-
gestants, opioids, butalbital, isomethptene, benzodiazepines,
ergotamine and triptans.

In contrast, for the more severe intermittent headache
episodes with migrainous qualities, analgesics should be con-
sidered. Approaches can include the use of migraine pain
relievers such as triptans, indomethacin or other nonsteroidal
anti-inflammatory agents. Compounds that contain caffeine,
barbiturates, opiates, or that have a high potential for rebound
should be limited or avoided. Patients typically find that when the preventive medication starts working, then the pain analgesics will become more effective also. Additional treatment strategies include dihydroergotamine, intravenous valproate or steroids. Non-pharmacological approaches to the headaches are also very important. Because of the chronic nature of the pain, some patients will benefit with a consultation with a psychologist to at least be introduced to the techniques of relaxation therapy and biofeedback. Many of the patients have been ill for months to years and have become physically ‘deconditioned’. Starting a reconditioning exercise programme is very important. Patients should be encouraged to start slowly. For the most severely affected patients, begin with 10 minutes of aerobic exercise a day and then increase the time by 10% a week. There is limited data looking at the outcome of chronic daily headache in children. The average time by 10% a week. There is limited data looking at the outcome of chronic daily headache in children. The average duration in childhood is unknown, but it is not unusual to see children who have chronic daily headaches persisting for months to years.

**TENSION TYPE HEADACHE**

Migraine and tension type headache are the most common types of headache in children and adolescents. The actual prevalence of tension type headache in children is uncertain because it varies with the defining criteria, but studies have reported anywhere from 0.9–73% of affected children. Age at onset has been reported in studies as between 5 and 12 years. The headaches tend to occur more frequently in females during adolescence and genetics plays less of a role in this disorder than in migraine. The pathophysiology is incompletely understood but may involve trigeminal activation. The headaches are characterised by a variable intensity, bilateral, dull, pressure pain with occasional associated phonophobia that lasts from minutes to days. There are three subtypes defined by the International Headache Society classification. Episodic tension type headache may be infrequent (less than one day per month) or frequent (1–14 days per month) and chronic tension type headache occurs 15 or more days per month. Diagnosis is based on the clinical history and a normal neurological examination including vital signs and funduscopic examination. The differential diagnosis is broad and includes a variety of organic disorders such as infection, malformation, bleed and systemic disorders. The value of neuroimaging in the presence of a typical history and normal neurological examination is low, but is recommended if there is vomiting, a history of trauma, seizure or an abnormality on examination. Tension type headache or medication overuse headache may progress into chronic daily headache. Treatment of episodic tension type headache involves reassurance, stress reduction, psychological and cognitive behavioural therapies and appropriate use of an acute analgesic medication, such as a nonsteroidal anti-inflammatory drug. Treatment of chronic tension type headache may involve the above in addition to a prophylactic medication such as an antidepressant (Anttila 2006; ICHD 2013).

**TRIGEMINAL AUTONOMIC CEPHALALGIAS**

Trigeminal autonomic cephalalgias refer to a group of headaches that are characterised by repetitive, brief episodes of severe unilateral pain associated with ipsilateral autonomic features including rhinorrhea, nasal congestion, lacrimation and conjunctival injection. They include cluster headache, paroxysmal hemicrania and short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT) syndrome. They each differ in the duration, frequency and rhythmicity of episodes. All are more common in adults and have rarely been reported in children.

**CLUSTER HEADACHE**

Cluster headache is the most common trigeminal autonomic cephalalgia. The prevalence in adults is less than 1% and has a male predominance. The prevalence in childhood and adolescence has been estimated to be 0.1%. Studies have noted childhood onset after the age of 5 years. The pathophysiology is not completely understood but theories involve hypothalamic activation and neurogenic inflammation. Symptoms include several bouts per day, generally with circadian rhythmicity, lasting weeks of severe unilateral orbital, supraorbital or temporal head pain lasting 15 minutes to 3 hours with associated unilateral autonomic features and associated restlessness (Majumdar et al. 2009). Children may experience thrashing about or emotional outbursts secondary to the severe pain. There are episodic (most common) and chronic forms and a familial predisposition. Diagnosis is made clinically but a head computed tomography (CT) or MRI should be performed to exclude an underlying brain lesion. The differential diagnosis includes other trigeminal autonomic cephalalgias and an underlying brain lesion. Treatment involves preventive medications such as verapamil and acute treatment such as oxygen, triptans or steroids. The patient should be cautioned against triggers, such as smoke and alcohol.

**PAROXYSMAL HEMICRANIA AND SUNCT SYNDROME**

Paroxysmal hemicrania is rare in children. Episodes are shorter (minutes), more frequent and less severe than in cluster headaches. These headaches are exceptionally responsive to treatment with indomethacin.

Short-lasting Unilateral Neuralgiform headache with Conjunctival injection and Tearing (SUNCT) syndrome is also rare in children. Episodes are very short in duration (seconds to minutes), triggered by touching the face or chewing, have limited associated autonomic features and occur up to hundreds of times per day.
ICE PICK HEADACHES

Ice pick headaches are a benign primary headache disorder characterised by sudden ice pick-like pains. These pains may last for seconds to minutes, typically occur at different parts of the child’s head, and are often seen in patients prone to migraines. They are fairly infrequent and most often do not require treatment. There are case reports of these headaches responding to indomethicin.

SECONDARY CAUSES OF HEADACHE

CEREBRAL VENOUS SINUS THROMBOSIS

Cerebral venous sinus thrombosis is a serious disorder that frequently presents with headache. Diagnosis and treatment may be delayed secondary to its varied clinical presentation unless it is considered and investigated as a potential aetiology (see Chapter 15). The annual incidence in a multicentre Canadian registry of children 18 years of age and younger was 0.67 per 100,000. In children there is no female predominance as is seen in young adults (deVeber et al. 2001). Risk factors and presenting symptoms are related to age. Neonates are most commonly affected and risk factors include hypoxic encephalopathy or other perinatal complications, infection and dehydration. In children, risk factors include acute or chronic systemic illnesses, anaemia, infection (especially of the head and neck), prothrombotic states and dehydration.

The clinical presentation in neonates includes seizures and diffuse neurological signs. In children it may include headache, changes in cognitive status, papilloedema, emesis and focal neurological signs. Headache is the most frequent symptom. The headache onset is generally acute to subacute, and the intensity moderate to severe. The pain is typically continuous and localised, exacerbated by recumbency and Valsalva manoeuvres, and unrelied by analgesics. Neuroimaging should be performed, and include head MRI and MRV because head CT may be normal in about 30% of patients. This will demonstrate an absence of blood flow in the cerebral veins. Treatment involves antithrombotic therapy utilising intravenous heparin followed by warfarin for several months. In cases of extensive thrombosis, thrombolytic therapy and mechanical thrombectomy may be considered. Outcomes vary from resolution with normal neurological function in about half to neurological sequelae (motor, cognitive, speech) and death (deVeber et al. 2001; Agostoni 2004; Sebire et al. 2005).

PSEUDOTUMOUR CEREBRI

(IDIOPATHIC INTRACRANIAL HYPERTENSION)

Idiopathic intracranial hypertension is a syndrome of increased intracranial pressure with normal neuroimaging studies, normal cerebrospinal fluid (CSF) composition and elevated CSF pressure (Friedman and Jacobson 2002). In adults it is frequently associated with obese females of childbearing age. In children, however, it is less frequently associated with obesity and female sex. Symptoms include those of elevated intracranial pressure: headache, nausea, vomiting and visual disturbances. Headache is the most common presenting symptom and may be daily, pulsatile and exacerbated by supine positioning. Infants with headache may present more subtly with only changes in sleep and behaviour. Neurological examination may demonstrate cranial nerve palsies, especially abducens palsy and papilloedema. Papilloedema is considered a characteristic finding; however, it may not be seen in infants because of their unfused sutures, and is an inconsistent finding in children and adolescents. Associated factors to inquire about in the history include the use of acne medications, antibiotics, vitamin A intake and oral contraceptives (Genizi et al. 2007).

Diagnosis is one of exclusion and is based upon the 1985 Modified Dandy Criteria: an awake and alert patient, signs/symptoms of increased intracranial pressure, absence of localising findings on neurological examination except for abducens nerve palsy, normal CSF findings except for increased pressure (>250mm water), absence of ventricular system anomaly on imaging studies and lack of other cause identified (Friedman et al. 2013). Neuroimaging should be performed to evaluate for mass lesions causing obstructive hydrocephalus or dural venous sinus thrombosis. A lumbar puncture should be performed after a mass lesion has been ruled out by imaging to evaluate for increased intracranial pressure. Treatment in children may involve acetazolamide, corticosteroids, serial lumbar punctures, lumboperitoneal shunting or optic nerve sheath fenestration. Patients should be referred to an ophthalmologist for an examination including visual field testing and continued visual monitoring as visual loss is a complication. Outcome is generally favourable (Soler et al. 1998).

HEADACHE IN CHIARI MALFORMATIONS

Headaches may be a presenting symptom of a Chiari I malformation (see Chapter 6). There are four types of Chiari malformations but because the other malformations are generally evident at birth, a type I malformation is the most likely to be discovered in childhood. Type I Chiari malformation refers to the downward displacement of the cerebellar tonsils through the foramen magnum. It may be associated with obstructive hydrocephalus and syringomyelia. The incidence is unknown because many patients are asymptomatic and remain undiagnosed. Headache is a common presenting symptom and may
be exacerbated by Valsalva manoeuvre or physical exertion. The head pain may be located in various areas and may occur multiple times daily and last seconds to minutes. Presenting complaints may also include neck pain, sensory, motor or gait impairments or oropharyngeal dysfunction. Neurological examination findings may include scliosis, abnormal deep tendon reflexes and cranial nerve deficits. Diagnostic testing should include brain MRI, including the posterior fossa, craniovertebral junction and upper cervical levels. Surgical treatment for children presenting with headache is generally controversial but may include suboccipital craniectomy and cervical laminectomy (Weinberg et al. 1998; Greenlee et al. 2002).

**TRAUMA RELATED HEADACHE**

**Epidural Haematoma**

Trauma is a common cause of injury and loss of consciousness in children and may be associated with a potentially life-threatening epidural haematoma. In an epidural haematoma there is haemorrhage, commonly from the middle meningeal artery, and accumulation of blood between the dura mater and the skull. This blood initially strips the dura away from the skull, causing pain and eventually exerts mass effect on the brain which can lead to herniation and death. Thus it is important to quickly recognise the symptoms and efficiently manage children with epidural haematoma who may present with headache.

Risk factors include falls, motor vehicle accidents, direct head injuries and skull fractures. Patients may experience an asymptomatic, lucid interval following the initial injury then develop headache with associated nausea, vomiting and altered cognitive status. Late and ominous findings indicating compression of the brainstem include focal neurological findings, pupillary changes, bradycardia, hypertension and respiratory depression. Clinical presentation varies with age. In newborn infants, epidural haematomas may complicate delivery and may present with seizures, hypotonia and pallor. Older children may present with headache, nausea and vomiting several hours following a head injury associated with loss of consciousness. Diagnosis is via head CT which demonstrates a concave, hyperdense mass which generally does not cross suture lines. Treatment depends on the physical examination and head CT findings. Surgical management involves haematoma evacuation, and non-surgical management involves serial imaging and observation. Outcome can be favourable with prompt diagnosis and surgical management (Heyman et al. 2005).

**Subdural Haematoma**

Subdural haematomas result from venous tearing and haemorrhage into the potential space located between the dura and arachnoid. Risk factors include falls, motor vehicle accidents and trauma. Infants are predisposed to subdural haematomas because they have relatively larger heads, subdural spaces and weaker neck muscles compared with older patients.

Other predisposing factors include a history significant for a haemorrhagic disorder, an arachnoid cyst or shunted hydrocephalus. Onset of symptoms may be delayed days to weeks due to the relatively lower pressure venous system. Infants may present with a bulging fontanelle and irritability. Young children may present with seizures, increasing head circumference, hypotonia and focal neurological signs. Non-accidental trauma should be considered in the differential diagnosis of a young child with a subdural haematoma. Associated factors may include retinal haemorrhages, bruises, fractures or a previous history of abuse. Older children may present with altered cognitive status, headache and vomiting. Late findings indicating compression of the brainstem include focal neurological findings, pupillary changes, bradycardia, hypertension and respiratory depression.

Diagnosis of subdural haematoma is by head CT which demonstrates a concave, hyperdense mass which crosses suture lines. Additional studies to consider in a child with a subdural haematoma include a blood count, coagulation studies, funduscopic examination and skeletal survey. Treatment depends on the physical examination and head CT findings and outcome varies. Surgical management involves haematoma evacuation or shunt placement and non-surgical management may involve serial imaging, observation and intracranial pressure monitoring (Jayawant et al. 1998; Vinchon et al. 2003).

**HEADACHE AND MENINGITIS**

Meningitis refers to inflammation of the tissues surrounding the brain and spinal cord. Aetiology includes bacteria, viruses, fungi and parasites (see Chapter 11). Headache is a frequent early symptom.

**Bacterial Meningitis**

Bacterial meningitis is life-threatening, and the most common causative agents depend on patient factors such as age, immunisation status and presence of underlying predisposing factors. Risk factors include living in an endemic area, immunocompromise, lack of immunisation against Haemophilus influenzae type b or Streptococcus pneumoniae, recent infection (especially upper respiratory, ear or sinus), head trauma, ventricular shunts or cochlear implants.

The most common aetiological organisms vary with age and location. In neonates, group B streptococci, *Listeria monocytogenes* and Gram-negative enteric bacilli (*Escherichia coli*, *Klebsiella*, *Enterobacter*, *Salmonella*) are common agents. Worldwide, *S. pneumoniae*, *N. meningitides* and *H. influenzae* type b are common causes of bacterial meningitis in young children and *S. pneumoniae* and *N. meningitidis* are common in older children. Clinical features and examination findings may include headache, fever, neck stiffness, photophobia, altered cognitive status, nausea, vomiting, irritability, seizures, cranial nerve palsies, petechiae and purpura.

Evaluation should include CSF cell count, differential, glucose, protein, culture and serum blood count, differential,
glucose, culture and possibly neuroimaging. Imaging should be performed prior to lumbar puncture if there is concern for increased intracranial pressure that may result in herniation during the lumbar puncture. Disease progression may be fulminant so empirical antibiotic therapy may need to precede lumbar puncture and imaging. However, a blood culture should be obtained initially.

CSF findings include pleocytosis with neutrophil predominance, elevated protein, decreased glucose and a positive Gram stain. A positive CSF culture is diagnostic as is a positive blood culture in the setting of CSF pleocytosis. Complications include shock, increased intracranial pressure, seizures, subdural effusions and abscesses. Treatment should be initiated empirically while awaiting culture results and then altered if necessary when a specific organism is identified. Recommendations for empirical therapy of bacterial meningitis by the Infectious Disease Society of America include vancomycin plus a third-generation cephalosporin for children older than 1 month. Adjunctive dexamethasone use to decrease the inflammatory response is recommended in infants and children with *H. influenzae* type b meningitis and should be given prior to the initiation of antimicrobials and continued for 2–4 days. Outcomes vary but persistent neurological sequelae are not uncommon following bacterial meningitis (Tunkel et al. 2004; Chavez-Bueno and McCracken 2005).

### Viral Meningitis

Viral meningitis is more common than bacterial meningitis in children. It is also known as aseptic meningitis and refers to an inflammation of the meninges without evidence of bacteria in the CSF. Various infectious agents such as enterovirus, herpesvirus, arbovirus, influenza and rabies may be responsible but non-polio enteroviruses are the most common cause of viral encephalitis in the United States. Worldwide, there is a diverse range of pathogens that may cause viral encephalitis. Arboviruses have a global distribution but are found primarily in tropical regions. West Nile virus is an arbovirus that is found in North America. Paediatric West Nile virus may present with a febrile illness and may include meningitis, encephalitis and a poliomyelitis-like illness (Gubler 1996).

Clinical presentation may include fever, headache, nausea, vomiting, photophobia and change in cognitive status. Young children may present with fever, irritability, rash or seizures. Common aetiologies include group B coxsackieviruses and echoviruses. Evaluation should include lumbar puncture and CSF analysis to rule out a bacterial aetiology. Pleocytosis is seen and may be neutrophilic initially and then become more lymphocytic. Treatment is supportive and prognosis is generally favourable (Rorabaugh et al. 1993; Sejvar 2006).

### HEADACHE AND BRAIN TUMOURS

Headache may be the presenting symptom of a brain tumour in children. Brain tumours (see Chapter 14) are the most common solid organ cancer and second to leukaemia as the most common overall cancer in children. Presenting signs and symptoms vary with the age of the child and with the location of the tumour but frequently include headache (especially nocturnal or early morning), nausea, vomiting, unsteadiness, seizures, behaviour changes, papilloedema and focal neurological deficits. The majority of childhood brain tumours are located infratentorially. Location of the tumour determines clinical presentation. For example, brainstem gliomas may present with cranial neuropathies due to their compression of exiting cranial nerves. Cerebellar astrocytomas and medulloblastomas may present with ataxia due to their location in the cerebellum as well as symptoms of increased intracranial pressure because of fourth ventricular compression. Ependymomas tend to arise from the floor of the fourth ventricle, which is near the vomiting centre, and may present with nausea, vomiting or obstructive hydrocephalus. Supratentorial midline tumours such as craniopharyngiomas and gliomas may present with visual deficits, eye movement abnormalities, neuroendocrine dysfunction, behavioural and appetite changes due to their location near the optic chiasm and pituitary gland (Pollack 1999).

Headache is a common complaint in children and deciding which children to image can be challenging. Recent studies have investigated clinical predictors of underlying brain tumour in children presenting with headache and found that a headache that causes nocturnal awakening or is present upon awakening, as well as a negative family history of migraine, were predictors of underlying brain tumour. Additional predictors include headache duration of less than 6 months, vomiting, seizures, confusion and an abnormal neurological examination. Diagnosis is via neuroimaging with and without the use of contrast. MRI is generally preferred over CT because the posterior fossa is better visualised. Treatment depends on the histological diagnosis, tumour location and age of the child but may involve surgery, chemotherapy, radiation and other modalities such as anticonvulsant medications or bone marrow or stem cell reconstitution. Prognosis varies with tumour type (Medina et al. 1997; Wilne et al. 2006).

### HEADACHE AND VASCULAR MALFORMATIONS

Cerebral vascular malformations include venous angiomas, arteriovenous malformations, capillary telangiectasias and cavernous malformations (see Chapter 15). Venous angiomas are the most common and are usually benign. Clinical presentation may include headache as well as dizziness, incoordination, seizures, motor or sensory deficits. Diagnosis is via MRI and treatment is conservative. Capillary telangiectasias are usually asymptomatic and may be found incidentally on neuroimaging studies (McLaughlin et al. 1998).

Cavernous malformations and arteriovenous malformations are more likely to cause neurological symptoms. Cavernous malformations may be sporadic or familial. Clinical presentation may include headache, haemorrhage, seizure or focal...
HEADACHE AND BRAIN ABSCESS

Brain abscesses are generally uncommon in children but may develop in children with predisposing factors. Studies have identified congenital heart disease, otitis media, sinus or intracranial infections, intracranial hardware, skull fractures, intracranial surgery and immunosuppression (organ transplantation, chemotherapy, HIV) as predisposing factors for brain abscess development. Pathogenesis involves the invasion of micro-organisms (bacteria, fungi, parasites) into the brain parenchyma and can result from direct extension, hematogenous spread or penetrating trauma. Infants being treated for meningitis may present with a bulging fontanelle and increased head circumference. Older children may present with more obvious signs including vomiting, fever, headache, photophobia, cognitive status changes, seizure and focal neurological signs such as hemiparesis or visual field deficits. Early diagnosis and treatment leads to improved outcome. A brain abscess should be considered in a child with a history of congenital heart disease, immunosuppression, recent neurosurgical procedure or ear or sinus infection presenting with new onset headache, seizure or focal neurological sign. Neuroimaging with contrast should be performed and will demonstrate an enhancing rim around an area of decreased attenuation. Treatment generally involves monitoring with frequent brain imaging, several weeks of antibiotics and possible surgical intervention. Adverse outcomes may include hydrocephalus, seizures, developmental delay, neurological deficits or death (Goodkin et al. 2004).

HEADACHE AND HYDROCEPHALUS

Hydrocephalus is due to the accumulation of CSF secondary to an imbalance in its production and re-absorption (see Chapter 7). This may result from increased CSF production, decreased absorption or obstruction to flow, which is the most common cause. The resultant increased pressure results in dilation of the ventricular system, affects its lining and the surrounding white matter. Congenital hydrocephalus may be a result of intrauterine infection, toxoin exposure, or central nervous system (CNS) tumour or malformation. Acquired hydrocephalus may be the result of CNS infection, haemorrhage or tumour causing ventricular obstruction. Signs and symptoms include an excessive increase in head circumference, headache (especially morning), nausea, vomiting and changes in vital signs, level of consciousness and papilloedema. Acute hydrocephalus presents more obviously than chronic hydrocephalus, as the system has time to adjust to the changes. Diagnosis can be made by neuroimaging, including cranial ultrasound in infants or head CT or MRI. Treatment depends on the underlying cause but may involve CSF drainage and shunt placement. Complications of shunts include mechanical malfunction and infection. Headache is a frequent complaint in patients with shunts and should raise the suspicion for shunt malfunction or infection. Prognosis depends on cause, time to treatment and complications but may include seizures and developmental delay. Prognosis in untreated hydrocephalus is poor and may include death (Kahle et al. 2016).

REFERENCES

Diagnosis is via MRI and treatment depends on symptoms and location but may involve surgical resection, or stereotactic radiosurgery (Labauge et al. 1998).

Arteriovenous malformations involve a loss of the normal vascular organisation. They consist of abnormal collections of dilated arteries and veins in the brain parenchyma. The most common presenting sign is haemorrhage but additional presentations include headache, seizures and neurological deficits. Haemorrhagic strokes are relatively common in children and may be due to an underlying arteriovenous malformation. Diagnosis is via neuroimaging, including CT angiography, which provides vascular detail, or MRI/MRA which provide visualisation of surrounding structures. Angiography is the criterion standard, however, because it allows for visualisation of the lesion and is useful in the assessment of haemorrhage risk. Treatment depends on many factors and may include surgical resection, radiosurgery or embolisation (Friedlander 2007).

Hydrocephalus is due to the accumulation of CSF secondary to an imbalance in its production and re-absorption (see Chapter 7). This may result from increased CSF production, decreased absorption or obstruction to flow, which is the most

Sleep Disorders

Patricia Franco

The mechanisms and role of sleep are still mysterious. In children sleep has different neurophysiological and clinical features from that in adults, while maturational changes with age in the development of clinical and electroencephalogram (EEG) sleep stages have been extensively studied (Dan and Boyd 2006).

Childhood sleep disorders are one of the most prevalent complaints in paediatrics (Halbower and Marcus 2003).

### PAROXYSMAL DISORDERS OF SLEEP

#### NIGHT TERRORS AND NIGHTMARES

Night terrors usually occur between the ages of 18 months and 5 years (Guilleminault 1987a) and are associated with partial arousal from deep slow sleep (Stages III–IV). They supervene mainly during the first hours of sleep, with the child starting to scream and usually sitting up, looking terrified and although appearing to be awake does not recognise his or her parents and cannot be consoled. An episode lasts a few minutes before the child goes back to sleep and keeps no memory of the event. Night terrors may occur every night for periods then disappear. They may persist to age 8 years in 50% of children and decrease during adolescence (DiMario and Emery 1987; Laberge 2000). Nightmares may appear similar but take place during rapid eye movement (REM) sleep, at the end of the night when REM sleep is predominant. Both night terrors and nightmares are benign conditions and require only reassurance.

#### SOMNAMBULISM (SLEEP WALKING)

Somnambulism is frequent in older children. It is the consequence of incomplete arousal that permits some semipurposeful activity without clear consciousness or memory of the event. Episodes are usually brief, with the child engaging in a simple activity such as going to the bathroom. Somnambulism may be associated with somniloquy and is characterised neurophysiologically by an incomplete arousal from slow sleep (Pedley 1983); hereditary factors may play a role in genesis. Night terrors and sleepwalking occur together in more than 50% of affected children and share the same genetic predisposition (DiMario and Emery 1987; Laberge 2000). They are grouped together under the term ‘non-REM parasomnias’.

#### HYPNAGOGIC PHENOMENA

These are brief episodes of auditory or visual hallucinations or distortions of perception, especially auditory or proprioceptive, that occur in the transition between wakefulness and sleep, most commonly on going to sleep. They may be a part of the narcolepsy tetrad (see below) but are more commonly a normal phenomenon.

#### RAPID EYE MOVEMENT SLEEP BEHAVIOUR DISORDER

Unconscious violent behaviour may arise from REM sleep in adolescents and adults but this syndrome is rare in childhood (Trajanovic et al. 2004).

#### ABNORMAL MOVEMENTS IN SLEEP

Restless legs syndrome can occur in children and adolescents (Kotagal and Silber 2004). It is characterised by an irresistible urge to move the limbs, usually accompanied by a peculiar discomfort in the lower limbs. It may cause difficulties in initiating or maintaining sleep and daytime sleepiness; a family history of the syndrome is frequently reported. Walters et al. (1994) reported it to be dominantly inherited in children with typical features of urge to move, paraesthesiae, motor restlessness and periodic limb movements (nocturnal
myoclonus). The syndrome may be associated with iron deficiency and affected children may be misdiagnosed as hyperactive or irritable, while the syndrome may be one cause of the so-called ‘growing pains’.

**Periodic movements in sleep** may be associated with restless legs syndrome and are more or less rhythmical, sometimes recognised only by pain in the legs on awakening (Martinez and Guilleminault 2004), while links with attention-deficit–hyperactivity disorder, narcolepsy and other sleep disorders are frequent (Picchietti and Walters 1999). Treatment with the dopamine agonist pramipexol or with gabapentin or the benzodiazepines can be useful.

Other involuntary movements of sleep in children include myoclonic jerks on falling asleep (Oswald 1959), **nocturnal myoclonus** that may be more or less rhythmical, jactatio capitis nocturna and nocturnal jerks sometimes associated with hyperekplexia (see also Chapter 19).

**Benign neonatal sleep myoclonus** is a well-defined and easily diagnosed condition, even though it is often mistaken for epileptic seizures or even status epilepticus. Rhythmic jerks of the limbs may be generalised or localised, occurring in brief or more prolonged bursts that can be repeated for hours, with the trunk and face remaining unaffected and jerks immediately ceasing on awakening (Resnick et al. 1986; Di Capua et al. 1993). Induction of the myoclonus by shaking the crib is a useful diagnostic manoeuvre (Alfonso et al. 1995): the myoclonus usually disappears in a few weeks but can persist up to several months. Physiological myoclonus should be differentiated from pathological myoclonus in newborn infants, which is not sleep-related, may involve the face and trunk and is associated with EEG abnormalities (Scher 1985; Alfonso et al. 1993).

**Nocturnal paroxysmal dystonia** (Lugaresi et al. 1986) is characterised by sleep-related seizures with choreoathetoid, dystonic and ballistic movements occurring every night in adult patients. Similar situations occur occasionally in children, with the symptomatology similar to that of some frontal lobe seizures; the disease often responds well to carbamazepine. Two subtypes are observed, short repeated episodes lasting only seconds to minutes and long-lasting episodes. It is currently recognised as a form of frontal lobe epilepsy that may be familiar (Chapter 16).

### SLEEP APNOEA SYNDROMES

Several syndromes are characterised by the occurrence of abnormally frequent or prolonged episodes of apnoea during sleep (see Table 18.1). Normally, REM sleep is characterised by irregular breathing. Sleep apnoea are a disabling problem because of their interference with sleep (sleep fragmentation and/or intermittent hypoxemia) which could induce growth impairment, school difficulties as well as learning and behavioural problems (Nixon and Brouillette 2005).

Episodes of apnoea that occur during sleep may be of three types (Guilleminault 1987b):

1. **Obstructive apnoea** is the unsuccessful maintenance of an airflow in spite of respiratory effort,
2. **Central apnoea** is the arrest of respiration because it fails to be initiated by the respiratory centres and
3. **Fixed apnoea** combines both mechanisms.

### OBSTRUCTIVE SLEEP APNOEA SYNDROME

Obstructive sleep apnea (OSAS) in children is characterised by recurrent events of partial or complete upper airway obstruction during sleep, resulting in disruption of normal ventilation and sleep patterns (American Thoracic Society 1995). The incidence of OSAS is estimated to be from 2–4% whereas habitual snoring is more common and estimated to occur in 6–9% of school-aged children (Lumeng 2008). It occurs in children of all ages including neonates. OSAS is frequently diagnosed in children without neurological disorders between the ages of 2 and 6 years in association with adenotonsillar hypertrophy. Children with craniofacial anomalies and/or neurological disorders, stockage diseases such as mucopolysaccharidoses affecting upper-airway configuration and collapsibility during sleep may present OSAS at any time from early infancy through childhood. OSAS may be more common in children with a family history of the syndrome, infants with gastrooesophageal reflux, children of African-American race, children who are obese, born preterm or with chronic upper and lower respiratory tract diseases (Redline 1999; Raynes-Greenows 2012). Clinical features of OSAS can be divided into nocturnal signs such as loud snoring, laboured or paradoxical breathing, movement arousals, neck extension during sleep, secondary enuresis and daytime symptoms such as morning headaches, slow rate of growth, excessive daytime sleepiness, hyperactivity or aggressive behaviour; however, clinical criteria are insufficient for diagnosis (Marcus 2012a). Both clinical and polysomnographic features are required for the diagnosis of OSAS in children (International Classification of Sleep Disorders-3 [ICSD-3]). Children with OSAS may demonstrate several breathing patterns during sleep from obstructive apnea to obstructive hypoventilation, which consists of long periods of persistent partial upper airway obstruction associated with hypercarbia and/or arterial oxygen desaturation. Some children may manifest a pattern of upper airway respiratory syndrome (UARS) similar to that seen in adults, including snoring without identifiable airflow obstruction: an increased frequency of night terrors and somnambulism may be observed in these children (Guilleminault 2003). In children upper airway obstruction occurs predominantly during REM sleep, with complications frequent and possibly severe. In early childhood OSAS can cause growth failure, with cognitive and behavioural
complications common and which may include developmental delay, poor school performance, attention-deficit–hyperactivity disorder and aggressive behaviour. Cardiovascular complications include pulmonary hypertension, cor pulmonale and systemic hypertension while severe complications may result including cor pulmonale, failure to thrive and permanent neurological damage (Oren et al. 1987). Adenotonsillectomy is the most common treatment for pediatric obstructive sleep apnea and the first line treatment in any child with significant adenotonsillar hypertrophy, even in the presence of additional risk factors (Guilleminault et al. 1986; Marcus et al. 1995; Nixon and Brouillette 2005; Marcus 2012). Residual obstruction

*a Gastrointestinal reflux remains a deleted cause of apnoea.

*b Exclusion diagnosis.

c Apnoea, pallor, cyanosis, impression of imminent death. About half the cases are due to known disorders (respiratory, digestive, neurological or cardiac); the remaining cases are idiopathic and may be related to the sudden infant death syndrome and to sudden unexpected death in epilepsy patients (SUDEP) (see Chapter 16).
is not rare (30–70%), especially in children with additional risk factors such as obesity, craniofacial anomalies, severe OSAS and those older than 6 years (Bhattacharjee 2010). Weight management is indicated for obese children while medications including nasal steroids or montelukast in short therapy could be helpful (Brouillette 2001; Goldbart 2012): exposure to environmental tobacco smoke and other pollutants should be avoided while referral to an orthodontist for rapid maxillary expansion is recommended in individuals affected by residual OSAS (Pirelli 2004). Continuous or bilevel positive airway pressure can be used successfully in children and adolescents, even in young infants (Marcus 2012) and should be considered a palliative rather than curative therapy. Other surgical procedures such as nasal septoplasty and/or maxillofacial surgery are performed, only in selected children. Tracheostomy is rarely indicated except in patients affected by severe, life-threatening obstructive sleep apnea.

**CONGENITAL CENTRAL ALVEOLAR HYPOVENTILATION SYNDROME**

Congenital central alveolar hypoventilation syndrome (CCAHs), also known as ‘Ondine’s curse’, is a rare syndrome that occurs considerably less frequently than obstructive sleep apnoea syndrome. It is characterised by the depression of central ventilatory drive during quiet sleep and resulting in central apnoeas during sleep that are rapidly lethal if untreated. Trang et al. (2005) reported on 70 patients from France and found an overall fatality rate of 38%, with 43 patients surviving at a mean age of 9 years at the time of the study and 49 of 50 who lived beyond 1 year of age receiving night-time ventilation. Additional problems may include swallowing difficulties while abnormalities of the brainstem auditory evoked potentials have been found in in patients with congenital or idiopathic CCAHS (Beckerman et al. 1986). A history of hydramnios is present in some patients (Alvord and Shaw 1982) and Hirschsprung disease (Commare et al. 1993) is probably the most common syndrome associated with episodes of apnoea. Boltshauser et al. (1987) and Magaudda et al. (1987) have reviewed these syndromes which include Joubert syndrome, Mohr syndrome and Dandy–Walker syndrome (Bordier and Aicardi 1990). Magaudda et al. (1988) described a syndrome of familial, fixed, congenital encephalopathy with an undifferentiated sleep–waking EEG cycle, excessive startles and continuous periodic breathing. Episodes of ‘microsleep’ during wakefulness occur especially in patients with nocturnal insomnia (Tassinari 1976), can be mistaken for epileptic absences and may have the same unpleasant or dangerous consequences for the patients.

**OTHER SYNDROMES FEATURING SLEEP APNOEA**

Pickwickian syndrome is a syndrome of hypoventilation with episodes of apnoea observed in some obese children. It is probably due, at least in part, to limitation of diaphragm movements by fat accumulation with resulting oxygen desaturation and hypercapnia. Daytime somnolence is a consequence of the disturbance of night sleep by apnoea with other neurological syndromes including, among their major features, apnoea or abnormal respiratory patterns: Rett syndrome (Chapter 9) is probably the most common syndrome associated with episodes of awake apnoea. Boltshauser et al. (1987) and Magaudda et al. (1987) have reviewed these syndromes which include Joubert syndrome, Mohr syndrome and Dandy–Walker syndrome (Bordier and Aicardi 1990). Magaudda et al. (1988) described a syndrome of familial, fixed, congenital encephalopathy with an undifferentiated sleep–waking EEG cycle, excessive startles and continuous periodic breathing. Episodes of ‘microsleep’ during wakefulness occur especially in patients with nocturnal insomnia (Tassinari 1976), can be mistaken for epileptic absences and may have the same unpleasant or dangerous consequences for the patients.

**HYPERSOMNIA AND INSOMNIA SYNDROMES**

**NARCOLEPSY-CATAPLEXY**

Narcolepsy consists of episodes of irresistible sleep occurring during daytime, most often during monotonous activity. The episodes, which last usually 10–20 minutes, appear on a background of more or less continuous sleepiness in most patients. Hypersomnia in narcolepsy is usually associated with one or more of the other elements of the tetrad of symptoms: cataplexy, hypnagogic hallucinations and sleep paralysis – but these do not necessarily occur together. Cataplexy is a sudden loss of muscle tone, precipitated by laughter or excitement: it results in the patient falling to the ground without losing consciousness and should be distinguished from epilepsy (Macleod et al. 2005), hyperekplexia, Niemann–Pick C disease and sudden falls that occur in patients with the Coffin–Lowry syndrome. The full tetrad occurs in only 10% of adult patients with many children presenting with behaviour problems or learning difficulties, both consequences of sleepiness and efforts to stay awake (Winter et al. 1996). Narcolepsy is a rare disease with an incidence of 0.03% in adult and paediatric population (Ohyayon 2002; Partinen 2012). However, many adults with narcolepsy retrospectively admit to having...
had the condition since childhood: about 80% of individuals have their onset before 20 years of age and up to 30% before age 15, with the earliest recorded onset in a 9-month-old child (Peyron 2000). Two types of narcolepsy are currently recognised in the ICSD-3 (American Academy of Sleep Medicine 2014). Type 1 narcolepsy, based upon actual or presumed hypocretin deficiency, includes either cataplexy or a reduction in measured cerebrospinal fluid (CSF) hypocretin-1 levels. The deficit in hypocretin-1 (also called orexin) peptides released from the dorso-lateral hypothalamic neurons (Peyron et al. 2000; Thannickal et al. 2000) is probably secondary to an autoimmune destruction of hypocretin cells (Aran et al. 2009; Cvetkovic-Lopes et al. 2010). Type 2 narcolepsy is associated with normal CSF hypocretin-1 levels (if a lumbar puncture is performed) and based upon polysomnographic evidence, including a mean sleep latency shorter than or equal to 8 minutes plus at least two sleep onset rapid eye movement periods during multiple sleep latency tests and night polysomnography.

Ninety-eight per cent of narcolepsy–cataplexy patients belong to the human leukocyte antigen (HLA)-DR2 groups, especially DQB1-0602 (Kramer et al. 1987; Mignot 2001), although an extremely small number of patients exist that do not belong to these HLA groups (Confavreux et al. 1988). The gene(s) for narcolepsy may act through an autoimmune mechanism resulting in loss of orexin/hypocretin neurons when the patient is exposed to environmental stress such as infections or H1N1 vaccines (Orenalla 1994; Dauvilliers et al. 2007; Aran 2009; Hallmayer et al. 2009; Cvetkovic-Lopes 2010; Han 2011; Dauvilliers 2013). Indeed, there was a five-fold increase in incidence of narcolepsy in paediatric and adult population post H1N1 vaccination (Dauvilliers 2013). This relationship is present only in idiopathic cases and does not hold for narcolepsy due to acquired brain injury (Aldrich and Naylor 1989) that can rarely be observed with hypothalamic or with pontomedullary lesions (D’Cruz et al. 1994). Such lesions most commonly induce coma or permanent hypopersomnia or sleepiness and the typical tetrad of narcolepsy–cataplexy is rarely complete. Narcolepsy proper refers to the brief episodes of sleep that occur three to five times daily on average, with half the patients easy to awake during an attack and most children feeling unrefreshed afterwards, contrary to narcoleptic adults.

Cataplexy is defined as more than one episode of generally brief (<2 minutes), usually bilaterally, symmetrical sudden loss of muscle tone with retained consciousness (ICSD-3). The episodes are precipitated by strong emotions, usually positive, with almost all patients reporting some episodes precipitated by emotions associated with laughter. The finding of transient reversible loss of deep tendon reflexes during an attack, while rarely observed, is a strong diagnostic finding. In children (and rarely adults) cataplexy may present close to disease onset as facial (or generalised) hypotonia with droopy eyelids, mouth opening and protruded tongue or gait unsteadiness, which are not clearly related to emotion (Plazzi 2011). Facial and masticatory movements may occur. In children, anticipation of reward is a common precipitant.

Hypnagogic hallucinations and sleep paralysis are less common, respectively found in 40% and 30% of patients. The latter consists of generalised hypotonia with inability to move during the transition between sleep and wakefulness, with partial paralysis with inability to move any one body part more common and nocturnal insomnia, also a frequent complaint of narcoleptic patients. In young children day naps are often long (20–120 minutes) and often unrefreshing.

Episodes of amnestic automatism simulating epilepsy occur in 8% of patients (Aldrich 1990; Schenck and Mahowald 1992).

Sleep paralysis, cataplexy and hypnagogic hallucinations appear to reflect the fact that motor manifestations of REM sleep, whose immediate or rapid onset after falling asleep characterises narcolepsy, may also occur in slight chronologic dissociation from the behavioural component of sleep in narcoleptic individuals. Hypocretin is not only involved in sleep regulation but has also been implicated in a number of behaviour and neuroendocrine actions including modulation of feeding behaviour and energy balance (Baumann and Bassetti 2005). Accordingly, body weight or body mass index is frequently increased in patients with narcolepsy. Obesity has been reported in 30% of adults with narcolepsy (Schulz 2000) and is also a frequent coexisting feature in childhood narcolepsy. It may occur in at least 50% of all children with narcolepsy, especially the youngest ones (Inocente 2013) with increasing weight manifested relatively early in the course of the disease (Aran 2010). The high incidence of precocious puberty, obesity and central hypothyroidism in children could reflect broadly-based hypothalamic abnormalities (Poli 2013).

The course of narcolepsy is lifelong and often psychologically distressing (Inocente 2013, 2014). A good regimen of sleep is an essential component of therapy and includes a regular schedule of night sleep, the avoidance of long naps and provision of short periods of day rest. Treatment of narcolepsy with modafinil (Bastuji and Jouvet 1988) is effective to alleviate excessive daytime sleepiness. Methylphenidate and amphetamines may help some patients but their action is often transitory. Antidepressants such as the selective serotonin reuptake inhibitors (SSRI) or imipramine have a beneficial effect on cataplexy, with sodium oxybate acting as well on cataplexy frequency as on excessive daytime sleepiness and dyssomnia (Mamelak et al. 2001; Xyrem International Study Group 2005). New therapies such as the inverse agonist of the histamine H3 receptor appear promising (Dauvilliers 2013). Making the correct diagnosis (Stores 2006), offering simple reassurance that the disorder is not a psychiatric one, multidisciplinary follow-up and help with academics are of great importance. Isolated cataplexy has been reported with pontomedullary lesions (D’Cruz et al. 1994) in patients with Coffin–Lowry syndrome (Stephenson et al. 2005) and in patients with Niemann–Pick C disease and with Norrie syndrome (Chapter 17), in which it may account for the atonic episodes previously reported (Vossler et al. 1996).
OTHER SYNDROMES WITH HYPERSOMNIA

Hypersomnia is encountered in patients with sleep fragmentation, especially children with the obstructive sleep apnoea syndrome or the increased airway resistance syndrome: however sleep deprivation, especially in adolescents is probably the most common causes of diurnal hypersomnia, with depression and neurotic states frequent factors in adolescent patients.

Recurrent hypersomnia is occasionally caused by lesions of the third ventricle or brainstem such as tumours or sequelae of encephalitis, trauma or vascular accidents (Plazzi et al. 1996; Autret et al. 2001). It should also be kept in mind that hypersomnia could be a form of Munchausen by proxy by repetitive administration of sedatives.

KLEINE–LEVIN SYNDROME

Originally described in the 1930s, Kleine–Levin syndrome has received attention in paediatrics and child psychiatry only in recent years. It occurs mostly in adolescent boys (population prevalence unknown), and presents with the combination of intense hunger or specific craving for certain foods, increased need for sleep (somnolence and withdrawal or fugue-like states may be difficult to distinguish from each other) and a variety of emotional/behavioural/neuropsychiatric problems.

This symptom constellation appears abruptly and is present for a few days to a few weeks, whereafter symptoms subside. Weeks to months later a new episode occurs and follows a similar pattern, albeit quite often of more limited duration. New episodes can occur for a period of one to several years. Gradually, however, relapses tend to occur less often and the episodes become shorter and shorter.

Hypothalamic dysfunction may account for the symptomatology because: (1) the appetite and sleep symptoms implicate hypothalamic systems; (2) the syndrome occurs mostly during adolescence; (3) it affects mostly boys and the episodic nature could be seen as a counterpart to variable behaviour in connection with onset of menarche in girls; and (4) some EEG findings are compatible with hypothalamic dysfunction (Arnulf et al. 2015).

The work-up should include a neuropsychiatric assessment. If the history and symptoms are typical there is no need for further work-up but in case of doubt neurological and laboratory tests to exclude other neurological disorders and metabolic problems may be essential, while a urine and/or blood screen for narcotics and other drugs might also be appropriate for some patients. The EEG sometimes shows mild to moderate increase of low-frequency activity and there may be subtle signs of damage to the CSF blood–brain barrier.

Management need often consist only of assessment and a proper diagnosis. In severe cases affecting school attendance over long periods, a trial of stimulants might be indicated. In most cases, however, information given to the affected child/adolescent and to his/her parents and teachers will suffice.

Because of similarities between Kleine–Levin syndrome and certain mood disorders, lithium and carbamazepine may be prescribed. Responses to treatment have often been limited. This disorder needs to be differentiated from cyclic reoccurrence of sleepiness during the premenstrual period in adolescent girls that may be controlled with birth control pills.

Long-term outcome is good, although a year or two of school work may be wasted and most affected individuals do well by early adult life. The behaviour problems encountered are extremely variable and are often associated with some degree of somnolence and clouded consciousness.

All sorts of psychiatric diagnoses may be discussed before a correct diagnosis is established. These may range from depression or manic depression to schizophrenia and drug abuse. Encephalitis is commonly suspected if the family seeks help during the first episode. The episodic nature of the disorder might not be evident until three or more episodes have occurred. There is also commonly partial or total amnesia for the episodes.

INSOMNIA

Many young children, about 30% before the age of 5 years, have periods when they have difficulty going to sleep or staying asleep. It is usual when parents stay with the child until she or he falls asleep and this is a physiological event that should be managed with parents.

The phenomenon occurs less commonly in school-age children in whom it is often related to anxiety, especially based on school problems or emotional difficulties. Quality and quantity of sleep are negatively related to the hours spent in front of TV, computers, internet and mobile phones, while difficulties in getting to sleep are also common in children with attention-deficit–hyperactivity disorder (Chapter 30) and in children with learning difficulties.

Certain drugs such as phenobarbitone and lamotrigine are an often unrecognised cause of sleep disturbances in, toddlers or children with epilepsy while sometimes, a true depressive state is responsible. In a significant proportion of patients no cause is found and the prognosis is variable, with individuals affected in adolescence and adulthood.

In many children with neurodevelopmental disabilities such as autism spectrum disorders (Chapter 29), Angelman syndrome, Smith-Magenis syndrome (Chapter 5), severely involved cerebral palsy (Chapter 8) and blindness, the circadian rhythms are considerably disturbed, which often produces severe family life disruption. Melatonin may be a potent treatment for such individuals (Jan and Freeman 2004; Phillips and Appleton 2004).

For most patients no drug therapy is indicated. The use of hypnotics such as nitrazepam or chloral hydrate is rarely considered, when severe daily fatigue results from insomnia. Nocturnal awakening in young children, followed by resumption of sleep in the small hours of the morning, is a fairly common and benign behaviour that requires no more than reassurance. Seizures are a rare cause of insomnia responsible for excessive daytime somnolence. In some patients the seizures are limited to awakening associated with paroxysmal EEG bursts.

Radiological Findings in Basal Ganglia Disease
Basal Ganglia Diseases and Movement Disorders

Paddy Grattan-Smith, Russell C Dale and Emilio Fernandez-Alvarez

The basal ganglia form what Gowers and Wilson called the ‘dark basement of the brain’. Dysfunction of the basal ganglia classically results in abnormalities of movement, and this will be the main focus of this chapter. However, many disorders that involve the basal ganglia also affect other parts of the nervous system. For example, diseases that were once thought to be caused only by dysfunction of the basal ganglia, such as Parkinson disease and Huntington disease, have been found to have diffuse abnormalities not only in the brain, but also in the peripheral and autonomic nervous systems (Obeso et al. 2014).

Movement disorders have always interested neurologists, but the emergence of movement disorders as a subspecialty discipline in neurology is a recent development. The Movement Disorders Society was formed in 1985, and in 1986 the Movement Disorders Journal was first published. The first paediatric textbook devoted to Movement Disorders, by Emilio Fernández-Alvarez and Jean Aicardi, appeared in 2001. In previous editions of Diseases of the Nervous System in Childhood, movement disorders were not treated as a distinct topic, but appeared in multiple places in the text.

At the time of writing, advances in genetics are producing profound changes in the approach to children with movement disorders. Previously, diagnosis was almost entirely reliant on the clinical prowess of the examiner, and required an encyclopaedic knowledge of a vast but scattered literature. Now, genetics is giving us answers that are at times surprising, and not uncommonly humbling. One example is the finding that paroxysmal kinesigenic dyskinesia is caused by mutations in the proline rich transmembrane protein 2 gene (Wang et al. 2011), a totally unexpected outcome in a condition that had long been assumed to be a channelopathy. It has also become clear that different mutations in the same gene can produce very different clinical pictures (genetic pleiotropy). A short list of genes that have been recently found to exhibit pleiotropy includes PRRT2, ATP1A3, ADCY5, GCH1 and SCL2A1 (GLUT1). These will be covered in the discussion that follows. In contrast to pleiotropy is genetic heterogeneity, where multiple different genes can cause the same clinical picture.

A textbook cannot hope to provide the latest information on pathophysiology or genetics, and, although these will be discussed at times, the main focus of this chapter will be clinical. A difficulty with an overview of movement disorders in childhood is that, apart from tics and stereotypes, the underlying conditions are usually uncommon, and are often rare. As Professor Aicardi has in previous editions of this book, we will concentrate on selected important conditions, supplemented by Tables. The topics that are discussed in more detail are chosen because of their clinical relevance, their response to treatment, or because they cover a relatively new or poorly understood area. As an example, although Wilson disease is rare in childhood, its clinical features are described in detail, as it is a disease that shadows the diagnosis of virtually every movement disorder of childhood.

CLINICAL ASPECTS OF BASAL GANGLIA DISEASES

Given the rapid advances in both genetics and imaging it is possible that in the future, words such as dystonia and chorea will have the same relevance to clinicians as ‘whispering pectoriloquy’ and ‘aegophony’ have for today’s doctors. The child will simply be described as having a movement disorder (perhaps subdivided into hypo- or hyperkinetic), and sophisticated imaging and genetic studies will be used to make the diagnosis. This day is still some time away. Previous diagnostic advances, such as the arrival of computed tomography (CT) and then magnetic resonance imaging (MRI), were accompanied by suggestions that the physical examination of patients would become obsolete. This, of course, did not occur and we believe an understanding of the clinical features of the various movement disorders remains relevant.

As a general rule, movement disorders cease when the person goes to sleep. This includes even the extremely violent movements of hemiballismus. Paradoxically, the exception is tics which are in a sense the most ‘voluntary’ of movement...
disorders, yet can be seen in multiple different stages of sleep (Cohrs et al. 2001).

The first difficulty in the diagnosis of movement disorders is found in the words themselves. It is important not to lose sight of the limitations of the words we use, and not to be intimidated by them. In the movement disorder lexicon, there are only a small number of terms such as dystonia, myoclonus, chorea, tremor, stereotypy and tics. These are applied to an extraordinarily wide variety of complex movements. These words are of an antiquity, with chorea being with us since 1686 and ‘modern’ terms such as dystonia and myoclonus more than 100 years old. Over time, the way these terms have been used has varied. It is also common for more than one movement disorder to be seen in the same patient. Diagnosis remains essentially clinical, and relies on the careful observation of the child. Neurophysiological testing is often not helpful in providing a clear label for a particular movement (Singer et al. 2010). With complex cases, a decision has to be made as to what seems to be the dominant, or most relevant, movement disorder. It must be recognised that even among so called experts in the field of movement disorders, disagreement is common. Treatment is influenced by the diagnosis, and therefore an accurate diagnosis is important. However, at times the movements present a mixed and confusing picture, and it is better to acknowledge this, than to insist that a particular word be applied, in what is essentially a futile attempt at self-reassurance.

In 1981, Professor Brian Neville observed: ‘The vast number of described diseases of the nervous system in childhood should not be allowed to disguise the low diagnostic rate’ (Neville 1981). The rate of diagnosis has improved in the last 30 years, but to paraphrase Professor Neville, the vast number of causes of abnormal movements in childhood should not be allowed to disguise the lack of effective treatment for so many of these diseases. In the following sections we discuss treatments, but unfortunately for many conditions, these are depressingly limited.

**Figure 19.1** (a) Axial T2 image demonstrating the basal ganglia structures in a normal adult. (b) Axial T2 image in the same person at a higher level. The increased iron content in adults makes these structures more easily identified. (Courtesy of Professor Paul Griffiths, Sheffield, UK.)

**BASAL GANGLIA RADIOLOGY**

The basal ganglia are no longer a dark basement of the brain, but are easily seen on MRI. It is important to have a good understanding of the MRI anatomy of the basal ganglia, as distinctive patterns of involvement can be very helpful in making a diagnosis. When describing MRI findings, rather than using terms such as ‘striatum’ and ‘lentiform nuclei’, which were coined before there was any real understanding of how the basal ganglia function, we feel it is preferable to name the individual structures involved. Detailed reviews of the anatomy of the basal ganglia are found in standard neuroanatomy texts. There have also been multiple articles dealing with the radiological anatomy and patterns of disease involvement in basal ganglia disorders (Anderson et al. 2004; Hathout 2009; Hegde et al. 2011; Bekiesinska-Figatowska et al. 2013). The following is a brief overview (Fig. 19.1).

The caudate nucleus (from cauda, Latin for tail) is medial to the internal capsule. It is a tadpole-like structure, and the caudate head is easily seen on MRI as it protrudes into the frontal horn of the lateral ventricle. With caudate atrophy the frontal horns appear dilated. The tapering body of the caudate is on the floor of the body of the ventricle, and the narrow tail follows the curve of the inferior horn. The putamen is located lateral to the internal capsule, just medial to the external capsule. The caudate and putamen share a common embryological origin, and are identical histologically. Small strands of grey matter cross the internal capsule, connecting the caudate and putamen. Anteriorly, the head of the caudate and anterior edge of the putamen fuse, forming the nucleus accumbens.

The globus pallidus is embryologically and histologically distinct from the caudate and putamen. It is located medial to the putamen, with the two separated by a thin band of myelinated fibres called the lateral medullary lamina. The globus pallidus lies lateral to the internal capsule. The globus pallidus is divided into a larger external, and a smaller internal...
The basal ganglia circuitry is complex and for a more detailed description, there are many reviews (Mink 1996; DeLong and Wichmann 2007; Nambu 2008; Haynes and Haber 2013). The following is an over-simplification that may help the reader in beginning to understand how the basal ganglia are thought to work.

Basal ganglia circuitry basically consists of multiple parallel loops, travelling from the cortex to the basal ganglia, then on to the thalamus, before returning to the cortex (Alexander et al. 1986). Overall, the function of the motor loops of the basal ganglia is to enable movement but not to initiate it. The basal ganglia act by selecting a desired motor programme, and inhibiting other potentially interfering programs (Hwang 2013.) Input to the basal ganglia is from the cortex to the caudate, putamen, and the STN. Output is via the globus pallidus interna and the substantia nigra pars reticulata (usually taken together and referred to as GPi/SNr). The output is to the thalamus, and from there to the cortex. The basal ganglia output is a tonic inhibitory output. A reduction in this inhibition allows movement to take place via ‘released’ thalamocortical projections. (There are also projections from the GPi/SNr to the pedunculopontine nucleus and superior colliculi but these will not be discussed here.)

There appear to be three main pathways involved in the basal ganglia control of movement. [The hyperdirect pathway has mainly been studied in primates (Nambu et al. 2002). It is included here as there is frequent reference to it in the literature.]

- **The hyperdirect pathway:**
  - cortex → STN → GPi/SNr → thalamus → cortex

- **The direct pathway:**
  - cortex → striatum → GPi/SNr → thalamus → cortex

- **The indirect pathway:**
  - cortex → striatum → globus pallidus externa → STN → GPi/SNr → thalamus → cortex

Stimulation of the direct pathway reduces inhibition of the thalamus, and allows movement. The other pathways increase or maintain inhibition of the thalamus, and restrict movement. Dopamine produced from the substantia nigra pars compacta and ventral tegmental area, modulates these pathways. An intricate co-ordination of these various components results in the production of a precise, selected movement.

There are multiple non-motor basal ganglia circuits. These are involved in human reasoning and adaptive function, the control of reward-based learning, and cognitive and emotional processes (Leisman et al. 2014). Therefore, it is not surprising that diseases of the basal ganglia can produce not only movement disorders, but psychiatric problems, such as obsessive–compulsive disorder and depression.

There is increasing interest in reciprocal pathways between the basal ganglia and the cerebellum. In primates there is a direct projection from the dentate nucleus to the dorsolateral putamen via the thalamus. The STN also connects to the cerebellum via the pontine nuclei. (For a review, see Kishore and Popa 2014.)
NEW CLASSIFICATION SCHEMES

The recent advances in genetics have resulted in a number of new classification schemes for movement disorders. The suggested new scheme for dystonia is discussed in the text. At the time of completion of this chapter, a paper suggesting a new nomenclature for genetic movement disorders was published (Marras et al. 2016). There appears to be much merit in this, but at times it is complex. For example, the condition that was once called neuroaxonal dystrophy, and then after the discovery of the gene, PLAN (PLA2G6-associated Neurodegeneration), under this new scheme would be called NBIA/DYT/PARK-PLA2G6. To avoid potential confusion and the reader having to make frequent reference to this new paper, we have retained the ‘old’ terminology, realising that it may well be replaced by this new scheme in the next few years.

DYSTONIA

There has been a recent change in the definition of dystonia. It is now defined as ‘a movement disorder characterised by sustained or intermittent muscle contractions causing abnormal, often repetitive, movements, postures, or both. Dystonic movements are typically patterned and twisting, and may be tremulous. Dystonia is often initiated or worsened by voluntary action and associated with overflow muscle activation’ (Albanese et al. 2013).

More than in any other movement disorder there can be confusion over the diagnosis of dystonia. Twisting of the limbs or trunk is the key clinical feature. The term torsion-spasm suggested by Flatau and Sterling in 1911 (Albanese et al. 2013), and subsequently employed by Wilson, nicely conveys the sense of sustained twisting of the body that separates dystonia from other movement disorders. However, what may not be appreciated, is that both children and adults with dystonia often also have fast movements. There may be repetitive jerking resembling a tremor, or isolated twitches that look like myoclonus.

Apart from the co-existence of sustained twisting movements and rapid jerking, there are many other traps in the diagnosis of dystonia. The term was coined by Oppenheim in 1911 to indicate that hypotonia and hypertonia can co-exist. At rest the child with dystonia may have arms that feel floppy to the examiner, but as soon as the child makes an attempt to reach for an object, the tone increases and the arm twists due to excessive co-contraction of agonist and antagonist muscles. The arm may then be jerked away from the target, or may twist in the opposite direction to what was intended.

In progressive generalised dystonia, over time the limbs generally develop increased tone at rest. Classically, the increased tone of dystonia is present throughout the range of movement, and is there when the arms are moved quickly or slowly (Sanger et al. 2003). There is considerable overlap between hypertonia due to dystonia, and rigidity, which is most commonly seen in adults with Parkinson disease, and where the term ‘lead-pipe’ rigidity is often used. In contrast, the characteristic feature of spasticity is that the increase in tone is velocity-dependent. An arm may be able to be moved slowly through a relatively wide range of motion, but with rapid movement there is a sudden increase in tone and the arm ‘catches’, suddenly resisting the movement. Dystonia and spasticity often co-exist, and this separation is not always easy in practice. Dystonia typically disappears during deep sleep. However, with severe and prolonged disease, contractures can develop which will persist in sleep.

A characteristic sign of dystonia in adults is the ‘geste antagonistique’ where touching a part of the body may reduce the intensity of the dystonia. For example, touching the side of the head may improve torticollis. Gestes are not commonly recognised in childhood. The term overflow refers to unintentional muscle contraction which occurs at the same time as the dystonic movement, but is anatomically distinct from it.

In dystonia there is usually an inability to suppress unwanted motor activity, resulting in excessive co-contraction of opposing muscle groups. This typically involves the same group of muscles, and so it appears in a specific distribution. The dystonic movements thus have a pattern. The term dystonic posturing is commonly used in descriptions of dystonia. Dystonic posturing can be defined as abnormal positions of the trunk or limbs, that result from the sustained co-contraction of opposing muscles. Dystonic postures are usually maintained for minutes or hours, but at times can be brought out by specific manoeuvres such as asking the patient to hold their arms up in front of them. The arms and fingers then twist. A common dystonic posture is an arm twisting up behind the back when walking. Dystonia can be mistaken for a psychogenic disorder, and the arm twisting behind the back while walking is a useful sign, as it is common in dystonia, but rare in psychogenic disorders. There are many other unusual postures that can occur in dystonia, such as the so called ‘flamingo’ stance, where the person is only able to stand on one leg, with the other flexed up against the trunk. These at times bizarre postures may also be mistakenly interpreted as psychogenic in origin.

It is important not to overuse the term dystonic posturing as similar postures can be seen in peripheral neuropathies and joint disease. In dystonia and other movement disorders such as chorea, children may hold themselves in a particular way that they have found reduces the severity of the movement.
disorder. So an apparent abnormality of posture may, in fact, be a position that the child has found allows better motor function.

There are certain specific dystonic syndromes that suggest the underlying cause. Severe oromandibular dystonia, especially with tongue biting is seen in neurodegeneration with brain iron accumulation syndromes (NBIA s), and Lesch–Nyhan syndrome (discussed below). In young adults, neuroacanthocytosis and neuroleptic drug-induced dystonia are also causes. Action-induced dystonic opisthotonus, in which the trunk tends to arch backwards when the patient stands, and occasionally even when lying down and attempting to move, is also a feature that may be seen in the NBIA s (Stamelou et al. 2013). An inability to produce words or sounds is associated with a relatively small number of dystonic syndromes (Ganos et al. 2016) – see Table 19.5. The pathophysiology of dystonia is uncertain. Traditionally associated with abnormalities of the basal ganglia, it may be better seen as a network disorder involving multiple regions. There is currently considerable interest in the role of the cerebellum in the development of dystonia (Prudente et al. 2014).

**CLASSIFICATION OF DYSTONIA**

As well as suggesting a new definition of dystonia, Albanese et al. (2013) also suggested a new classification scheme. The diagnosis of dystonia can now be divided into two main axes: (1) the clinical features and (2) aetiology.

**Clinical Features of Dystonia**

The clinical features of dystonia can be approached in five different ways.

1. The first is the age at onset: infancy (birth to 2 years); childhood (3–12 years); adolescence (13–20 years); early adulthood (21–40 years); and late adulthood (>40 years).

2. Dystonia can also be classified according to its distribution. Discrete body regions involved by dystonia can be subdivided into: (a) the upper or lower cranial region, (b) the cervical region, (c) the larynx, (d) the trunk, (e) the upper limbs, and (f) the lower limbs. In focal dystonia, only one body region is affected. A typical example is blepharospasm. In segmental dystonia, two or more contiguous body regions are involved. An example is blepharospasm combined with dystonia of the lower face and jaw or tongue. In multifocal dystonia, two noncontiguous or more (contiguous or not) body regions are involved. In generalised dystonia, the trunk and at least two other sites are involved. Generalised forms with leg involvement are distinguished from those without leg involvement. A typical example of hemidystonia is a person with arm and leg dystonia on the same side of the body following a destructive lesion to the contralateral basal ganglia.

3. The third component is the temporal pattern, that is, whether the disease course is static or progressive, and whether there is variability in the symptoms such as diurnal variation. Albanese et al. (2013) make a distinction between paroxysmal dystonia which typically continues after the trigger has ended, and action dystonia which is no longer evident after the inducing action has been completed. For example, with paroxysmal kinesigenic dyskinesia, sudden movement provokes an episode of dyskinesia which can continue for 20 seconds, at a time when the child is no longer moving forward.

4. The fourth component is whether the dystonia is isolated or combined with another movement disorder such as myoclonus or parkinsonism. (If there is tremor, it is still considered to be an isolated dystonia.)

5. The fifth component is whether there are other neurological or systemic manifestations.

In this scheme rather than the potentially confusing term ‘primary dystonia’ used previously, ‘isolated dystonia’ is preferred. The terms ‘dystonia plus’ and ‘heredodegenerative dystonias’ have been replaced by ‘combined dystonia’.

**Aetiology of Dystonia**

The second axis is aetiology. There are two main components: (1) the presence of nervous system pathology and (2) whether the condition is inherited, acquired or idiopathic. This part of the classification is more easily visualised in a Table (see Table 19.1). As always with movement disorders, words can be a problem. Those accustomed to a division into *congenital* meaning present at birth, versus *acquired* meaning occurring later, have to accept that acquired here effectively means a non-genetic disorder. A child who has an intrauterine stroke causing dystonia will have an acquired disorder. A condition that is idiopathic can be sporadic or familial, but if a causative gene is found, it will then be reclassified.

**GENETIC DYSTONIAS WITH ONSET IN CHILDHOOD**

A relatively small number of genetic dystonias have so far been identified. Table 19.2 lists the well-established genetic dystonias of childhood. There are multiple reviews of the genetics of dystonia (e.g. Klein 2014; Balint and Bhatia 2015; van Egmond et al. 2015; Marras et al. 2016) and the topic will be covered only briefly.

**DYT1** is the form of dystonia first described by Oppenheim in 1911 (Klein and Fahn 2013). Almost all cases are caused by a GAG deletion in the coding region of the *TORIA* gene (Ozelius et al. 1997). It accounts for 80–90% of cases of generalised dystonia among the Ashkenazi Jewish population, but also occurs in people who are not Jewish. It is dominantly inherited, but with reduced penetrance. Only around 30% of those who carry the gene develop symptoms.
The clinical phenotype is variable. Some members of a family who carry the gene can be asymptomatic, whereas others are so severely affected that they develop status dystonicus (Opal et al. 2002). Onset of symptoms is commonly between 5 and 15 years, but onset as late as 64 years has been reported (Opal et al. 2002). In the younger child, the first sign is often inversion of the foot with plantar flexion when walking. Older children may present with arm involvement, and have difficulty writing, or specific manual tasks. The symptoms may fluctuate and worsen with stress or anxiety, resulting in an initial suspicion of a psychogenic disorder. The dystonia usually generalises and can become very severe. Lordosis and trunk twisting are common. Intelligence is preserved. Prior to the development of the surgical techniques of pallidotomy and deep brain stimulation (DBS) of the GPI, many affected individuals become wheelchair dependent or bedridden, and were left with horrible distortions of the body. Life threatening episodes of status dystonicus can also occur in patients with DYT1 dystonia (Allen et al. 2014).

Heiman et al. (2004) found that both manifesting and non-manifesting carriers of the DYT1 mutation had an increased risk of an early-onset, recurrent, major depressive disorder, suggesting that depression is another clinical expression of the gene mutation.

**DYT2** A consanguineous family has been described with generalised dystonia most prominent in the upper half of the body and presenting in the first decade of life. Inheritance was autosomal recessive and the patients were found to have mutations in the HPCA gene (Charlesworth et al. 2015).

**DYT4** Mutations in TUBB4 have been found in an Australian family with 'whispering dysphonia' (Lohmann et al. 2013). In addition, TUBB4 mutations have also been found to be responsible for the condition Hypomyelination with Atrophy of the Basal Ganglia and Cerebellum (HABC) where dystonia can be a very prominent and disabling feature (Simons et al. 2013) (Fig. 19.11). In some patients, the MRI appearance of HABC is virtually diagnostic, with hypomyelination, cerebellar atrophy and progressive loss of the putamen over time. However, this combination of radiological signs is not seen in all patients. In older individuals with HABC, there may be complete loss of speech (Ganos et al. 2016).

**DYT5a and DYT5b** Before the underlying genetic abnormalities were identified, the terms ‘dopa-responsive dystonia’ or ‘Segawa syndrome’ were used to describe children with
dystonia who had a dramatic and sustained response to L-dopa. The most common cause of DRD is a dominant mutation in the enzyme GTP cyclohydrolase1 (GCH1), which catalyses the first step in perin synthesis (Ichinose et al. 1994). Rarely, recessive mutations in the tyrosine hydroxylase (TH) gene are responsible (Ludecke et al. 1995). (Inborn errors of dopamine metabolism, and other dopa-responsive disorders are covered in detail in the Parkinsonism section of this chapter.)

In classic Segawa syndrome, the child presents in the first decade of life with dystonia that shows diurnal variation (Segawa et al. 1976). After an overnight sleep or a daytime nap, the child seems normal but within an hour or so dystonia appears, and continues to increase during the day. (A perhaps apocryphal description of this condition is that the child can walk to school, but has to come home in a wheelchair.) The dystonia typically affects the legs, and onset is usually around 6 years of age. There is a strong female predominance. Symptoms are reversed by L-dopa therapy usually in relatively low doses. With Segawa syndrome, even if the diagnosis is delayed by more than 40 years, there can be a good response to treatment (Harwood et al. 1994).

Not all children with GCH1 deficiency have the typical clinical picture. There may be no diurnal variation. Usually the reflexes are brisk, and the Babinski sign may appear positive. As a result the child may be mislabelled as having ‘cerebral palsy’ (CP) (Boyd and Patterson 1989; Fletcher et al. 1993). Tremor can predominate, and the presentation may be with exercise-induced dystonia (Dale et al. 2010). There is a report of a 17-year-old boy with with GCH1 deficiency presenting as a myoclonus-dystonia syndrome (Leuzzi et al. 2002). When the onset of the disease is in adulthood, presentation of GCH1 deficiency includes writer’s cramp, torticollis and postural tremor (Segawa 2011). Recessive forms of GCH1 deficiency can present in infancy with a dystonia/parkinsonism syndrome (Furukawa et al. 1998; Nardocci et al. 2003).

**DYT6** is caused by mutations in mutations in the THAP domain containing 1 (THAP 1) gene. It is inherited as an autosomal dominant condition with penetrance of around 40%. The clinical presentation can overlap with DYT1 dystonia, but the onset is usually later. In addition, in contrast to DYT1 dystonia, there is frequent involvement of the cranial muscles with speech commonly affected by oromandibular dystonia or laryngeal dystonia (Segawa et al. 2011). Recessive forms of GCH1 deficiency can present in infancy with a dystonia/parkinsonism syndrome (Segawa et al. 2011). Recessive forms of GCH1 deficiency can present in infancy with a dystonia/parkinsonism syndrome (Segawa et al. 2011).

**DYT6** is caused by mutations in the THAP domain containing 1 (THAP 1) gene. It is inherited as an autosomal dominant condition with penetrance of around 40%. The clinical presentation can overlap with DYT1 dystonia, but the onset is usually later. In addition, in contrast to DYT1 dystonia, there is frequent involvement of the cranial muscles with speech commonly affected by oromandibular dystonia or laryngeal dystonia (Segawa et al. 2011). Recessive forms of GCH1 deficiency can present in infancy with a dystonia/parkinsonism syndrome (Segawa et al. 2011). Recessive forms of GCH1 deficiency can present in infancy with a dystonia/parkinsonism syndrome (Segawa et al. 2011).

**DYT11 – Myoclonus Dystonia** is a dominant condition where myoclonus and dystonia co-exist. It is mainly due to mutations in the epsilon sarcoglycan (SGCE) gene. With SGCE mutations, genetic imprinting reduces the penetrance when the gene is inherited from the mother. Myoclonus is often the earliest feature and may remain the only manifestation. The myoclonus typically involves the upper limbs, with at times quite violent shock-like jerks that may be action-induced. It appears to be a subcortical form of myoclonus. Dystonia is often mild. In younger children, leg dystonia may be prominent and transient (Kyllerman et al. 1993), whereas in adults, the upper body is more involved. The jerks may be reduced by alcohol ingestion. Depression, obsessive–compulsive symptoms, anxiety and panic attacks may be prominent (Peall et al. 2013). Large deletions involving SGCE and the contiguous COL1A2 gene cause, in addition, associated skeletal problems and osteoporosis (Asmus et al. 2007a). Zonisamide may have an important role in the treatment of myoclonus dystonia reducing both myoclonus and dystonia (Hainque et al. 2016).

There have been reports of families with the myoclonus dystonia phenotype due to mutations in (*KCTD17*) (Mencacci et al. 2015a) and *CACNA1B* (Groen et al. 2015). Some members of the family with the *CACNA1B* mutations had addition problems not usually seen in myoclonus dystonia, including unsteadiness while standing due to high-frequency continuous myoclonus in the legs, cardiac arrhythmias, and episodes of painful cramps in upper and lower limbs.

**DYT12** also known as rapid onset dystonia-parkinsonism (RODP) is caused by a mutation in the *ATP1A3* gene (de Carvalho Aguiar et al. 2004). Typically in adolescence there is a rapid onset of dystonia and parkinsonism which appear over hours or weeks. The onset often appears to be provoked by emotional or physical distress, and the disability is permanent. Again there is craniofacial involvement with oromandibular dystonia, facial involvement and dysphagia, and at times typical parkinsonian features (Brashear et al. 2007). There is usually minimal or no tremor at onset. With RODP once the symptoms have been present for around a month, there is usually no further deterioration. except for rare ‘second onsets’, or abrupt worsening of symptoms later in life (Brashear et al. 2007). The parkinsonism does not respond to L-dopa. When the onset of symptoms is over several weeks and follows an emotional trauma, children in the 10–14-year age range with ATP1A3 mutations, are at risk of being diagnosed as having a psychogenic problem, as signs such as a geste may be misinterpreted.

Brashear et al. (2012) reported a child with an ATP1A3 mutation who presented at 9 months of age with fluctuating episodes of hypotonia and ataxia, followed by the development of oromandibular dystonia. There are other disorders that have been found to be associated with ATP1A3 gene mutations including alternating hemiplegia of childhood (Heinzen et al. 2012), and CAPOS syndrome (cerebellar ataxia, areflexia, pes cavus, optic atrophy and sensorineural hearing loss) (Demos et al. 2014). Mutations in ATP1A3 have also been found in a child who developed seizures 4 hours after birth and went on to have an intractable seizure disorder with episodes of status epilepticus, and another child with seizures beginning from 6 weeks followed by recurrent episodes of prolonged apnoea required tracheostomy (Paciorkowski et al. 2015). Also reported in association with ATP1A3 mutations are children with presentations intermediate between alternating hemiplegia of childhood and RODP, including the
presence of dopa-responsive oculogyric crises (Termsarasab et al. 2015). Adult patients with an \textit{ATPIA3} mutation may have a relapsing encephalopathy characterised by recurrent episodes of cerebellar ataxia and altered consciousness during febrile illnesses (Dard et al. 2015). With presentations from the neonatal period to adult life, and multiple different clinical scenarios, \textit{ATPIA3} mutations illustrate how much genetic advances have overturned previous concepts, in particular the ‘one gene, one phenotype’ hypothesis.

\textbf{DYT16} is caused by mutations in the gene \textit{PRKRA} and has autosomal recessive inheritance (Camargos et al. 2008). There is generalised, early-onset dystonia with axial muscle involvement, oromandibular and laryngeal dystonia and, in some cases, parkinsonian features that do not respond to L-dopa therapy. The initial report was in 2008, describing two unrelated Brazilian families. Subsequently a child was described who had an early, acute presentation with hypotonia, bradykinesia, pyramidal signs, and developmental regression associated with a febrile illness (Lemmon et al. 2013). At 18 months of age, he was noted to have limb dystonia, and a progressive dystonia followed with involvement of the trunk, oromandibular and limb regions and limbs. There was a transient response to biotin. MRI showed progressive loss of the caudate, putamen and globus palidus. There was also white matter loss. Further reports of Polish (Zech et al. 2014) and Brazilian families (de Carvalho Aguiar et al. 2015) have confirmed that \textit{PRKRA} mutations are pathogenic and can also cause isolated dystonia.

\textbf{DYT24} is caused by \textit{ANO3} mutations. The age at onset can vary from early childhood to the forties (Stamelou et al. 2014). Cervical and laryngeal dystonia are the usual presenting features. The presentation is similar to DYT6, except that in DYT24, tremor is frequently seen. At times tremor can be the sole initial manifestation, leading to a misdiagnosis of essential tremor.

\textbf{DYT25} caused by \textit{GNAL} mutations, is another cause of cervical and oromandibular dystonia where onset can be in childhood (Fuchs et al. 2013). Loss of the sense of smell may be a clue to the diagnosis (Balint and Bhatia 2015).

\textbf{DYT27} is caused by mutations in the \textit{a3} (VI) collagen gene \textit{COL6A3} (Jochim et al. 2016). It is the third form of dystonia showing recessive inheritance. Clinical features include tremulous cervical, oromandibular, laryngeal, upper limb and trunk dystonia. Only a few patients have been described but one developed writer’s cramp at the age of 6 years (Jochim et al. 2016).

At the time of writing the condition had not yet been allocated a DYT ‘number’, but Meyer et al. (2017) have described 27 patients with a childhood-onset dystonia due to mutations in the histone methyltransferase gene, \textit{KMT2B}. The median age at onset was 4 years, with most patients having lower limb dystonia at onset. With increasing age, the dystonia generalised with cervical, facial, and oromandibular dystonia producing dysarthria or anarthria (see also Table 19.5), and difficulties in chewing and swallowing. Severe dysphonia could also develop. Dysmorphic features were seen, including a characteristic elongated face and bulbous nasal tip. Subtle, symmetrical abnormalities of the globus pallidi were noted on MRI. Ten patients showed a good response to bilateral DBS of the GPi. There seems little doubt that over the next 10 years, as next generation sequencing becomes widely available, many new dystonia genes will be found.

In terms of the recent classification, DYT1 and DYT6 are considered isolated dystonias, whereas DYT5, DYT11 and DYT12 are combined dystonias (Klein 2014).

The paroxysmal dystonias DYT8 and DYT10, are discussed in Chapter 16.

\section*{NEURODEGENERATION WITH BRAIN IRON ACCUMULATION}

The term neurodegeneration with brain iron accumulation (NBIA) is used for a group of conditions characterised by movement disorders, progressive neurodegeneration and iron accumulation in the basal ganglia (Hogarth 2015). Dystonia is commonly seen, and therefore these disorders are discussed in the Dystonia section of the chapter. However, spasticity is also a common finding in this group of disorders. Other features include parkinsonism and intellectual decline. On MRI there is usually a symmetrical increase in iron content in those grey matter nuclei that normally contain more iron than other parts of the brain. These include the globus pallidus, substantia nigra, red nucleus, dentate nucleus, putamen and thalamus. Areas rich in iron are hypointense on T2-weighted sequences, and isointense on T1 sequences. T2*-weighted acquisitions such as gradient-echo sequences may accentuate this degree of hypointensity, and may be helpful in identifying NBIA disorders, as may susceptibility-weighted images. Iron typically appears markedly hypointense on both standard diffusion-weighted and apparent diffusion coefficient sequences (Krueger et al. 2012). In NBIA s, the changes are usually symmetrical. When the MRI is performed using magnets of increased strength such as 3T and beyond, it is important to remember that normal iron containing structures will appear more prominent than in scans where magnets of lesser strength were used.

Most of the major NBIA subtypes of childhood are autosomal recessive disorders, except beta propeller associated neurodegeneration (BPAN), which shows an X-linked pattern of inheritance.

\section*{PANTOTHENATE KINASE-ASSOCIATED NEURODEGENERATION}

Pantothenate kinase-associated neurodegeneration (PKAN) is the most frequently encountered form of NBIA, but is
Chapter 19 Basal Ganglia Diseases and Movement Disorders

PLA2G6-ASSOCIATED NEURODEGENERATION

PLA2G6-Associated Neurodegeneration (PLAN: NAD: PARK14) is caused by mutations in the gene encoding calcium-independent phospholipase A2 (PLA2G6) (Figs 19.6a and 19.6b). The disease can present as classic infantile neuroaxonal dystrophy (INAD), atypical NAD, and PLA2G6-related dystonia-parkinsonism (Kurian and Hayflick 2013). INAD presents around the age of 14–18 months, and the child is never able to walk independently (Adams and Lyon 1982a). There is developmental arrest, then regression of language and motor skills. Affected children typically show a combination of upper and lower motor neurone signs, with the reflexes then being lost. There may be profound hypotonus and marked leg wasting. Optic atrophy leads to blindness, and dementia is usually relentlessly progressive. Seizures sometimes occur. On electroencephalogram (EEG) there may be prominent fast activity. Dystonia tends to be milder than in PKAN. Atypical NAD may present more with ataxia than spasticity, and the phenotype is not as severe as the infantile form. The adult form of PLAN presents with dystonia-parkinsonism and spasticity, along with cognitive and psychiatric features (Paisan-Ruiz et al. 2009). There may initially be a good response to L-dopa followed by disabling dyskinesias.

Cerebellar atrophy is the most common neuroimaging finding in both INAD and atypical NAD. It is present in most patients even early in disease, and in almost all well-established INAD cases (Hogarth 2015). Iron accumulation may not be seen on MRI in young onset cases. In later onset cases, the substantia nigra may be more heavily involved than the globus pallidus.

FATTY ACID HYDROXYLASE-ASSOCIATED NEURODEGENERATION

Fatty acid hydroxylase-associated neurodegeneration (FAHN) is caused by mutations in FA2H (Kruer et al. 2010). It has clinical similarities to NAD. The first signs are usually focal dystonia and gait impairment. Other features include ataxia, progressive spastic quadriparesis, and optic atrophy. Intellect may be relatively spared. Neuroimaging features of FAHN include increased iron in the globus pallidus and substantia nigra, but this is not always present. There may be confluent subcortical and periventricular white matter T2 hyper-intensities, along with thinning of the corpus callosum. Cerebellar and brain stem atrophy are progressive and severe (Hogarth 2015).

MITOCHONDRIAL MEMBRANE PROTEIN ASSOCIATED NEURODEGENERATION

Mitochondrial membrane protein associated neurodegeneration (MPAN) is caused by mutations in an open-reading frame on chromosome 19 (C19orf12) (Hogarth et al. 2013).

Rare, with an estimated prevalence of 1:1 million (Hayflick et al. 2006). It is caused by mutations in the HANK2 gene (Zhou et al. 2001). This gene encodes pantothenate kinase 2, which is involved in the first key regulatory step of coenzyme A biosynthesis, and is thus essential for intermediary and fatty acid metabolism. In 75% of cases of PKAN, the presentation is with the classic early-onset form beginning in infancy. The child has slow development, often with bilateral pyramidal tract signs, and may initially appear to have CP. A phase of regression follows between 5 and 10 years of age, with decline of motor and language abilities, and lower limb dystonia which may be asymmetrical. Cognitive deterioration is variable. The regression often has a step-like pattern, with loss of skills followed by a stable period, followed by another period of deterioration. As the disease progresses status dystonicus is a common problem. There may be a pigmentary retinopathy and other eye signs (Egan et al. 2005), and acanthocytes may be present in the blood film. The diagnosis is usually suggested on the basis of the typical MRI findings, and then confirmed by genetic testing.

With the less common juvenile form of PKAN, the initial diagnosis may be of a psychiatric disorder, as prominent early features can include hyperactivity, impulsivity, obsessive compulsive disorder, and vocal and motor tics, as well as depression and anxiety. A typical example is the patient described by Scarano et al. (2002) who began to stutter at the age of 10 years. At 17 years he developed an unsteady gait with frequent falls. Motor tics, repetitive movements, compulsive behaviour, and vocalisations appeared following the over the following 12 months, together with increasing hyperactivity and impulsiveness. There was also slowly progressive cognitive impairment. The diagnosis was made when an MRI scan revealed the typical ‘eye of the tiger’ sign (Scarano et al. 2002).

As discussed above, in PKAN oromandibular dystonia with tongue mutilation, and an action-induced dystonic opisthotonus can be particularly troublesome. Parkinsonism and other movement disorders such as choreoathetosis may also be seen.

The typical MRI finding in PKAN is the so-called ‘eye of the tiger’ sign. This is seen on T2-weighted sequences. The globus pallidus is hypointense with an anteromedially placed region of hyperintensity representing the ‘eye’. Pathologically, an area of neuronal depletion and tissue rarefaction corresponds to the area of bright signal. Relatively early in the course of the illness, there may only be hypointensity of the globus pallidus with no eye of the tiger sign seen, and a mitochondrial disorder, or some other metabolic problem may be suspected. Conversely, the ‘eye of the tiger’ sign has been found in pre-symptomatic, mutation-positive children, identified after a sibling has been diagnosed with PKAN (Hayflick et al. 2001). There are also eye of the tiger ‘mimics’ including membrane protein associated neurodegeneration (MPAN), COASY protein-associated neurodegeneration (CoPAN), carbon monoxide poisoning survivors, multiple system atrophy and neuroferritinopathy (Hogarth 2015). Therefore, some caution is needed in interpreting this sign.
MPAN usually manifests as a juvenile-onset, slowly progressive disorder with predominant lower limb spasticity and cognitive impairment. Dystonia may be limited to the hands and feet (Hogarth 2015). The mean age at onset is around 10 years. Typical additional features include axonal motor neuropathy, which is a distinctive feature of MPAN (Schottmann et al. 2014), and optic atrophy. In adults the disease may be rapidly progressive (Dogu et al. 2013). MPAN is also reported to cause a parkinsonism-pyramidal syndrome (Krueer et al. 2014).

MRI in MPAN shows iron deposition in the globus pallidus and substantia nigra. In some cases, hyperintense streaking of the medial medullary lamina is seen and may discriminate MPAN from other NBIA subtypes (Hartig et al. 2013). (The medial medullary lamina separates the internal and external segments of the globus pallidus.)

KUFOR-RAKEB SYNDROME

Kufor-Rakeb syndrome (KRS) (PARK 9) is caused by mutations in the ATP13A2 gene. In the initial report, typical features included parkinsonism, pyramidal signs, a supranuclear palsy with upgaze paresis, and dementia (Nisipeanu et al. 1994). There was a rapid progression to a bedridden state within 12 months. Rest tremor was absent. Bradykinesia and rigidity were exquisitely sensitive to levodopa, but it had no effect on the pyramidal signs. At subsequent review of the family, it became clear that L-dopa therapy was limited by the development of dyskinesia. Other clinical features that have been noted included mini-myoclonus involving the face, tongue and fingers, visual hallucinations, and oculogyric crises (Williams et al. 2005; Behrens et al. 2010.) Aggression and episodes of psychosis, including frank hallucinations, may occur. MRI show generalised cerebral, cerebellar and brain stem atrophy, along with progressive atrophy of the pyramids. There may also be iron deposition in the globus pallidus, caudate and putamen.

BETA PROPELLER ASSOCIATED NEURODEGENERATION

BPAN was initially called static encephalopathy of childhood with neurodegeneration in adulthood (SENDA), a name that clearly evokes the clinical course. The disease is caused by mutations in WDR45 located on the X chromosome, which encode for a beta propeller protein that has a presumed critical function in autophagy (Haack et al. 2012). Being X-linked dominant, in theory it should be lethal in males, but there are reported male cases and the genetics must be complex (Hogarth 2015). BPAN begins with early childhood intellectual impairment which can be severe. Common early comorbidities include seizures, spasticity and disordered sleep. The course is then static, sometimes for decades. In adulthood, severe dystonia and parkinsonism develop. As with PLAN and Kufor-Rakeb syndrome, L-dopa treatment may initially improve the parkinsonism, but disabling dyskinesias rapidly develop, and it has to be discontinued.

On brain MRI, with T2-weighted sequences the substantia nigra and globus pallidus are hypointense consistent with iron deposition. In the substantia nigra, a linear streak is seen. On T1 sequences, this same area of the substantia nigra is surrounded by a hyperintense ‘halo’ extending to the cerebral peduncles, thought to represent neuromelanin release from degenerating neurons (Krueer et al. 2012). Significant cerebral and milder cerebellar atrophy are also seen. Basal ganglia calcification has been reported with BPAN (Van Goethem et al. 2014).

COASY PROTEIN-ASSOCIATED NEURODEGENERATION

COPAN is caused by mutations in the coenzyme A synthase gene (COASY) and is in the same metabolic pathway as the defect in PKAN (Dusi et al. 2014). Only a small number of cases have been described, but a pattern typical of the NBIA, of oromanibular dystonia, progressive spasticity, neuropathy, and then parkinsonism is seen. MRI demonstrates non-homogenous T2 pallidal hypointensity, with a region of medial hyperintensity that is reminiscent of the ‘eye of the tiger’ sign seen in PKAN (Hogarth 2015).

Summary of Neurodegeneration with Brain Iron Accumulation Syndromes

The NBIA are a rare to ultra-rare group of disorders that nevertheless have the potential to teach us much about brain function. Although iron deposition is a characteristic feature, this may not be pathogenic. Only experts in the area are likely to easily remember the distinctive clinical and radiological profiles of each condition. However, there are common features including movement disorders, spasticity and neuropathies. Dystonia and parkinsonism are the usual movement disorders. With PLAN, BPAN and KRS there may be L-dopa responsiveness but this is followed by intolerable dyskinesias. The diagnosis of NBIA can be suspected clinically, but MRI findings are most likely to point to the correct diagnosis. (Table 19.3 summarises some distinctive MRI features.) As a group, these conditions do not respond well to treatment. However, DBS can lessen the severity of the dystonia, and improve the quality of life (Timmermann et al. 2010).

OTHER CONDITIONS THAT MAY PRESENT WITH DYSTONIA

The genetic dystonias described above, are relatively rare. Dystonia is more commonly seen in the setting of CP where
there may also be other movement disorders, and commonly spasticity. The massive list of other causes of dystonia is too broad a topic to be dealt with in any detail here. However, a list of potential causes can be found in Table 19.4.

As a general rule in a child who presents with dystonia where there are no other clues in the history or examination, neuroimaging should be performed. Other standard investigations include copper and caeruloplasmin (Wilson disease), serum uric acid (Lesch–Nyhan syndrome) and alpha-fetoprotein and immunoglobulins (ataxia telangiectasia). The urine metabolic screen may detect one of the many metabolic disorders that can cause dystonia such as propionic aciduria, methylmalonic aciduria, cobalamin defects and glucaric aciduria type I (van Egmond et al. 2015). Rarely mutations in the a-tocopherol transfer protein can present with cervical dystonia, or dystonic head tremor (Becker et al. 2016). As this is a potentially treatable condition, checking plasma vitamin E levels is worthwhile in this setting. Other investigations are determined by the clinical features.

**LESCH–NYHAN DISEASE**

Lesch–Nyhan disease (LND) is an X-linked recessive disorder caused by deficiency of hypoxanthine guanine phosphoribosyltransferase. This enzyme is involved in the recycling of the purine bases, hypoxanthine and guanine, back into the purine nucleotide pools (Nyhan 1997). The resultant elevated uric acid levels may result in orange, sand-like crystals of uric acid in the nappies of an affected infant. Haematuria may also be an early feature.

In the first 6 months of life, the infant typically is hypertonic and has delayed motor development. Involuntary movements usually develop between 6 and 24 months of age. Patients with LND are classically described as having choreoathetosis, but in a review of 44 patients, dystonia was present in all, and was the most severe movement disorder (Jinnah et al. 2006). Other movement disorders noted in this study included choreoathetosis (50%) and ballism (30%). Spasticity was noted in 23% of the patients. The dystonia was particularly prominent with action, and was so severe that the patients were wheelchair-dependent and unable to feed or even grasp. Oromandibular and lingual dystonia, blepharospasm and limb contractures were also seen, as was opisthotonic posturing. The movement disorders progressed over a 1–2 year period, and then were relatively static. Intellectual disability was present in most patients, but was usually not severe.

Self-injurious behaviour is a characteristic feature of LND and tends to develop between 1 and 8 years of age. Biting of the lips and fingers is prominent but the extent of the self injury ‘is only limited by the imagination and by the nature of the motor defect’ (Nyhan 1997). Patients with LND not only injure themselves, but will attempt to injure others if given the chance. They may have compulsive spitting, and behave in other socially unacceptable ways. They feel remorse when hurting themselves or others, and say they are compelled to act aggressively against their will (Nyhan 1997).

There are variants of LND where there may be no self-injurious behaviour, only mild or no motor disability, and relatively normal intelligence (Jinnah et al. 2010). In these patients, serum uric acid is usually, but not always, above the upper limits of normal, and there may be excess excretion of uric acid in the urine.

Treatment of LND includes allopurinol to prevent the development of gout. Jinnah et al. (2013) found that the dystonia in LND does not respond well to anticholinergics, levodopa, dopamine agonists, dopamine depletors or antagonists. Benzodiazepines and baclofen are often used. The self-injurious behaviour is both extremely distressing and difficult to treat. Restraints, mouth guards, dental extraction, neuroleptics and behaviour modification have all been tried with limited success (Ragazzini et al. 2014). Pallidal DBS may not only improve dystonia but dramatically reduce the self-injurious behaviour (Piedimonte et al. 2015).

**INFANTILE BILATERAL STRIATAL NECROSIS**

Infantile bilateral striatal necrosis (IBSN) was probably first described by Paterson and Carmichael in 1924, and the term was coined by Friede (1975). In the early descriptions, a wide variety of clinical manifestations were reported including dystonia, and the diagnosis rested on the finding at postmortem of symmetrical degeneration of the caudate, putamen, and sometimes globus pallidus (Röyttä et al. 1981). With the advent of modern neuroimaging, it became clear there were milder cases, and many different causes, including infections and metabolic abnormalities (Dale et al. 2002). There were also variable outcomes.

Genetic causes of IBSN include mutations in mitochondrial genes (*ATP6, ND1, ND6* and *NDUFV1*), and in *NUP62* which codes for a nuclear pore complex protein. Other causes are thiamine transporter–2 deficiency, glutaryl-CoA dehydrogenase deficiency and mutations in the *ADARI* gene (Livingston et al. 2014). *ADARI* is the gene encoding the editing protein adenosine deaminase, which is involved in the recognition of self versus non-self double stranded RNA.

Mutations in *ADARI* are an example of a ‘type 1 interferonopathy’ where aberrant stimulation or unregulated control of the system, leads to inappropriate and/or excessive interferon output (Crow 2011). Testing for elevated interferons

is technically difficult. An elevated cerebrospinal fluid (CSF) neopterin is a non-specific measure, but upregulation of interferon-stimulated genes (ISGs), the so called ‘interferon signature’ can be used as a measure of increased interferon activity (Livingston et al. 2014).

**TREATMENT OF DYSTONIA**

Dystonia is a difficult condition to treat. This is not surprising given our current lack of knowledge of its pathophysiology, and the many different causes of dystonia. There are many potential abnormalities that might contribute to the development of dystonia including: abnormal inhibition, altered plasticity, macroscopic or microscopic structural alterations in the striatum and its connections, abnormalities of cerebellar input, dopamine dysfunction, and abnormalities of function associated with cholinergic, α-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), N-methyl-D-aspartate receptor (NMDA), gamma-aminobutyric acid receptor (GABA) and glutamate receptors (Breakefield et al. 2008). In an individual patient we usually have no idea which of these many potential factors could be operative.

A comprehensive review of the treatment of dystonia in childhood has recently been published by Roubertie et al. (2012). A widely practised approach in children with generalised dystonia is to first give the child L-dopa. If this fails, then the next drug is an anticholinergic such as trihexyphenidyl (also known as benzhexol). Further attempts at treatment are influenced by the clinical features of the child and include botulinum injections, oral baclofen, low-dose benzodiazepines, a number of newer oral agents, and DBS. Rehabilitation measures are important, but are usually not the province of the neurologist and are too vast a subject to be discussed here.

**Trial of L-dopa**

In children with an inborn error of dopamine metabolism such as GCH1 deficiency, treatment with L-dopa can be dramatically effective. Therefore, a trial of L-dopa should be

A difficulty with the L-dopa trial is that dopamine may produce some improvement in dystonia even when the child does not have an inborn error, including in the setting of CP (Brunstrom et al. 2000). A not uncommon situation is a child with dystonia started on L-dopa, who to the examiner’s mind has not dramatically changed, but the parents feel has a better quality of life while taking it. There is a longstanding concern that L-dopa, because of its propensity to promote the formation of cytotoxic free radicals and other reactive oxygen species, might be neurotoxic. In the much more common situation of the treatment of adults with Parkinson disease, this has not yet been fully resolved (Olanow 2015). As the brains of children may be more vulnerable to oxidative stress than adults, caution is warranted in the long-term use of L-dopa. When the problem is an inborn error of dopamine metabolism, and treatment is aimed at returning low brain dopamine levels to their normal range, the risk would seem low. In those children who have shown questionable improvement, it is important not to simply leave the child on long-term L-dopa based on an initial good impression, but to periodically question its efficacy.

Other Treatments

Our impression is that trihexyphenidyl is the drug most likely to be effective if the L-dopa trial has failed. There is experimental support for the use of trihexyphenidyl as it has been found to correct synaptic plasticity deficits in the striatum of mice with the DYT1 dystonia mutation (Maltese et al. 2014). There is also clinical evidence to support its efficacy (Balash and Giladi 2004). However, some patients initially classified as primary torsion dystonia who had a good response to anticholinergic therapy, were subsequently found to have GCH1 deficiency (Jarman et al. 1997a), which makes assessment of the older literature difficult. With anticholinergics, a ‘start low and go slow approach’ is recommended with a starting dose as low as 0.03mg/kg/day. In the past, doses of trihexyphenidyl of 40–80mg per day have been used (Fahn 1983). In children who are essentially helpless because of severe motor disability, it is difficult to assess side effects such as cognitive impairment, drowsiness, dry mouth, blurred vision, and constipation. We would suggest these high doses should only be used if there is compelling evidence of efficacy. Urinary retention is an additional potential side effect.

Oral baclofen may be helpful with dystonia but can worsen pre-existing hypotonia (Roubertie et al. 2012). Intrathecal baclofen is used for severe generalised dystonia, but the evidence of its efficacy is not as impressive as it is in the treatment of spasticity (Berweck et al. 2014). Because of the technical difficulties involved, its use should be confined to specialised centres with considerable expertise.

Tetrabenazine (TBZ) has a complex pharmacology, and although sometimes used for dystonia, it is more commonly used for hyperkinetic movement disorders such as chorea (Jankovic and Oman 1988; Jain et al. 2006; Gras et al. 2012). The main action of TBZ and its active metabolites is to

considered in any child with unexplained dystonia. In older children with GCH1 deficiency, dyskinesia is generally not a problem and the introduction of L-dopa does not require the slow escalation that is usually required in infancy. (This is covered in detail in the Parkinsonism section.) The starting dose of L-dopa (with a dopa-decarboxylase inhibitor) is around 1mg/kg/day with a target dose of 5mg/kg/day or higher. In typical GCH1 deficiency, doses of between 50–100mg of L-dopa, given two to three times a day, will often be sufficient to make the child essentially normal. As GCH1 is a cofactor in both dopamine and serotonin metabolism, brain serotonin levels potentially are low. However, 5-OH tryptophan has generally not been added to L-dopa, as depression and other potential manifestations of serotonin deficiency do not seem to be common clinical problems in typical GCH1 deficiency (Segawa 2011). Consistent with the clinical impression, Furukawa et al. (2016) found at postmortem in the striatum of a patient with GCH1 deficiency, very low levels of dopamine but normal concentrations of serotonin.

Most children with unexplained dystonia will not have an inborn error of dopamine metabolism, and this raises the difficult question of how high a dose of L-dopa should be given, and for how long should the trial continue? If the child has been on L-dopa (with a dopa-decarboxylase inhibitor) in a dose of 5mg/kg/day for several months with no substantial clinical response, then generally speaking, it is unlikely that continuing with it will make a significant difference.
Deep Brain Stimulation

This is a huge and complex subject and can only be dealt with briefly. (For a review, see Cif and Coubes 2016.) If a child has a genetic dystonia, such as DYT1, DBS of the GPi can be extraordinarily effective, returning a severely incapacitated child to near normality (Cif et al. 2003). Unfortunately, most children have an acquired form of dystonia, usually in the setting of CP, and have sustained damage to the basal ganglia. They often have other movement disorders, and also spasticity. When children with acquired dystonia are treated with DBS, scales developed for adult patients with dystonia often indicate little improvement. However, these scales may underestimate significant improvements in areas such as pain relief, hand function, and the ability of the child to sit comfortably (Lumsden et al. 2015). These are issues that are of particular concern for patients and their families. At the same time, it must be acknowledged that when a child has DBS there is a strong emotional investment, both from the family and the treating doctors, that it has been a good idea, and assessment of the outcome should be based on hard data and preferably by someone independent of the process. There is a report of patients with CP receiving pallidal DBS who did well with extended follow-up (Romito et al. 2015). Keen et al. (2014) found improvement including in speech, a finding not previously reported, in a small number of children with dystonic CP treated with DBS.

In treating a child with milder forms of dystonia, as is true of all movement disorders, it is always important not to overlook common comorbidities such as intellectual disability, attention deficit disorder, anxiety and obsessive compulsive disorder. These problems can cause significant impairment and may be more responsive to treatment than the dystonia itself.

**STATUS DYSTONICUS (DYSTONIC STORM)**

Status dystonicus is a life threatening form of dystonia where complications include severe pain and exhaustion, respiratory failure and metabolic disturbances such as rhabdomyolysis and renal failure. It can be an extremely difficult condition to treat, and there is as yet no satisfactory definition of what constitutes status dystonicus in childhood (Baxter 2013).

Fasano et al. (2012) reviewed 89 episodes of status dystonicus in 68 patients, of whom almost 60% were under the age of 15 years. This is by far the largest review of status dystonicus. The study included 27 of their own patients, and 41 reviewed from the literature. Fasano et al. divided the clinical features into (1) tonic status dystonicus where there were sustained contractions and abnormal postures, and (2) phasic status dystonicus where there were rapid and repetitive dystonic contractions. The tonic subtype was the more common, accounting for two-thirds of the episodes. In one-third of patients there was no clear trigger. When a trigger was evident, it was infection (52%), changes to medication (30%), a surgical procedure (7%), metabolic disorders (5%) and failure of a DBS device (5%). Initial treatment was with medication in most patients, but in only around 10% was the status dystonicus stopped in this fashion, most often by using tetrabenazine and benzhexol. Other treatments included intravenous benzodiazepines, propofol sedation, muscle paralysis, surgery (either DBS or ablutions), barbiturate anaesthesia, and intrathecal baclofen. Overall, 10% of patients died, 37% returned to their pre-existing clinical state, 37% improved (some markedly) and 16% were worse than they had been prior to the episode of status dystonicus.

Allen et al. (2014) stress the importance of allowing the child with status dystonicus to sleep to reduce the otherwise unrelenting dystonic spasms. They recommend the judicious use of oral or nasogastric chloral hydrate to obtain this. Allen et al. also list features differentiating status dystonicus from similar conditions such as neuroleptic malignant syndrome, serotonin syndrome, malignant hyperthermia and paroxysmal autonomic instability with dystonia (a condition which can occur after a severe head injury).
To prevent status dystonicus catching hold, it is important to recognise when a child’s dystonia is worsening. For example, patients with dystonia who have surgery need to be watched very carefully, so as they do not slowly slip into status dystonicus. A Dystonia Severity Action Plan has been developed (Lumsden et al. 2013). Allen et al. (2014) incorporate this into a logical flowchart for the management of status dystonicus. They also review surgical approaches including pallidotomy and DBS.

Status dystonicus most often occurs in patients known to have dystonia. Therefore, if life threatening dystonia develops in a previously well person, (1) underlying genetic and metabolic deficiency (discussed Treatable Movement Disorders section); and (2) other potentially treatable conditions should be considered, such as anti-NMDA receptor antibody encephalitis, where the treatment is primarily with immunosuppression rather than with anti-dystonic agents.

Advances in the management of status dystonicus are likely to come from carefully conducted international trials. However, the most important part of management will always be the recognition that a child with dystonia is worsening, allowing preventive action to be taken. The incidence of status dystonicus with surgical procedures seems too low to recommend routine, peri-operative preventive treatment in children with established dystonia, but this might be considered in some patients.

**ATHETOSIS AND CHOREA**

**ATHETOSIS**

The term athetosis was coined by William Hammond in 1871 to describe continuous, slow, writhing movements of the fingers, toes, and face. Subsequently, its use changed to describe what we now call dystonia (Morris et al. 2002a). It is a term that has now gone out of favour, mainly appearing as the hybrid ‘choreoathetosis’ when both fast and slow movements co-exist. Morris et al. (2002b) have suggested the term athetosis should be retained and used in its original sense. It is a distinctive form of dystonia seen with mild CP. Typically there are independent, quivering movements of the face and eyebrows. Similarly irregular, brief, jerky movements occur in the hands and sometimes feet. Sanger et al. (2010) proposed the following definition of athetosis: ‘athetosis is a slow, continuous, involuntary writhing movement that prevents maintenance of a stable posture’. They suggested athetosis could be distinguished from dystonia by the lack of sustained postures, ‘although it is frequently associated with dystonia so the distinction can be difficult in practice’.

**CHOREA**

The word chorea comes from the Greek *choreia*, a ‘choral dance’, and the concept of a dance remains helpful in its recognition. The characteristic feature of chorea is the flow of movement from one part of the body to the next. As is typical of most movement disorders, variability is the rule. At times chorea can consist of brief sudden twitches similar to tics or myoclonus, and at other times there are longer duration sinuous movements that are called choreoathetosis. The severity of chorea can vary from (1) a child that simply looks restless with a mild intermittent exaggeration of gestures or expressions; (2) to a more obvious chorea with a ‘dancing’ gait; and (3) at the extreme a continuous flow of violent, and totally incapacitating ‘ballistic’ movements.

The essence of chorea is an impression of an unpredictable flow of the movement. Other movement disorders such as dystonia, myoclonus, and tics tend to form patterns, and there is a degree of predictability in the muscles that are involved. Clinically, with chorea there is no such pattern. This can be helpful in differentiating multifocal tics from jerky chorea. Another feature helping to distinguish chorea from multifocal tics, is that chorea disturbs normal motor function, whereas tics usually do not.

Except when it is very severe, children with chorea are able to perform voluntary movements, but cannot control additional, unwanted movements. They may attempt to disguise their unwanted movements. For example, when an arm flies upwards, they will brush their hair, and then keep moving. Chorea typically involves the face. This is reflected in Kinnier Wilson’s dictum that the child with Sydenham chorea is punished three times before the diagnosis is made – ‘once for general fidgetiness, once for breaking the crockery, and once for making faces at grandmother’.

Other manifestations of chorea include motor impersistence. The child is unable to keep their arms extended out in front of them, and the arms repeatedly drop downwards, or flex at the elbow. Other well-known manifestations of motor impersistence include difficulty in keeping the tongue protruded, and difficulty maintaining a steady grip (‘milkmaid’s grip’).

Generalised chorea is often asymmetrical, but when confined to one side of the body, the term hemichorea is used. The cause is often injury to the contralateral basal ganglia. Hemiballismus is generally regarded as an extreme manifestation of chorea. It is characterised by unpredictable, wild, flinging movements, particularly affecting the limbs proximally. While the patient is awake the limb is in constant and violent motion, but with sleep it becomes completely still (Purdon Martin 1927). Hemiballismus is rare in childhood but in adults is classically caused by a lesion of the contralateral STN. Bilateral ballistic movements can be seen in children with a variety of severe encephalopathies.
In Table 19.6 we list some of the large number of potential causes of chorea. In the following discussion, we will concentrate on a limited number of important causes of chorea.

**SYDENHAM CHOREA**

Sydenham chorea was the first form of chorea to be described and the first movement disorder to be recognised as immune-mediated. It is a consequence of a group A β-haemolytic streptococcal infection. It usually occurs between the ages of 5 and 15 years, and girls are more commonly affected.

The clinical manifestations of Sydenham chorea include the classic features of chorea described above. In mild cases the child may just appear restless. Dysarthric, explosive speech, combined with chewing and swallowing difficulties, may occur in the more severe cases. Attempts at movement tend to make the chorea worse, but some children can integrate the chorea into normal movements lessening their impact. There may be irritability, emotional lability and the development of obsessive–compulsive symptoms (Swedo et al. 1993). Asymmetry of chorea is common. Although some authorities believe an isolated hemichorea may occur in Sydenham chorea (Ford 1960), Sheldon (1940) was of the view that...
'whether a pure hemichorea of rheumatic origin ever occurs is doubtful. ‘There may be an apparent hemiparesis (chorea mollis) associated with hypotonia and difficulty initiating voluntary movements. Severe and unrelenting movements (chorea insatiens) can lead to exhaustion and be a medical emergency.

A recent detailed review of the literature found that obsessive–compulsive symptoms and difficulties with attention, were the commonest neuropsychological problems associated with Sydenham chorea (Punukollu et al. 2016). The older literature reports dramatic emotional changes. From Sheldon’s textbook (1940) comes the following: ‘Rarely the child becomes more and more excited until acute mania develops; the behaviour is then very odd, and the child will tear up anything within reach, soil herself, shout, and abuse all and sundry. Eventually a normal mentality is regained, but it may be six months or more before the behaviour settles down.’ (Whether the problem here was actually another condition such as anti-NMDA receptor encephalitis will, of course, never be known.)

In the developed world, Sydenham chorea is uncommon, and is in a sense a diagnosis of exclusion. The many other causes of chorea such as systemic lupus erythematosus and moyamoya have to be considered. The presence of carditis supports the diagnosis of Sydenham chorea.

The first task in the treatment of Sydenham chorea is the elimination of the streptococcal infection. Typically, penicillin 500mg twice daily is given for 10 days combined with bed rest. The movement disorder of Sydenham chorea has been regarded by many as a self-limiting condition, and even in developed countries some authorities recommended treatment be given only when the chorea is severe (Carapetis et al. 2007). When used, treatment has been based on suppressing the movements with medications such as haloperidol (Shenker et al. 1973), carbamazepine (Roig et al. 1988), or valproic acid (Alvarez and Novak 1985).

Peña et al. (2002) compared the use of valproic acid, carbamazepine and haloperidol in 18 patients who had Sydenham chorea of several weeks’ duration. Complete recovery was observed in five of the six patients treated with valproic acid following 5 days of treatment. There was moderate improvement in the remaining case. Full recovery was achieved in five of the six patients treated with CBZ. Three recovered after 5 days of treatment, whereas the other two required treatment for 7 days before there was a disappearance of symptoms. The remaining patient failed to improve. No side effects were noted with either drug. Three of the six patients treated with haloperidol showed improvement following 5 days of treatment, but one had excessive somnolence, and another a dystonic reaction. Four patients treated with haloperidol were changed over to valproate and within a week were symptom-free. The authors concluded that valproate was the most effective drug in the treatment of Sydenham chorea.

Although acute and long-term psychiatric morbidity has long been recognised with Sydenham chorea, it has tended to be overshadowed by the motor symptoms. Ford (1960) observed: ‘The mental symptoms may persist for a long time and, indeed, many children who have had chorea remain sensitive and unstable throughout life.’ Freeman et al. (1965) reviewed 40 patients at an average of 29 years after their admission with Sydenham chorea. Seventy-five per cent of the group were found to have evidence of psychiatric disturbance, compared with an incidence of 25% in a comparison group. Given that Sydenham chorea is an immune-mediated neuropsychiatric disorder that has the potential for long-term morbidity, there is increasing interest in the use of immunosuppressive agents such as steroids and immunoglobulin in the hope of preventing both long-term physical and psychological disturbance (Wärker and Wilmshurst 2010; Mohammad et al. 2015).

It is important to not lose sight of the risk of valvular heart disease in children with Sydenham chorea. In the classic paper of Aron et al. (1965), 34% of 50 patients examined an average of 29 years after their initial episode, had developed valvular heart disease. In a more recent study of Sydenham chorea from Turkey, using echocardiography, carditis was detected in 71% of 69 children at initial presentation (Ekici et al. 2012). The carditis was silent in 28.9%. In this study, most patients had mild or moderate valvular regurgitation.

Patients who have had rheumatic carditis, with or without valvular disease, are at a relatively high risk for recurrences of carditis. They are likely to sustain increasingly severe cardiac damage with each episode. Therefore, it has been recommended that patients who have had rheumatic carditis should receive long-term antibiotic prophylaxis well into adulthood (Gerber et al. 2009). If there is valvular heart disease the prophylaxis may need to be lifelong. In deciding the duration of the prophylaxis, it is important to assess the likelihood of ongoing exposure to group A β-haemolytic streptococcal infection. Prophylaxis usually takes the form of intramuscular benzylpenicillin every 28 days, or oral penicillin 250mg b.d., unless the person has penicillin allergy, where sulfadiazine or macrolide antibiotics can be used (Gerber et al. 2009). It should be remembered that penicillin prophylaxis is to prevent further episodes of carditis. It may not prevent relapses of chorea which can occur in up to 20% of patients. The relapses appear to be unrelated to repeated streptococcal infections (Ekici et al. 2012), but may be triggered by other infections, the oral contraceptive pill or pregnancy.

THE SYNDROME OF BENIGN HEREDITARY CHOREA

An autosomal dominant non-progressive form of chorea without intellectual deficit was described in 1967 (Haerer et al. 1967; Pincus and Chutorian 1967). At one point, doubt was cast as to the existence of this condition (Schrag et al. 2000). However, genetic studies then revealed that mutations in the gene NKX2.1 (also known as TITF1) was responsible for some cases (Devriendt et al. 1998; Breedveld et al. 2002). Recently other genes have been described with clinical manifestations that broadly fit into the spectrum of benign hereditary chorea (BHC).
NKX2.1/TITF1 Mutations

The NKX2.1 gene encodes a transcription factor that is expressed early in the development of the basal ganglia, hypothalamus, thyroid and lungs (Thorwarth et al. 2014). With mutations in this gene, as well as chorea there may be hypothyroidism and lung disease. There is a female predominance, and the first signs are often hypotonia and motor delay, with the median age at onset of chorea being 3 years of age (Peall et al. 2014). There may be no lung or thyroid disease, or the manifestations may be subtle with a mildly elevated thyroid stimulating hormone (TSH), but otherwise normal thyroid function tests. The lung disease when present, has a wide spectrum from neonatal respiratory failure, through recurrent chest infections and asthma, to lung cancer in adults (Gras et al. 2012). Confusing for the clinician, but not surprising when considering the function of NKX2.1, there may be other movement disorders such as dystonia, myoclonus and tics (Asmus et al. 2007b; Gras et al. 2012).

There are a number of reports of children with NKX2.1 mutations initially presenting with frequent falls, with chorea appearing subsequently (Fons et al. 2012; Rosati et al. 2014). If the contiguous gene PAHX is deleted there may also be poor development of the teeth (Devos et al. 2006).

Gras et al. (2012) found that the chorea improved after puberty, and occasionally myoclonus becomes the most disabling problem in adults. They also found a relatively high incidence of learning difficulties and attention deficit disorder. Short stature and cardiac defects have also been reported, and as discussed above, mutations in the NKX2.1 gene may predispose to the subsequent development of malignancies (Thorwarth et al. 2014). In some patients, MRI reveals a cystic pituitary mass (Veneziano et al. 2014).

There is limited information about the treatment of the movement disorders that can appear in NKX2.1 gene mutations. Peall and Kurian (2015) in a recent review observed: ‘Multiple reports have described single cases treated with a variety of agents including trihexyphenidyl, corticosteroids, sodium valproate, propranolol, ropinirole, and sulpiride, each with varying results.’ There are reports of patients with NKX2.1 mutations responding to L-dopa therapy. Asmus et al. (2005), described two patients who showed improvement of gait and chorea with L-dopa, using relatively high doses of 20mg/kg/day. In one of these patients, increasing the dose to 33mg/kg/day led to worsening of gait, and a return to the lower dose. CSF pterins, measured in one of the patients were normal. Fons et al. (2012) using a dose of 9mg/kg/day of L-dopa, given from 3.5 years of age, with a very slow titration, found that after 6 months of treatment including physiotherapy, there was a significant improvement in neurological symptoms. After a year there was an attempt to stop the L-dopa, but this resulted in a deterioration in gait and frequent falls. The patient continued on a lower dose of 3mg/kg/day for a further 14 months. The L-dopa was then stopped after a total of 3 years of treatment, without any clinical deterioration. A detailed analysis of this patient’s CSF neurotransmitters did not reveal any abnormalities, suggesting that there was no lack of production of L-dopa.

In the study of Gras et al. (2012), eight patients with NKX2.1 mutations (children and adults), were given tetra-benzazine for their chorea, and five rapidly showed a moderate to marked benefit. However, three stopped the drug within days because of side effects.

Adenylyl Cyclase 5 (ADCY5) Mutations

The original family with this condition was described as having ‘familial essential (‘benign’) chorea’ (Bird et al. 1976). Subsequently the diagnosis was changed to ‘familial dyskine sia and facial myokymia’ because of distinctive facial movements that in some members of the family were thought to be myokymic (Fernandez et al. 2001). Subsequently, mutations in the ADCY5 gene were found to be the cause of the movement disorder in this family (Chen et al. 2012). A re-analysis of the facial movements has concluded that the movements are not myokymic, but due to either chorea or dystonia (Chen et al. 2015). Recent reports have described patients with isolated chorea and dystonia without facial myokymia (Carapito et al. 2015; Chen et al. 2015; Mencacci et al. 2015b). Both familial and sporadic cases have been described. It appears likely there will be a broad spectrum of manifestations of ADCY5 mutations, from severely affected patients, often carrying the label of dyskinetic CP through to older children where the clinical picture is somewhere between benign hereditary chorea and myoclonus dystonia (Chang et al. 2016).

Chen et al. (2015) have listed the following clues to the diagnosis of ADCY5 mutations: (1) axial hypotonia, sometimes accompanied by weakness; (2) facial chorea or dystonia; (3) nocturnal paroxysmal dyskinesia, often pronounced; (4) movement related pain; (5) dramatic fluctuations in frequency and severity of movements; (6) no or mild cognitive impairment; (7) normal MRI; and (8) little or no progression. They have suggested the term ‘ADCY5 dyskinesia’ be used in view of the broad range of clinical manifestations and the multiple movement disorders that can be seen associated with the various mutations.

Assessment of the response to medication can be difficult, as some patients follow a waxing and waning course. Benzodiazepines may help the severe nocturnal episodes of dyskinesia that can last hours, and prevent sleep. Three patients treated with DBS before their ADCY5 mutations were identified showed some improvement in their dyskinesia (Dy et al. 2016).

Although there are a wide range of manifestations, ADY5 mutations should be particularly considered in children carrying the label of dyskinetic CP especially when there are unusual facial movements, or bouts of prolonged dyskinesia during drowsiness.

Clinical Overlap of NKX2.1, Epsilon Sarcoglycan and ADCY5 Mutations

In the young child who has a hyperkinetic movement disorder, it is often difficult to be certain whether the movements should
be called chorea, dystonia or myoclonus, and at times they co-exist. If neuroimaging is normal, and the child is not severely delayed, then mutations in \textit{NKX2.1}, \textit{ADCY5} and epsilon sarcoglycan mutations come into the differential diagnosis. Abnormal thyroid function tests, including an isolated raised TSH, suggest the diagnosis of \textit{NKX2.1} mutations in this setting.

### OTHER GENETIC CAUSES OF CHOREA

Allan-Herndon-Dudley syndrome (AHDS) is an X-linked disorder due to mutations in the \textit{SLC16A2} gene encoding the monocarboxylate transporter 8 (MCT8) (Dumitrescu et al. 2004). Affected patients have early-onset hypotonia, and there may also be dystonic posturing of the limbs, as well as paroxysmal dyskinesias (Brockmann et al. 2005; Gika et al. 2010). In AHDS, there are characteristic abnormalities of thyroid function tests including high free or total T3, normal or mildly decreased free thyroxine, and normal or slightly elevated thyroid stimulating hormone. As T3 levels are not routinely measured by most laboratories, in males it could be confused with mutations in \textit{NKX2.1}. However, in AHDS, there is usually severe intellectual disability (Brockmann et al. 2005). There may also be facial dysmorphic features, and MRI shows delayed myelination which can be of such severity that the diagnosis of Pelizaeus–Merzbacher syndrome comes into consideration (Gika et al. 2010).

\textit{PDE10} mutations can cause a relatively benign form of chorea with onset in childhood (Mencacci et al. 2016). A distinguishing feature from other conditions carrying the ‘BHC’ phenotype, is the presence of bilateral abnormalities of the caudate and putamen on MRI.

Mutations in \textit{GNAO1}, in contrast, can produce a very severe hyperkinetic movement disorder, usually on a background of hypotonia and developmental delay, with normal MRI (Ananth et al. 2016; Kulkarni et al. 2016). Hyperkinetic status is a feature and is precipitated by multiple factors including infections, excitement, anxiety and emotional stress. There are frequent admissions to the Intensive Care Unit, and the child may die despite maximum medical therapy. DBS shows promise in controlling the bouts of hyperkinetic status (Kulkarni et al. 2016).

### CHOREOATHETOSIS FOLLOWING HERPES SIMPLEX VIRUS ENCEPHALITIS

In 1967 in a review article, Olson et al. described a 70% mortality rate for herpes simplex virus encephalitis (HSE) (Olson et al. 1967). In 1973, adenosine arabinoside was introduced and was the first effective treatment for HSE. Acyclovir was introduced in 1982 and has become the treatment of choice, reducing mortality to between 0 and 25% (Whitley et al. 1986).

Soon after the development of effective therapy, ‘relapses’ following treatment of HSE were reported. In 1979, Koenig et al. reported an adult patient who developed ‘post infectious encephalomyelitis’ after treatment with adenosine arabinoside for HSE. In the 1980s and 1990s multiple papers were published describing relapses after HSE. It became clear that these involved two different populations. In one group there was a reactivation of the herpes virus. In the other, the process was immune-mediated. De Tiège et al. (2005) described the typical features of the immune-mediated form. These included (1) choreoathetoid movements; (2) absence of new destructive changes on imaging; (3) absence of efficacy of acyclovir; (4) diffuse white matter involvement in some cases (see Fig. 19.12); and (5) absence of virus isolation from brain biopsies.

Pruss et al. (2012) looked at the serum of 44 adult patients who were PCR-positive for herpes simplex virus. One-third were found to have antibodies to the NMDA receptor. Subsequent papers (Armangue et al. 2013; Hachen et al. 2014; Mohammad et al. 2014a) have established that anti-N-methyl-D-aspartate receptor (NMDAR) antibodies are found in children who develop the syndrome of choreoathetosis following HSE. It seems likely that the mechanism is lysis of infected neurons releasing antigens, leading to a secondary immunological insult (Titulaer et al. 2014).

It has long been recognised that an immune-mediated encephalitis can follow infections such as measles and varicella, where the brain was not initially involved. With HSE, a destructive encephalitis seems to provoke a secondary immune-mediated encephalitis. There may be a role for aggressive immunotherapy in these children. Armangue et al. (2013) treated their patient with intravenous methylprednisolone and immunoglobulin, but she did not respond well. Four months after onset, as there had been no improvement, rituximab and cyclophosphamide were added with benefit. It may be difficult to assess the efficacy of aggressive therapy in this condition. It is rare, and there is a variable degree of initial destruction by the herpes virus itself, and presumably a variable immune response, given that the diffuse white matter changes are seen only in some patients.

### HUNTINGTON DISEASE

Huntington disease is dominantly inherited and characterised by movement disorders, psychiatric disturbance and progressive dementia. It is caused by an unstable, expanded \textit{CAG} triplet repeat in the \textit{IT15} gene producing an enlarged polyglutamine stretch in the huntingtin protein (The Huntington’s Disease Collaborative Research Group 1993; Schiefer et al. 2015). In Huntington disease, the number of repeats markedly influences the onset and course of the disease (Andresen et al. 2007; Langbehn et al. 2010). Normal individuals have less than 26 \textit{CAG} repeats. If there are between 27 and 35 repeats the person will not develop symptoms, but could pass the disease on to their children. With 36–39 repeats there is a risk the person will develop the disease, and there is a 50% risk of transmission to their children. If there are 40 or more repeats, the person will develop the disease and there is again a 50% risk of transmission to their children. Anticipation (progressively earlier appearance
of the disease with successive generations) is a feature of Huntington disease, and is more common when the father is affected.

Huntington disease is traditionally subdivided into adult and juvenile-onset forms (where the onset is less than 20 years of age) (Koutsis et al. 2013). In adult onset disease, chorea is often the dominant movement disorder, but rather than being similar to the large amplitude, flowing movements seen in Sydenham chorea, it takes the form of jerky, non-repetitive and arhythmic movements that affect the facial muscles, fingers and toes (Schiefer et al. 2015). These movements may be misinterpreted as agitation or nervousness, and the affected person is often initially unaware of their presence. In the juvenile form, the traditional view is that rigidity is the most typical early manifestation (known as the Westphal variant).

Huntington Disease Presenting at Less Than 10 Years of Age

It is more useful to subdivide juvenile Huntington disease into children with onset before 10 years of age, and those with an onset between 10 and 20 years. Osborne et al. (1982) described three cases of Huntington disease presenting at less than 10 years of age, and reviewed 43 other cases from the literature (acknowledging the limitations of such a study). Of the 46 patients with onset less than 10 years of age, 26 were clearly identified as having the rigid variant, and nine predominantly had chorea. Seizures were reported in 24 children, and they were mainly tonic-clonic seizures, which became more difficult to control as the disease progressed. In one family, seizures were the presenting symptom. Speech disorders were common appearing in 33 of the 46 patients.

Gonzalez-Alegre and Afifi (2006) looked at 12 children affected with Huntington disease. At the time of onset of their symptoms, seven children were under the age of 10 years, with six of them aged between 4 and 5 years. The onset of symptoms in the other five children was between 10 and 14 years. Seizures only appeared in the children with onset at less than 10 years of age. Ophthalmoplegic dysfunction was common in both groups, but present in all the older children. Chorea was more common in the younger group, whereas rigidity was more a feature of the older group. Two patients in the younger group developed paroxysmal dystonia initially affecting the right arm when walking or running. This subsequently became generalised and almost continuous. The most frequent presenting symptom of the earlier onset group in this study was cognitive decline. Two of the patients were initially diagnosed by a child psychiatrist as having attention-deficit–hyperactivity disorder (ADHD), and another had frequent motor tics. In four children (three in the under-10 group), the initial CT or MRI was normal. Caudate atrophy was found in the other scans, sometimes with more diffuse atrophic changes. Although juvenile Huntington disease is traditionally associated with paternal inheritance, the affected parent was the mother in three of the seven children presenting at under 10 years of age. One of these children had 120 CAG repeats. None of the 12 patients had the abnormalities of eye movements that are frequently seen in adult patients with Huntington disease.

Looking at their own patients and previous reports, Gonzalez-Alegre and Afifi (2006) felt that childhood-onset Huntington disease could be seen in three phases; (1) an initial phase of behavioural disorder, learning difficulty, gait disturbance and mild chorea; (2) a florid phase with signs of cognitive deterioration, rigidity, speech disturbance and seizures; and (3) a terminal phase of bed confinement, hypotonia, and increasing seizures.

Huntington Disease Presenting after 10 Years of Age

Ribaï et al. (2007) described 29 patients with juvenile Huntington disease. The mean age at onset was 14 years with a standard deviation of 5 years, and almost half had less than 60 repeats. They thus represented the ‘older’ group of juvenile Huntington disease. The initial problem was motor in ten patients, cognitive in ten patients, and in nine, it was psychiatric disturbance. Overall, psychiatric and behavioural difficulties were severe enough to be reported as the first sign by patients and relatives in 66% of patients. Seven patients attempted suicide at least once. Cognitive decline ranged from slight attentional difficulties to subcortical dementia. At onset the motor signs were atypical, including ‘myoclonic head or limb tremor’, shoulder twitching and writing difficulties. Only three had chorea at the onset of the illness. None of the patients were initially rigid, but during the course of the disease, parkinsonism was present in 62%, and dystonia in 72%. Over time, chorea appeared in 62%, cerebellar signs in 24% and seizures in 21% of patients. When the patients presented with behavioural or psychiatric disturbance, even with a known family history of Huntington disease, diagnosis was often delayed. In one case, the carrier father remained asymptomatic at 69 years of age. Ribaï et al. (2007) suggested that Huntington disease be considered in a child or young adult with an atypical movement disorder, combined with severe, progressive psychiatric or cognitive disturbances, even in the absence of family history of Huntington disease.

Delayed speech or severe dysarthria can be an important clue to the diagnosis of childhood Huntington disease. As well as the above studies, this was found in 18 out of 20 patients in the review of Hansotia et al. (1968). Yoon et al. (2006) described three patients with Huntington disease where speech delay preceded motor symptoms by 2 years. Ataxia was a feature of 50% of the children in the study of Hansotia et al., and was also noted by Ruocco et al. (2006). In a multi-centre review of 90 patients with juvenile Huntington disease, seizures occurred in 38% and were more likely to occur with earlier age at onset and greater expansion size (Cloud et al. 2012). There is a report of Huntington disease presenting as a progressive myoclonic epilepsy (Gambardella et al. 2001).

The issue of when to test for Huntington disease is difficult. Koutsis et al. (2013) reviewed the notes of 76 patients...
suspected of having juvenile the disease. All of the 24 patients who carried the Huntington disease expansion, had a positive family history of Huntington disease. Overall, 23% of patients with a family history of genetically confirmed Huntington disease, did not have an expansion. Clinical symptoms were not reliable in predicting who would carry the abnormal gene. Koutsis et al. concluded that in the absence of a family history, the diagnosis of Huntington disease was unlikely, and there should be no delay in performing investigations to look for other causes.

In an accompanying editorial Lehman and Nance (2013) discussed the challenge of the 10–20-year-old patient, with a family history of Huntington disease, presenting with symptoms common at that age such as depression, anxiety, and behavioural, cognitive or attention problems. They suggested that to avoid both delayed diagnosis, and either a premature or incorrect attribution of symptoms to the disease, a period of observation of around 1 year should be undertaken. If over this time a clearly progressive course was established, then testing could reasonably be done. Some authorities take the view that under the age of 18 years, testing should not be done. The reasons are discussed by Lehman and Nance (2013), and in multiple other reviews.

There is as yet no effective treatment for Huntington disease, and therapy for juvenile Huntington disease tends to be symptomatic, and aimed at reducing patient and family distress. In a survey of 45 patients with juvenile the disease from Europe and the United Kingdom, 24 were receiving antipsychotic agents, 17 anti-depressants, 15 anti-parkinsonian medications and eight valproic acid for seizures (Robertson et al. 2012). Reflecting the difficulty of management, polytherapy was common, with five patients taking more than eight medications, and one patient received 16 different medications. In the United Kingdom opioids were also used for pain relief.

**Compound heterozygotes of the Huntington gene**

using exome sequencing, compound heterozygotes of the Huntington gene have been detected in two families, where affected individuals presented with severe development delay, and a Rett-syndrome-like picture (Lopes et al. 2016; Rodan et al. 2016).

---

**TREMOR**

Tremor particularly affects the upper limbs but can involve almost any part of the body including the head, face, eyelids, tongue, vocal cords and trunk. In a Consensus Statement of the Movement Disorders Society, tremor was defined as ‘a rhythmic, involuntary, oscillatory movement of a body part’ (Deuschl et al. 1998). There is a paucity of data on the prevalence of tremor in childhood, but in the personal series of Fernández-Alvarez of children under 18 years with movement disorders, 129 (19%) of 673 cases presented with tremor as the sole or predominant feature. It was seen twice as commonly in boys, and the apparent age at onset was typically around 6 years (Fernández-Alvarez and Aicardi 2001).

While taking the history, watching how the child manipulates toys, or plays a computer game can give useful information. There are a number of ways of formally assessing a child for tremor. These include asking the child to hold their arms out in front, and then getting them to do mental arithmetic (at a level that challenges them). With mental arithmetic, a pathological tremor often becomes worse, whereas it may disappear if the problem is psychogenic. Other useful techniques include with the arms abducted getting the child to keep both index fingers as close as possible to the nose without touching it, and copying an Archimedes spiral.

Tremor is traditionally divided into resting tremor and action tremor. Using tremor of the upper limbs as an example, with resting tremor, the tremor is seen when the arm is totally relaxed. Full relaxation is not always easy to achieve, but asking the child to rest the arm on the bed and let it become ‘loose’ may be effective. Action tremor is any tremor that is produced by voluntary contraction of muscle. It is further subdivided into (1) postural tremor which occurs when a limb is voluntarily maintained against gravity for example, when the arms are held steadily against the forehead of the child, and (2) kinetic tremor defined as any tremor that occurs during voluntary movement.

Kinetic tremors can in turn be subdivided. Intention tremor worsens as a target is approached, classically in the ‘finger-nose’ test. Simple kinetic tremor occurs during voluntary movements that are not goal-directed for example, during pronation/supination movements of the forearm. Task specific tremors occur during, or are provoked by, a particular action; for example, writing. Titubation is the slow head tremor typically seen with cerebellar disease, but also in adults with essential tremor. The head movements can be in an anterior-posterior or lateral direction. Holmes tremor is present at rest, with intention, and with posture. It is typically slow and coarse. It can be extremely disabling. In Holmes tremor, with the finger-nose test, as the hand returns to the nose there may be extreme oscillations of the head, and the threat of injury to the eyes or face. The term Holmes tremor is now preferred to such terms as rubral or midbrain tremor which were used in the past. It is believed to be caused by involvement of both the nigrostriatal and dentato-rubro-thalamic pathways (Deuschl et al. 1998).

Children with irregular jerking movements of the hands or arms are often described as having dystonic tremor. This can be confusing as the movements are often neither rhythmic nor oscillatory, features that are generally regarded as mandatory in the diagnosis of tremor. If the person has other signs of dystonia, then the diagnosis is not difficult. However, a common presentation is the child who has mild, intermittent, irregular
jerking of the hands, but is otherwise normal, and all investigations are negative. This possibly represents a mild form of dystonic tremor.

Tremor studies can be done relatively easily in children but the diagnosis is usually made on clinical grounds. Singer et al. (2010) observed: ‘Electromyography, accelerometers, and other instruments are sometimes used to quantitate tremors, but the clinical utility of this information, that is, its ability to improve diagnostic and/or therapeutic medical decision making, has not been demonstrated in children.’ However, Canavese et al. (2008), in a retrospective review of 61 children who had a tremor study, found that in 31% the polygraphic features allowed the identification of a clinically unclassified movement disorder. Further, in 19.6% it disclosed an associated movement disorder which was not clinically evident. It was also useful in supporting the clinical diagnosis of psychogenic movement disorder.

At present, tremor studies can be seen as a useful adjunct that may help to confirm the clinical impression. When the child has a psychogenic movement disorder, tremor studies also can be helpful in persuading the parents and child that there is ‘scientific’ evidence supporting the diagnosis.

‘JITTERINESS’

As many as half of all term infants are jittery and as such, this is the most common form of tremor in childhood. It usually settles over a few days, but in some infants persists for months. Asphyxiated infants may show it in an extreme form. In jitteriness high-frequency, rhythmic oscillatory movements, particularly of the limbs and chin, can be provoked by startle, and be stopped by gently holding the moving limb, or changing its position. The main differential is a clonic seizure where the limb jerking will usually continue despite gentle restraint or repositioning. A fundamental difference is that the ‘to and fro’ movements of jitteriness are of equal amplitude, whereas in clonic seizures, the phase of flexion is usually more sustained than that of extension (Scher 1997).

TREMOR IN INFANCY

There are a relatively small number of causes of tremor in infancy (see also Table 19.14).

Inborn Errors of Dopamine Metabolism

These are rare and the infant may be misdiagnosed as having the much more common CP. This subject will be discussed in more detail in the Parkinsonism section.

Cobalamin (Vitamin B12) Deficiency

In 1962, Jadhav reported the syndrome of vitamin B12 deficiency in Indian infants characterised by apathy, developmental regression, involuntary movements and skin pigmentation. Subsequently there have been multiple similar reports from the ‘developed’ world. The typical story is that the mother has vitamin B12 deficiency due either to her diet, or undiagnosed pernicious anaemia. The infant is exclusively breastfed. From around 4–8 months there is progressive developmental regression. The infant may not be anaemic, but the blood film is often macrocytic. The movement disorder can be present before diagnosis, but is more often seen after treatment with vitamin B12 has started. It is commonly described as ‘choreoathetosis’ (Graham et al. 1992), but in some children the movement disorder is more rhythmic (Higginbottom et al. 1978). At times it takes the form of a violent tremor that can cause the cot to shake (Emery et al. 1997). In a series of three patients, two had pronounced limb shaking thought to be a mixture of tremor and myoclonus (Grattan-Smith et al. 1997). One of these infants also had marked jerking of the tongue and pharynx causing vocalisation. The third infant had persistent movements of the right hand resembling epilepsia partialis continua, which appeared before treatment was started.

Both seizures and movement disorders can occur in vitamin B12 deficiency, and it is important to try to separate the two. The violent tremor that appears after the initiation of treatment usually settles over 4–6 weeks. Why it occurs is not known.

In the developing world, the ‘kwashiorkor shakes’ has been described in severely malnourished children on re-feeding (Kahn and Falcke 1956). Again the cause is unknown.

Head Tremors in Infancy

Head tremor at all ages can be further subdivided into ‘negative’, when the head shakes from side to side, and ‘positive’ (or affirmative) when the shaking takes the form of a vertical nodding. Some children with congenital nystagmus have head shaking movements. It is not clear why these head movements occur, but there are usually no diagnostic difficulties when shaking occurs in the presence of coarse, horizontal, pendular nystagmus. Totally blind children may also have repetitive head movements that may be a form of self-stimulation (Fazzi et al. 1999). The term ‘bobble-head doll syndrome’ (BHS) was introduced by Benton et al. (1966) and subsequent reports have not improved upon their description. Two children were described with ‘to and fro’ bobbing or nodding of the head and trunk. ‘The movement is reminiscent of that seen in dolls with weighted heads resting on a coiled spring’. Both children had cysts in relation to the third ventricle with associated hydrocephalus. Subsequent reports have confirmed that BHS is typically caused by mass lesions around the third ventricle causing CSF obstruction.

Nellhaus (1983) lists hypomagnesemia, uremia, thyrotoxicosis, citrullinaemia, antihistamines, antipsychotic agents and amphetamine as other causes of head tremor in childhood.

In spasmus nutans there is asymmetrical, rapid head nodding, nystagmus (often monocular) and head tilt or torticolis. The nystagmus and head shaking typically occur in bursts.
lasting 5–30 seconds in association with fixation. Classically described as a benign phenomenon, at times it is caused by an anterior visual pathway glioma (Antony et al. 1980).

Head Stereotypies in Infancy

Some infants and young children have intermittent, rhythmic, side to side head movements that can persist for years with no other signs present. Sometimes these will be more obvious when the child is otherwise unoccupied, and the movements may disappear with intense concentration, or if the child is asked to stop the movement. However, this is not always the case. This appears to be an unusual form of stereotypy. Hottinger-Blanc et al. (2002) described eight children with onset in the first year of life of an isolated head stereotypy. All were of normal intelligence but were clumsy, and two had abnormalities of cerebellar development. Di Mario (2000) described four children with persistent head tremor with no cause identified. Three of these four children had shuddering attacks (also thought by some to be a form of stereotypy) prior to the development of the head movements.

Because of the many potentially serious underlying causes, neuroimaging should always be considered in children with head tremors.

TREMORS IN CHILDHOOD AND BEYOND

A common situation is the child thought to have a tremor at home or school, but when examined, there is either nothing to see, or there are intermittent, subtle and uncommonly irregular, finger movements. Investigations such as thyroid function tests, copper and caeruloplasmin, a urine metabolic screen and neuroimaging are normal. Whether this represents enhanced physiological tremor, the earliest presentation of essential tremor, or a mild form of dystonic tremor without other signs present, is unclear. However, it is prudent to follow these children over time.

ENHANCED PHYSIOLOGICAL TREMOR

All of us have a tremor which is usually only seen under conditions of stress, such as extreme fatigue, anxiety or after vigorous exercise. This is physiological tremor, an action tremor that takes the form of an oscillation of the outstretched hands at a frequency of 8–12Hz. Probably the commonest example of enhanced physiological tremor in childhood, is the child with severe asthma receiving intensive bronchodilator therapy. Other causes include thyrotoxicosis, hypoglycaemia, withdrawal syndromes and phaeochromocytomas. In a review of 110 cases of acquired thyrotoxic tremor identified over a 1-year period in the United Kingdom and Ireland, tremor was identified in 58% of children, and was the second most common sign, with only goiter (78%) being more common (Williamson and Greene 2010). No details of the nature of the tremor were provided. Fernández-Alvarez and Aicardi (2001) have seen children with intellectual disability, whose exaggerated physiological tremor was so intense in stressful situations, that the tremor seemed more disabling than the intellectual problems.

ESSENTIAL TREMOR

Essential tremor is typically a bilateral, largely symmetrical, postural or kinetic tremor, involving mainly the arms (Deuschl et al. 1998). The head and voice may also be involved. There is a paucity of literature on essential tremor in children, especially under the age of 10 years. Reflecting this, the authors have rarely made the diagnosis with confidence in a young child. Essential tremor was once seen as a straightforward diagnosis in adults, but despite the frequency of the diagnosis, and its apparently dominant inheritance, genetic studies have failed to identify a single causative gene. It seems likely to that essential tremor will be found to be a family of diseases, with some patients having underlying cerebellar dysfunction, and others a neurodegenerative process (Elbe and Deuschl 2011; Grimaldi and Manto 2013).

A number of conditions can produce a tremor that may be mistaken for essential tremor including hydrocephalus, hereditary and motor sensory neuropathies, Wilson disease and Klinefelter syndrome (Fernández-Alvarez and Aicardi 2001). Hyperthyroidism should also be considered.

PALATAL TREMOR

Palatal tremor was previously called palatal myoclonus, and is classified into symptomatic and essential forms (Deuschl et al. 1994). Symptomatic palatal tremor is usually seen in adults, and results from a stroke or other lesion involving the dentato-olivary pathway including polymerase-γ (POLG) mutations (Mongin et al. 2016). There may be hypertrophy of the inferior olivary nucleus which can be demonstrated on MRI. The palatal movement is produced by contraction of levator veli palatinii. There may be widespread jerks involving muscles of many areas, including the face and diaphragm. These are synchronous with the palatal movements. There are no ear clicks.

In essential palatal tremor, the movements result from contraction of tensor veli palatini. Ear clicks are commonly present, and the movements are restricted to the palate. There are no abnormalities of the inferior olivary nucleus. Campistol-Plana et al. (2006) reported four children with a mean age of 6 years with essential palatal tremor, and found there was a good response to piracetam. In some cases, essential palatal tremor appears to be a psychogenic disorder. Stamelou et al. (2012a) reappraised ten patients with isolated palatal tremor, and concluded that in seven of them, the problem was, in fact, psychogenic.
TREMOR IN SPINAL MUSCULAR ATROPHY AND NEUROPATHIES

Moosa and Dubowitz (1973) emphasised the diagnostic value of the presence of a tremor in children with what we now call types II and III spinal muscular atrophy (SMA). They found limb tremor to be more common than fasciculations of the tongue, a better known sign of SMA. The tremor was an action tremor present with outstretched hands, or noted during the manipulation of toys. Similar movements can also be seen in children with congenital neuropathies (Yiu et al. 2011) and in chronic inflammatory demyelinating neuropathy (Ouvrier et al. 1999). The movements are due to the firing of large motor units in muscles with chronic denervation and reinnervation (Riggs et al. 1983). They are not entirely rhythmic and terms such as ‘contraction fasciculations’ (Denny-Brown and Pennybaker 1938) have been used. Spiro (1970) describing children with SMA, called these movements ‘minipolymyoclonus’ a term coined by his colleague Dennis Giblin, and now confusing as it was subsequently used in the setting of epileptic myoclonus (Wilkins et al. 1985). Riggs suggested ‘contraction pseudotremor of chronic denervation’ might be the best term (Riggs et al. 1983).

OTHER DISEASES WITH TREMOR

Tremor is a common symptom of Wilson disease. In his original description Wilson noted: ‘In all my own cases tremor was one of the earliest symptoms, as it was one of the most marked’ (Wilson 1912). The wide range of manifestations of Wilson disease will be discussed in the Treatable Movement Disorders section.

Glucose transporter deficiency can cause a dystonic tremor. It will also be discussed in the Treatable Movement Disorders section.

CONDITIONS THAT CAN MIMIC TREMOR

In epilepsy partialis continua (EPC) there is continuous focal jerking of a body part, usually localised to a distal limb, occurring over hours, days or even years (Cockerell et al. 1996). Sometimes it ceases in sleep. Usually there is sufficient variability in timing and amplitude for the movements to be recognised as not a tremor, but there is a report in the adult literature of a man with EPC initially felt to have a parkinsonian tremor (Al-Hayk and LeDoux 2003). There are many causes of EPC, but if it is due to a focal cortical dysplasia there may be jerking that is localised, and no alteration of consciousness, causing potential diagnostic difficulty. Other causes include Rasmussen syndrome, viral encephalitis (including subacute measles encephalitis) and POLG1 mutations (Cardenas and Amato 2010). In these conditions, there is usually alteration of consciousness and intense seizure activity, taking the diagnosis away from tremor as a possibility.

Familial cortical myoclonic tremor with epilepsy (FCMTE) is a rare disorder which can be mistaken for essential tremor (Van Rootselaar et al. 2005; Licchetta et al. 2013). It is more common in adults, but the onset can be as early as 10 years of age. Typically, there is no tremor at rest but the tremor appears with posture and movement. The ‘tremor’ is actually the result of high-frequency myoclonic jerks of cortical origin. In the video of a case shown by Van Rootselaar, the jerking was mainly present in the fingers and hands. It was high-frequency, semi-rhythmic and of varying amplitude. It was stimulus sensitive and neurophysiology was consistent with a cortical reflex myoclonus. The inheritance of FCMTE is autosomal dominant. At the time of writing, the genetic abnormality has not been identified. Tremor is usually the first symptom, with epilepsy developing over time, typically generalised tonic-clonic seizures or prolonged myoclonic seizures.

Hereditary geniospasm (literally ‘chin spasm’) or chin quivering is a highly distinctive disorder involving the mentalis muscle of the chin. Typically, there is ‘up and down’ movement of the chin with quivering of the lip. The movements do not have the rhythmicity of tremor, rather they come in irregular bursts. They tend to be worse with anxiety. The movements can be quite strong and may give the impression that they emanate from the jaw. If there is significant social disability from the movements, botulinum toxin injections can quell them. In some families, as well as the cosmetic problems, severe tongue lacerations from nocturnal tongue biting can be a significant cause of disability (Jarman et al. 1997b). The inheritance is autosomal dominant.

TREATMENT OF TREMOR

Treatment of tremor in childhood generally depends on the underlying cause. Children with the mild, non-specific jerkiness described above, do not need treatment but require reassurance and observation. Holmes tremor is generally a very disabling problem due to destructive lesions involving the red nucleus and neural fibres originated in the cerebellum and substantia nigra. There are multiple causes including ischaemia, haemorrhage, trauma, metabolic disorders, infections, and neoplasms. L-dopa is helpful in some cases of Holmes tremor (Velez et al. 2002; Katschnig-Winter et al. 2015). Levetiracetam may also have a role (Ferlazzo et al. 2008). Surgery has also been used including ablative procedure such as subthalamic lesions in the fields of Forel, Vim thalamotomy, pallidotomy, and more recently DBS of the globus pallidus interna or ventralis intermedius nucleus of thalamus (Peker et al. 2008; Espinoza Martinez et al. 2015). Unfortunately, Holmes tremor in childhood is often the result of severe head trauma with diffuse brain injury, and there are limited options for treatment.
Myoclonus is a complex hyperkinetic movement disorder characterised by sudden, brief, involuntary jerks of a single muscle, or a group of muscles (Zutt et al. 2015). In negative myoclonus, rather than a sudden muscle contraction, there is sudden muscle inhibition with loss of tone, causing the affected limb to drop under the influence of gravity. In 1949, describing this phenomenon in patients with liver failure, Adams and Foley coined the term ‘asterixis’ from the Greek ‘sterein’ (to fasten or to support).

There are multiple ways of classifying myoclonus (Fahn et al. 1986; Caviness 2014; Zutt et al. 2015). These include: (1) its distribution, which can be focal or generalised; (2) its occurrence, that is, whether it occurs spontaneously, with movement, or in response to a stimulus; (3) its site of origin based on neurophysiology; and (4) its clinical aspects where it is divided into physiological, essential, epileptic and symptomatic. These categories often overlap.

The neurophysiological classification of myoclonus is complex and is based on techniques which are not widely used in children. Nevertheless, it is discussed here as frequent reference is made to it in the literature. It can be seen in terms of the following subdivisions: cortical, cortical-subcortical, subcortical-nonsegmental, segmental and peripheral (Caviness 2014).

Cortical myoclonus typically produces brief focal or multifocal electromyographic (EMG) bursts. The usual duration of the burst is less than 100ms. Cortical myoclonus can occur at rest but more typically occurs with movement (action myoclonus), or in response to various stimuli (reflex or stimulus sensitive myoclonus). The distal muscles of the arms, and the face, tend to be more obviously involved in cortical myoclonus, but all muscle groups can be affected. With cortical myoclonus, when a jerk occurs in the arms, back-averaging techniques reveal low amplitude cortical spikes 6–22ms before the jerk (Caviness 2014). The spikes are of too low amplitude to be detected on a routine EEG. Giant somatosensory evoked potentials are also often present with cortical myoclonus. As with dystonia, there is considerable interest in the role of the cerebellum in the genesis of cortical myoclonus (Ganos et al. 2014).

Causes of cortical myoclonus in childhood include mitochondrial diseases (such as MERRF), neuronal ceroid lipofuscinosis, Unverricht-Lundborg syndrome, Lafora body disease, sialidosis, and epilepsy partialis continua. In adults, cortical myoclonus is seen in parkinsonian syndromes such as corticobasal degeneration. Here, the myoclonus is distal, involving the fingers and may be unilateral. Although of cortical origin, this is not regarded as a form of epileptic myoclonus. With myoclonic epileptic seizures the jerks are often bilaterally synchronous, and are more prominent proximally.

Subcortical myoclonus has its origin between the cortex and the spinal cord. Caviness (2014) cites examples of subcortical myoclonus and the putative source: myoclonus-dystonia syndrome (basal ganglia); opsoclonus-myoclonus syndrome (brainstem-cerebellar circuits); reticulofugal reflex myoclonus (brainstem reticular formation); and propriospinal myoclonus (spinal cord). The electrophysiological characteristics of subcortical myoclonus are a burst duration of more than 100ms, and absence of cortical excitability (Zutt et al. 2015).

Brainstem myoclonus is characterised by abnormal activity starting in the brainstem and spreading in both rostral and caudal directions, producing bilaterally synchronous, generalised EMG bursts. The duration is longer than cortical myoclonus, being between 50 and 150ms. The burst usually first appears in the sternomastoid muscles, and then spreads up and down the neuraxis, giving a typical appearance when the EMG of multiple muscles is recorded. Clinically, there is bilateral synchronous jerking, with adduction of the arms, and flexion of the head and trunk, and at the elbows. Most jerks are induced by stimuli. Particularly potent in producing brainstem myoclonus are taps in the ‘mantle’ area – the nose, lips and head. However, the jerks can also be produced by loud noises and unexpected visual stimuli.

Brainstem myoclonus can be caused by similar insults to those that cause cortical myoclonus such as anoxia. Both cortical and brainstem myoclonus may appear in the same patient. There is overlap between brainstem myoclonus and startle syndromes such as hereditary hyperekplexia.

Spinal myoclonus is rarely seen in childhood. Spinal segmental myoclonus consists of rhythmic and repetitive, bilaterally synchronous, jerking at rates of 30–130 per minute. This is confined to one or two adjacent body segments, and is often caused by a structural lesion. In propriospinal myoclonus, there is orderly recruitment of muscles innervated by many spinal segments producing trunk flexion. It has been suggested that propriospinal myoclonus arises from a spinal generator, recruiting axial muscles up and down the spinal cord via long propriospinal pathways. However, there has been considerable controversy about this condition, and many patients carrying this diagnosis are thought to have a psychogenic disorder (van der Salm et al. 2010, 2014).

The term peripheral myoclonus is used in the setting of anterior horn cell disease and peripheral neuropathies. The bursts are typically of short duration (<50ms) and may be multifocal. The rather confusing term minipolymyoclonus is sometimes used in this setting. (This is discussed in the Tremor section.)

It is both the speed, and the brevity of the movements, which help to distinguish myoclonus from other movement disorders.
When the jerks are subtle, it may be difficult to separate myoclonus from fasciculations and myokymia (Espay and Chen 2013). Fasciculations are spontaneous contractions of muscle fibres supplied by a single motor unit. With myokymia there are involuntary, subtle, continuous, rippling and quivering movements of muscles. Both fasciculations and myokymia are usually of lower amplitude than myoclonus, and as a rule, unlike myoclonus, they do not alter the position of the body parts in which they occur.

Many causes of myoclonus are discussed in other parts of the book. Myoclonus dystonia is discussed in the Dystonia section; Benign Neonatal Sleep Myoclonus and Benign Myoclonus of Early Infancy in Chapter 16; myoclonic seizures and the progressive myoclonic epilepsies in the chapter dealing with seizure disorders; and opsoclonus-myoclonus syndrome in the Para-infectious Diseases chapter. As in previous sections, here we focus on a small number of clinically important causes of myoclonus.

### JERKING IN SLEEP AND DROWSINESS

Jerking movements as the child drifts off to sleep, and during sleep, are common in typically developing children. This is a frequent cause of concern for parents, who may not be reassured when simply told this is nothing to worry about, and the movements are unlikely to be epileptic.

The many types of jerking movements described in sleep can be confusing for those who are not specialists in sleep medicine, because of their number, and because different terms may be used for the same phenomena. The different types of jerks include rapid eye movement (REM)-related EMG activity, hypnic jerks (sleep starts), faciomandibular myoclonus, excessive fragmentary myoclonus, neck myoclonus and high-frequency leg movements (also known as hypnagogic foot tremor, and alternating leg muscle activation). Apart from REM-related EMG activity and hypnic jerks these are not common clinical problems in children, but they make us aware of the complexity of the movements that can occur in sleep.

### REM Sleep Related EMG Activity

In normal rapid eye movement (REM) sleep there is a profound inhibition of muscle tone, punctuated by bursts of myoclonic limb twitching. Parents are more likely to be reassured if they are informed that careful study has found these twitching movements are common in both humans and animals, and that they may be necessary for normal brain development. The twitches have been found to be a primary activator of neural networks throughout the central nervous system, and are thought to help instruct the brain about the rapidly developing body. (For a review, see Tiriac et al. 2015.)

### Hypnic Jerks (Sleep Starts)

With hypnic jerks there are usually one or two whole-body jerks which occur as the person is drifting off to sleep. Typically, there is simultaneous involvement of the muscles...
of the trunk and extremities. The abdominal muscles are not primarily involved. During EEG recordings, hypnic jerks can be seen when K-complexes appear, and during arousals (Vetrugno and Montagna 2011). Hypnic jerks can be associated with autonomic activation with transient tachycardia, tachypnoea, and sweating. There may be an associated feeling of sudden tipping backwards, which adults have likened to ‘falling downstairs, over a cliff and into a pit’ (Oswald 1959). At least five different motor patterns have been described with hypnic jerks (Calandra-Buonaura et al. 2014). Hypnic jerks seem to have a subcortical origin, but ‘the description of several physiological types of motor patterns for the same phenomenon leaves uncertainty on its features and pathophysiology’ (Calandra-Buonaura et al. 2014).

Hypnic jerks can occur in a brief cluster in normal people, due to a physiological oscillation between sleep and wakefulness during drowsiness, which has been called the ‘cyclic alternating pattern’ (CAP) (Serino and Fusco 2015). In children with neurological impairment there is a reduction in control of the CAP, and more prominent hypnic jerks may occur. Serino and Fusco (2015) have reported a 27-month-old child with epileptic seizures during sleep, characterised by initial short-lasting tonic posturing followed by hypomotor behaviour with autonomic signs. This child also had prominent jerks on going off to sleep which resembled hypnic jerks but were found to be epileptic in origin. Both the more obvious seizures, and the jerking when going off to sleep, stopped when carbamazepine was prescribed. The authors concluded that when what are thought to be hypnic jerks are clinically seen when K-complexes appear, and during arousals (Vetrugno and Montagna 2011). Hypnic jerks can be associated with autonomic activation with transient tachycardia, tachypnoea, and sweating. There may be an associated feeling of sudden tipping backwards, which adults have likened to ‘falling downstairs, over a cliff and into a pit’ (Oswald 1959). At least five different motor patterns have been described with hypnic jerks (Calandra-Buonaura et al. 2014). Hypnic jerks seem to have a subcortical origin, but ‘the description of several physiological types of motor patterns for the same phenomenon leaves uncertainty on its features and pathophysiology’ (Calandra-Buonaura et al. 2014).

Hypnic jerks can occur in a brief cluster in normal people, due to a physiological oscillation between sleep and wakefulness during drowsiness, which has been called the ‘cyclic alternating pattern’ (CAP) (Serino and Fusco 2015). In children with neurological impairment there is a reduction in control of the CAP, and more prominent hypnic jerks may occur. Serino and Fusco (2015) have reported a 27-month-old child with epileptic seizures during sleep, characterised by initial short-lasting tonic posturing followed by hypomotor behaviour with autonomic signs. This child also had prominent jerks on going off to sleep which resembled hypnic jerks but were found to be epileptic in origin. Both the more obvious seizures, and the jerking when going off to sleep, stopped when carbamazepine was prescribed. The authors concluded that when what are thought to be hypnic jerks are clinically stereotyped and/or hyperkinetic, a more detailed neurophysiological evaluation might be necessary.

A not uncommon clinical problem is the child who has had an event which might have been a seizure, and the parents then become aware of the child having hypnic jerks. In this setting, rather than blithely dismissing the parental concerns, getting a sleep EEG in the hope of recording the jerks is probably the most sensible way to proceed. Asking the parents to video an episode can also be helpful.

MYOCLONUS AND ENTEROVIRUS 71 INFECTIONS

Since it was identified in 1969, enterovirus 71 has caused epidemics in multiple parts of the developed and developing world (Ooi et al. 2010). Mostly it causes a mild illness, but in outbreaks there can be severe neurological sequelae. Typically, there is a prodrome lasting around 3 days, where there may be hand-foot-and-mouth disease or herpangina, with vomiting and fever, followed by neurological manifestations (Huang et al. 1999). (With hand-foot-and-mouth disease, there is a papulovesicular rash on the palms and soles, and multiple oral ulcers. In herpangina there are multiple oral ulcers that mainly affect the posterior pharynx.)

Multiple reports have noted a high incidence of myoclonus in children with enterovirus 71 infections (Ishimaru et al. 1980; Huang et al. 1999; Nguyen et al. 2014). The myoclonus appears to be subcortical on clinical and EEG grounds. Huang et al. (1999) described 41 children with neurological complications of enterovirus 71. They identified three neurological syndromes: (1) aseptic meningitis (three patients), (2) acute flaccid paralysis (four patients), and (3) rhombencephalitis (37 patients). (Three patients with rhombencephalitis went on to develop acute flaccid paralysis.) Myoclonus, which ranged in severity from mild myoclonic jerks during sleep, to very frequent myoclonus during both sleep and waking hours, was present in 32 patients (86%), and was the most common initial symptom. In seven patients there was transient myoclonus followed by the rapid onset of respiratory distress, shock, coma, loss of the doll’s eye reflex and apnoea. Five of these patients died within 12 hours of admission. Three of the patients with acute flaccid paralysis, had myoclonus and tremor before the onset of paralysis.

Myoclonus can be caused by other infectious diseases (see Table 19.8), but it seems to appear more commonly with enterovirus 71 infections. Therefore, in the child who presents with fever and myoclonus, with or without hand-foot-and-mouth disease or herpangina, the possibility of enterovirus 71 infection should be considered, and preparations made in case the child suddenly deteriorates.

MYOCLONUS AND ANTIBIOTICS

Many drugs can cause myoclonus (see Table 19.8). The beta-lactam antibiotics penicillin and the cephalosporins, may cause myoclonus as part of a generalised encephalopathy with lethargy, confusion, agitation, and coma (Grill and Maganti 2011). In this setting subtle myoclonus of the eyelids can be a clinical clue that the patient is in non-convulsive status epilepticus. With the cephalosporins, the risk seems higher if there is renal impairment. The possibility that the antibiotic is responsible for myoclonus and other seizures, may not be considered as the patient is often febrile and unwell, and may have structural abnormalities of the brain. Keskin and Konkol (1993) described a 3-year-old boy with hemimegalencephaly, who on three separate occasions when given antibiotics for a febrile illness, had a marked exacerbation of his pre-existing seizure disorder. On two of these occasions he was given oral cefadroxil, and on the other oral amoxicillin. During the exacerbations, the seizures lasted for 40–50 seconds and occurred up to 40 times a day. There was ‘clenching of the teeth and generalised tonus and myoclonus of the extremities, followed by respiratory irregularities’. In response to parental concern about the antibiotics being responsible, the child was given intravenous penicillin when well, and immediately had a tonic seizure.

When an antibiotic is responsible, myoclonus or generalised seizures usually develop within days of it being introduced (Bhattacharyya et al. 2016). The EEG is abnormal, showing epileptiform activity, triphasic waves or slowing. The symptoms settle a few days after the antibiotic has stopped. The mechanism appears to be inhibition of neurotransmission
at GABA\textsubscript{A} receptors, and consequent central excitotoxicity (Bhattacharyya et al. 2016).

Such reactions should be contrasted with Hoigne syndrome which is an acute, toxic, nonallergic reaction described following the intramuscular administration of procaine penicillin (Silber and D’Angelo 1985). The multiple potential manifestations of Hoigne syndrome occur almost immediately following the injection, and include abnormal taste and vision, hallucinations, a sense of impending death (angor animi) and generalised convulsions. There is then a rapid recovery.

**SEROTONIN SYNDROME (SEROTONIN TOXICITY)**

In the serotonin syndrome there is a classic triad of mental state changes, autonomic hyperactivity, and neuromuscular abnormalities (Boyer and Shannon 2005). Myoclonus can be a feature and has been seen in several reports of serotonin syndrome in childhood (Gill et al. 1999; Arora and Kannikeswaran 2010; Grenha et al. 2013). As well as myoclonus, a frequently described sign is clonus and hyper-reflexia which is much
more obvious in the legs than the arms. The clonus occurs spontaneously, and is also easily induced. In the child who is extremely agitated or has marked rigidity, these signs may be difficult to detect. In a severe case, serotonin syndrome is a medical emergency with hypertension, coma, shock, renal failure, rhabdomyolysis and respiratory failure occurring. Treatment is based on the severity of the symptoms, and begins with stopping the offending medication. Benzodiazepines, 5HT antagonist such as cyproheptadine, nitroprusside and ventilation with muscle paralysis may be required (Volpi-Abadie et al. 2013).

With the widespread use of selective serotonin reuptake inhibitors (SSRIs), it is important to consider serotonin syndrome in children with unexplained sudden encephalopathy. Symptoms usually begin within 24 hours of an increased dose of an SSRI, or the addition of another serotonergic agent. Rarely a single but relatively high dose of an SSRI can provoke serotonin syndrome (Gill et al. 1999). It is important to remember that there are a large number of medications that may unexpectedly have a serotonergic action (Volpi-Abadie et al. 2013). These can be unwittingly given to a child already on an SSRI. The medications include herbal supplements such as St. John’s Wort, over-the-counter cold remedies containing dextromethorphan, amitriptyline, ondansetron and narcotic agents including tramadol and pethidine. Certain combinations such as fluoxetine and carbamazepine, and fluoxetine and risperidone, seem to carry a higher risk of serotonin syndrome (Volpi-Abadie et al. 2013).

**TREATMENT OF MYOCLOONUS**

It is important to look for reversible causes of myoclonus such as a metabolic disturbance or a drug effect. Some epileptic causes of myoclonus respond well to sodium valproate and/or benzodiazepines. Epileptic negative myoclonus may be very responsive to ethosuximide (Oguni et al. 1998). Treatment of the progressive myoclonic epilepsies can be very difficult. A full discussion of the treatment of epileptic myoclonus can be found in Chapter 16. Often treatment of cortical forms of myoclonus involves polytherapy with sodium valproate, levetiracetam, piracetam and benzodiazepines used in various combinations. Botulinum toxin can be used for focal and segmental myoclonus. Treatment is based on the underlying cause and more detailed information can be found in the reviews of Kojovic et al. (2011), Caviness (2014) and Zutt et al. (2015).

As with most movement disorders the list of potential causes of myoclonus is huge. Table 19.8 lists some causes.

**EXCESSIVE STARTLE**

Sometimes it can be difficult to separate a startle response from myoclonus. A startle reaction is a normal response to a sudden fright. The stimulus may be a loud sound, or unexpected touch. Neurophysiology has revealed two components to the normal startle response (Brown et al. 1991). The first is a short latency reflex component that starts with an eye blink, and progresses down the body with generalised flexion of the head, trunk and limbs. The second component occurs up to a second later, and is a behavioural response that is influenced by the circumstances of the stimulus.

In a number of conditions, the startle response is enhanced. Hyperekplexia is a neurogenetic condition characterised by hypertonia that is predominantly seen in the trunk or lower limbs, and an excessive startle response easily provoked by touch or noise (Thomas et al. 2013). In severe cases, infants exhibit marked hypertonia from birth that only disappears during sleep. Umbilical and inguinal hernias are frequently present, and are probably the consequence of increased abdominal pressure due to sustained muscle contraction. Noise may precipitate intrauterine startle responses in some cases. The neonatal manifestations of the disease were initially reported as the ‘stiff baby syndrome’ or ‘congenital stiff-man syndrome’ before the condition was fully recognised. There is little or no habituation of the startle reflex. Tactile stimuli, particularly nose tapping are especially effective in provoking the response (Shahar et al. 1991). However, this can induce episodes of prolonged apnoea that require resuscitation, and can be fatal. In this situation flexion of the trunk may immediately relieve the spasm (Vigevano et al. 1989). From 12 months onwards there tends to be a spontaneous decrease in the generalised hypertonia but violent, often repetitive, jerks of the limbs on falling asleep may appear (Andermann and Andermann 1988). In older children unexpected noises can provoke sudden unprotected falls ‘en statue’ with injury. Developmental delay is not uncommon.

Hyperekplexia is caused by mutations in genes responsible for glycine neurotransmission. Two genes encode for subunits of the postsynaptic inhibitory glycine receptor GLRA1 (encoding the α1 subunit) and GLRB (encoding the β subunit) (Thomas et al. 2013). A third, SLC6A5, encodes the presynaptic glycine transporter 2. Further rare mutations have been identified in collybitin (ARHGGEF9) and gephyrin (GPHN) which are postsynaptic proteins involved in orchestrating glycineric neurotransmission (Rees et al. 2003). These rare mutations are associated with a more severe phenotype. Hyperekplexia was initially recognised as a dominant condition, but in a recent review of 97 cases, 84% showed recessive inheritance (Thomas et al. 2013). Most patients respond well to clonazepam, which may offer more relief from effects of the startle reactions, than the hypertonia (Tijssen et al. 1997).

An acquired hyperekplexic syndrome can be caused by autoimmune encephalitis, classically associated with glycine receptor antibodies. Other antibodies have also been described. It is more common in adults, but young children can be affected. They have an acquired excessive startle response plus rigidity, and sometimes seizures (Carvajal-González et al. 2014). Investigation other than serum and CSF autoantibody findings can be unremarkable, and it is
Part VIII  Movement Disorders

Syndrome can have unexpected falls with sudden tactile or auditory stimulation. They appear to be awake during the episodes, and in some cases the episodes have similarities to hyperekplexia (Hahn and Hanauer 2012).

Probably the most common type of exaggerated startle reaction in childhood is a psychogenic disorder. With psychogenic startle, on neurophysiology the latency of the response and its EMG signature conform to that of a voluntary movement, rather than a true reflex response (Pal 2011). To a degree the lag between the stimulus and the response can also be identified clinically.

Jumping induced by a startling stimulus has been known for a long time in various populations under exotic names such as ‘Jumping Frenchmen of Maine’, ‘latah’ or ‘myriachit’. (Tourette, in his famous 1885 paper, discussed these conditions as well as tics.) Saint-Hillaire et al. (1986) based on personal observation of eight cases of ‘Jumping Frenchmen’ believed the phenomenon was not a neurological disease, but could be explained in psychological terms as operant conditioned behaviour.

Important to recognise this condition as it is treatable with immune therapy.

Rarely children can present with the classic features of stiff-man syndrome, including lumbar lordosis, lower-extremity stiffness or spasms causing gait difficulties, and an exaggerated startle response (Clardy et al. 2013). An IgG specific for the 65-kDa isoform of glutamic acid decarboxylase (GAD65-IgG) is commonly detected. Children with stiff-man syndrome frequently have other auto-immune disorders especially diabetes mellitus. Symptomatic treatment with benzodiazepines and baclofen is often combined with immunosuppression.

In Tay-Sachs and Sandhoff disease, an exaggerated startle response may be the first sign of the onset of the disease (Adams and Lyon 1982). Hand clapping or other loud noises provoke a startle reaction. This continues to occur if the clasp is done multiple times in rapid succession that is, the response shows no adaptation. An excessive startle reaction can be seen as part of other degenerative diseases, such as Krabbe Disease and juvenile GM2 gangliosidosis. Patients with Coffin-Lowry syndrome can have unexpected falls with sudden tactile or auditory stimulation. They appear to be awake during the episodes, and in some cases the episodes have similarities to hyperekplexia (Hahn and Hanauer 2012).

Probably the most common type of exaggerated startle reaction in childhood is a psychogenic disorder. With psychogenic startle, on neurophysiology the latency of the response and its EMG signature conform to that of a voluntary movement, rather than a true reflex response (Pal 2011). To a degree the lag between the stimulus and the response can also be identified clinically.

In adults, parkinsonism is common and is usually caused by idiopathic Parkinson disease (PD). In paediatric practice, parkinsonism is a rare problem with many causes. The core clinical signs of Parkinson disease are bradykinesia, rigidity, tremor and postural instability (Jankovic 2008). All these signs can be seen in in children with parkinsonism. A distinction is made between bradykinesia meaning slowness of movement, and hypokinesia meaning a poverty of spontaneous movements, such as the immobile facial expression seen in adults with Parkinson disease (Berardelli et al. 2001). A typical feature of milder forms of parkinsonism is that with repeated performance of the same task (such as opening and closing the hand while touching the thumb against the fingers), there is a progressive decrement in the amplitude of the movement. As has been emphasised throughout this chapter, patients frequently have multiple movement disorders, and dystonia often coexists with parkinsonism in children.

Parkinsonism in children can be approached on the basis of whether the child presents in infancy or later.
Clinical Features

Although there are multiple causes, the clinical features of inborn errors involving dopamine metabolism are similar (Table 19.10). The signs substantially result from dopamine deficiency which in effect is a deficiency of both dopamine and noradrenaline (norepinephrine), as noradrenaline is formed from dopamine. Dopamine deficiency produces hypokinesia, rigidity, tremor, dystonia and oculogyric crises (Grattan-Smith et al. 2002). In addition, noradrenaline deficiency produces ptosis, miosis, profuse oropharyngeal secretions and possibly hypotension. The signs of noradrenaline deficiency may give the false impression that the infant has a neuromuscular disorder. Sometimes there is generalised hypotonia, further complicating the clinical picture. Many of the inborn errors cause both dopamine and serotonin deficiency. The clinical features of serotonin deficiency in infants are not as well established, but probably include disorders of sleep and temperature regulation.

The tremor of dopamine deficiency is typically slow and coarse. It does not usually have the ‘pill-rolling’ character that can be seen in adults with Parkinson disease. Tremor is not seen in all cases, but when present is a most important clue to the diagnosis. Tremor has been described with tyrosine hydroxylase deficiency (de Rijk-Van Andel et al. 2000), 6-pyruvoyl-tetrahydropterin synthetase deficiency (Factor et al. 1991), an undefined disorder of biotyper synthesis (Snyderman et al. 1987), with AADC deficiency (Korenke et al. 1991) and with sepiapterin reductase deficiency (Neville et al. 2005). They also occur, among other abnormalities of eye movement, in dopamine transporter (DAT) deficiency (DeRijk et al. 2006) and also with defects in the cycle adenosine monophosphate (AMP) regulatory component of the gene (Verbeek et al. 2007). The older boy presented at 2 years and 9 months with unexplained CP and had very frequent oculogyric crises that did not seem to trouble him. They disappeared soon after treatment with L-dopa was started. His younger sister had less prominent oculogyric crises but has found that as she is approaching adolescence, despite treatment with L-dopa, she still has occasional oculogyric crises which she finds distressing. Oculogyric crises are a particularly common sign in AADC deficiency (Brun et al. 2010) where they may last hours, and sepiapterin reductase deficiency (Neville et al. 2005). They also occur, among other abnormalities of eye movement, in dopamine transporter deficiency (Kurian et al. 2009). Dopa-responsive oculogyric crises have also been reported with ATP1A3 mutations (Termsarasab et al. 2015).

as CP. Treatment of parkinsonism in children can be dramatically effective, and it is important that, although the conditions are rare, children affected by inborn errors causing dopamine deficiency are correctly identified.

Neurotransmitter Pathways and CSF Analysis

It is likely that ‘gene panels’ will soon be available to identify the underlying cause in infants with parkinsonism, but at present the analysis of CSF neurotransmitter metabolites is the most useful initial test in suggesting the underlying cause.

Abnormalities of CSF pathways can be viewed in terms of defects in the pathways of the pterins, of dopamine and of serotonin (see Fig. 19.2).
Figure 19.2 Pathways in the synthesis and cataholm of dopamine and serotonin. GTPCH, GTP cyclohydrolase; 6PTPS, 6-pyruvoyltetrahydropterin synthase; SR, sepiapterin reductase; PCD, pterin a-carbinolamine dehydratase; DHPR, dihydropteridine reductase; TRYPH, tryptophan hydroxylase; 5HTP, 5-hydroxytryptophan; 7,8-BH2, 7,8-dihydrobiopterin; B6, pyridoxal 5’-phosphate. Reproduced from Hyland et al. (2007, vol 137, American Society of Nutrition, with permission.

The pterin pathway produces tetrahydrobiopterin (BH4) which is required for the conversion of phenylalanine to tyrosine, tyrosine to L-dopa, and tryptophan to 5-OH tryptophan. There are five steps in the pterin pathway where defects can cause a reduction in BH4. The relevant enzymes are (1) GCH1, (2) 6-pyruvoyl tetrahydropterin synthase, (3) sepiapterin reductase (SR), (4) dihydropteridine reductase (DHPR) and (5) pterin-4alpha-carbinolamine dehydratase. The two conditions that are of particular interest to neurologists are GCH1 deficiency and sepiapterin reductase deficiency. The other pterin disorders usually cause elevated phenylalanine levels, and are therefore detected by newborn screening, and tend to be managed by specialists in metabolic disorders.

Neopterin is generated by the action of GCH1. It is also released by macrophages, and is an immunological marker for the activation of the cell-mediated immune system. Elevated neopterin levels are non-specific, as they can be found in infections, and auto-immune and inflammatory diseases of the CNS (Huber et al. 1984; Dale et al. 2009). Biopertin and dihydrobiopterin (BH2) are the oxidative products of BH4.

There are two enzymes in the dopamine pathway whose deficiency produces infantile parkinsonism, tyrosine hydroxylase and AADC. With tyrosine hydroxylase there is pure dopamine deficiency, and its breakdown product homovanillic acid (HVA) is low in the CSF. With AADC both dopamine and serotonin are deficient. Therefore, both the breakdown product of serotonin, 5-hydroxyindole acetic acid (HIAA) and HVA are low in the CSF. In both conditions pterins are normal. At the time of writing, no inborn errors restricted to the serotonin pathway have been found to have a significant role in infancy (see also Table 19.9).

‘TRANSPORTOPATHIES’

Defects in monoamine transporter have been recently recognised, and are a further cause of parkinsonism in infancy. In dopamine transporter deficiency (DTD) there is a mutation in the SLC6A3 gene that encodes the presynaptic dopamine transporter (Kurian et al. 2009, 2011). This mediates the active reuptake of dopamine, and regulates the amplitude and duration of dopamine neurotransmission. The first report described infants presenting with irritability, hypotonia and feeding difficulties, as well as a movement disorder that was initially hypokinetic, and then evolved into a hypokinetic parkinsonism–dystonia picture. Unusual eye signs were a feature, including ocular flutter, saccadic abnormalities and oculogyric crises. As the disease progressed the children were severely affected with the development of dystonic crises, and life threatening episodes of status dystonicus. All patients became parkinsonian over time. Four of the 11 children had died.

In DTD, there is a raised ratio of HVA to HIAA in the CSF, a finding not seen in other neurotransmitter disorders. It appears to be explained by defective reuptake of dopamine into the presynaptic neuron. The result is an accumulation of extraneuronal dopamine, producing high CSF levels of HVA. The CSF HIAA levels remain normal, as the dopamine transporter does not affect the serotonin biosynthetic pathway.

Treatment of the severe forms of DTD is generally ineffective. Recently three brothers have been reported with DTD who presented at around 10 years of age with juvenile parkinsonism, having previously been normal (Ng et al. 2014). In these three boys, the response to L-dopa was not able to be assessed.

In vesicular monoamine transporter disease, there are mutations in SLC18A2 which encodes the dopamine-serotonin vesicular transporter. Rilstone et al. (2013) described eight individuals from a large family who presented with a loss-of-function mutation in this transporter. All children had global developmental delay, and presented with a picture of dopamine and serotonin deficiency. In one patient, CSF neurotransmitters were normal but in the urine, dopamine and noradrenaline levels were low, with HVA and 5-HIAA elevated. L-dopa treatment was given to four children, and within 1 week resulted in ‘major deterioration, with the appearance of intense chorea and worsened dystonia’. The dose used was not recorded in the article. There was a rapid return to baseline function when the medication was stopped. There was a good response to the dopamine agonist pramipexole, in particular in the parkinsonian features.
A second family has been reported by Jacobsen et al. (2016). Two brothers were severely delayed with profound immobility and bradykinesia. They required nasogastric feeding and orthopedic interventions for subluxation of the femoral heads and thoracic-lumbar scoliosis. They communicated with facial expression, vocalisation, a few words and limited use of a modified Makaton sign language. A 1-week trial of L-dopa at a dose of 1–2mg/kg three times a day in the older sibling, at age 3 years, was discontinued due to worsening of dystonia, however improvement in irritability, drooling and verbal communication was noted. At 14 years, he was given paramipexole, building to a dose of 0.5mg three times daily. He did not tolerate higher doses. Improvement in vocalisation and a reduction in the abnormal conjugate eye movements improved his communication and social interaction.

There was no improvement in his gross motor skills, and only a subjective small improvement in dystonia and parkinsonism. CSF neurotransmitters were initially normal apart from a subjective small improvement in dystonia and a reduction in the abnormal conjugate eye movements. Improvement in communication and social interaction. There was no improvement in his gross motor skills, and only a subjective small improvement in dystonia and parkinsonism. CSF neurotransmitters were initially normal apart from a subjective small improvement in dystonia and a reduction in the abnormal conjugate eye movements. Improvement in communication and social interaction.

Jacobsen et al. acknowledge that the dose of L-dopa they used was higher than recommended for dopamine deficiency disorders. It is possible that with vesicular monoamine transporter disease, starting dopamine in very low doses followed by a slow increase in dose, will prove beneficial as has been found in other causes of dopamine deficiency, as discussed below.

SECONDARY NEUROTRANSMITTER DISORDERS

There are many conditions where there can be abnormalities of CSF neurotransmitters, which seem to result from injury to, or malfunction of, neurotransmitter pathways, rather than inborn errors of their metabolism. Low CSF HVA with normal CSF 5-HIAA levels have been found in conditions such as Aicardi-Goutières syndrome (AGS), Lesch–Nyhan syndrome and Rett syndrome. (For a detailed list of the many secondary causes of CSF neurotransmitter abnormalities, see Ng et al. 2015.) Low CSF HIAA levels appearing in isolation are also a common, and perhaps non-specific finding. Ng et al. (2015) have also reported 15 children who had the typical profile of tyrosine hydroxylase deficiency in their CSF, but were negative for mutations both in the tyrosine hydroxylase gene and its promoter region. These children presented with neonatal apnoea, axial hypotonia and limb rigidity. Later they developed features of infantile parkinsonism–dystonia with dyskinesia, and some had oculogyric crises. There was a variable response to L-dopa therapy in this group, and relatively high mortality.

Treatment of Parkinsonism in Infancy

The response to treatment of inborn errors of dopamine metabolism varies according to the severity of the deficit, and the enzyme involved. AADC deficiency may be particularly difficult to treat (Brun et al. 2010; Helman et al. 2014.) This is understandable because the mainstay of treatment of other neurotransmitter disorders, L-dopa, cannot be converted to dopamine because of the enzyme deficit. There is also concern over the use of L-dopa in patients with AADC as it may cause further L-dopa accumulation, with consequent depletion of S-adenosylmethionine, the universal methyl donor (Marecos et al. 2014). Many patients with AADC deficiency receive combination therapy including a dopamine agonist, MAO inhibitor, pyridoxal-5’-phosphate and folic acid. This regime is often of limited efficacy, and as a result in a small number of patients, transfer of the human AADC gene into the putamen has been attempted using adeno-associated viral vectors (Hwu et al. 2012).

There have been excellent recent reviews that look at the complexities of treatment of paediatric neurotransmitter disorders (Roubertie et al. 2012; Marecos et al. 2014; Ng et al. 2015). Here we concentrate on broad principles. L-dopa is used particularly in the treatment of tyrosine hydroxylase deficiency, sepiapterin reductase deficiency and in the recessive forms of GCH1 deficiency which present in infancy (Furukawa et al. 1998; Nardocci et al. 2003). The major problem with the use of L-dopa in this setting is the development of severe dyskinetic reactions, even with low doses (Grattan-Smith et al. 2002; Pons et al. 2013). The initial dose of L-dopa (combined with a dopa-decarboxylase inhibitor) should be very low and it should be given in divided doses, for example a total of 0.3mg/kg/day given in four divided doses. To achieve this, dispersible forms of L-dopa such as Madopar Rapid can be used. The dose may then need to be slowly increased over many months.

If with an increase in dose, dyskinesia develops, then it is worthwhile returning to the previous dose, waiting a month or more and then making another attempt to increase the dose. The target dose may be in the realm of 10–15mg/kg of L-dopa per day, combined with a dopa-decarboxylase inhibitor (Grattan-Smith et al. 2002). In conditions where there is both dopamine and serotonin deficiency, the L-dopa can be combined with 5-hydroxytryptophan (5HT), a serotonin precursor. The dose of 5HT ranges from 1 to 16mg/kg and is also given in multiple fractions. 5-HT should be given at the same time as the L-dopa/dopa-decarboxylase inhibitor as this will also prevent its peripheral decarboxylation, reducing side effects and allowing more 5-HT to get into the brain (Roubertie et al. 2012).

PARKINSONISM APPEARING AFTER INFANCY

A list of the large number of potential causes of parkinsonism can be found in Table 19.11. Parkinsonism occurring after infancy is more easily identified than in infants. The history and investigations, in particular the MRI findings, may help
return to normality; (2) near normality; (3) a substantial but incomplete response and so on, supported by carefully performed before and after videos.) Unfortunately in a number of these conditions, although there may be a good initial response to L-dopa, this is then followed by the early onset of disabling dyskinesia, and progressive loss of efficacy. Neuronal intranuclear inclusion disease (NIID) typically begins in childhood but it can occur in adults. It is often a multisystem disorder, and may not be a single disease. Possible presentations include ataxia, seizures, autonomic dysfunction and parkinsonism. In children presenting before the age of 5 years, a rapidly progressive cerebellar syndrome is common (Sloane et al. 1994). In older children and adults, behavioural change, swallowing difficulties, parkinsonism and multisystem neurodegenerative features are more prominent. NIID may present with a picture of dopa-responsive parkinsonism (Lai et al. 2010). NIID is characterised pathologically by eosinophilic intranuclear inclusions in neurons of the central, peripheral and autonomic nervous systems, associated with varying degrees of neuronal loss (Malandrini et al. 1998). NIID can be diagnosed by rectal biopsy (Goutières et al. 1990). This does not need to be full thickness, but it should be remembered that the intranuclear inclusions may be found in as few as 10% of autonomic ganglion cells, and the biopsy must be of adequate size to include a sufficient number of these cells (Lai et al. 2010). Among those patients presenting with NIID and parkinsonism, a good initial response to L-dopa is soon followed by the development of dyskinesia and progressive loss of efficacy. Neuronal intranuclear inclusion disease (NIID) typically begins in childhood but it can occur in adults. It is often a multisystem disorder, and may not be a single disease. Possible presentations include ataxia, seizures, autonomic dysfunction and parkinsonism. In children presenting before the age of 5 years, a rapidly progressive cerebellar syndrome is common (Sloane et al. 1994). In older children and adults, behavioural change, swallowing difficulties, parkinsonism and multisystem neurodegenerative features are more prominent. NIID may present with a picture of dopa-responsive parkinsonism (Lai et al. 2010). NIID is characterised pathologically by eosinophilic intranuclear inclusions in neurons of the central, peripheral and autonomic nervous systems, associated with varying degrees of neuronal loss (Malandrini et al. 1998). NIID can be diagnosed by rectal biopsy (Goutières et al. 1990). This does not need to be full thickness, but it should be remembered that the intranuclear inclusions may be found in as few as 10% of autonomic ganglion cells, and the biopsy must be of adequate size to include a sufficient number of these cells (Lai et al. 2010). Among those patients presenting with NIID and parkinsonism, a good initial response to L-dopa is soon followed by the development of dyskinesia and lack of benefit (Paviour et al. 2005; Lai et al. 2010). Clues that bring the diagnosis of NIID to mind in a person with juvenile parkinsonism, include gaze-evoked horizontal nystagmus, oculogyric crises, severe dysarthria and blepharospasm.

PARKINSONISM-PYRAMIDAL SYNDROMES

In 1954 Davison described five patients with parkinsonism and pyramidal signs. The term pallido-pyramidal disease has been used for such patients. Parkinsonism-pyramidal syndrome seems a better term given the overall paucity of pathological examinations. Although some question the concept of parkinsonism-pyramidal syndromes (Horstink et al. 2010), it can be helpful clinically. When there is both parkinsonism and spasticity, conditions that should be considered include spastic paraplegia type 11 (SPG11), Kufor-Rekab syndrome, mitochondrial membrane protein associated neurodegeneration (MPAN), and FBX07 mutations (Table 19.13). Typically, onset is from 10 years of age onwards.

Mutations in the spastic paraplegia gene SPG11, which encodes spatacisin, cause an autosomal recessive disorder characterised by spastic paraplegia with a thin corpus callosum. There may be intellectual disability followed by progressive cognitive decline, peripheral neuropathy, pseudobulbar palsy and parkinsonism (Anheim et al. 2009). The parkinsonism may be responsive to L-dopa (Guidubaldi et al. 2011). FBX07 mutations (Park 15) cause an early-onset, progressive parkinsonism with associated pyramidal tract signs. In the initial report, spasticity was the first sign appearing in childhood, followed by the appearance of parkinsonism 5–20 years later in three of the ten patients (Shojaee et al. 2008). The response to L-dopa was variable, but one of the patients had a rapid response that was sustained for 4 years. In a subsequent paper describing four patients, parkinsonism was present as an initial sign with the age at onset being between 10 and 19 years (Di Fonzo et al. 2009).

TREATABLE MOVEMENT DISORDERS

There are a large number of neurological diseases that have no effective treatment, and the early recognition of a treatable problem is clearly a priority. Table 19.14 gives a list of some of the potentially treatable movement disorders. As has been our practice throughout this chapter, we will concentrate the discussion on a number of important causes.

Early recognition and treatment is always a goal, but many of these conditions are rare and difficult to diagnose, having diverse and unusual clinical manifestations. With advances in genetic technology, it is likely that there will be many children unexpectedly found to have a potentially treatable condition. The question will then arise as to whether they have been harmed by the delay in diagnosis? The concept that the earlier a treatment is given, the better will be the outcome, is intuitive and a belief that probably goes back to beyond recorded history. In this setting we need to be cautious, and certain that there is hard evidence that earlier treatment does make a difference, as the prospect that the delay has cost the child a chance of a normal life, is profoundly upsetting to both the parents and the treating doctors.

Glucose transporter deficiency syndrome (GTDS) is well-known as a treatable disorder and is discussed in detail below. It seems logical that early treatment with the ketogenic diet, using ketones as an alternative brain energy fuel to glucose, would produce a major difference in outcome. There is no doubt the ketogenic diet is very effective in stopping seizures (Alter et al. 2015), but long-term studies suggest it may not prevent intellectual disability (Alter et al. 2015; Fujii et al. 2016). Alter et al. (2015) reviewed 13 patients with GTD who had been followed for an average of 14 years, and found that earlier introduction of the ketogenic diet was associated with better outcome in motor skills, but not with improved intellectual and adaptive behaviour scores. The study included two children who started the ketogenic diet within the first months of life, yet had intellectual disability. The authors suggested that ketones may not be able to replace glucose metabolism in all its complexity, particularly in vulnerable regions such as the thalamus and cerebellum, with their diverse associated connections and circuits. They postulated that damage in infancy set the scene for the later development of dystonia, as a parallel to delayed onset dystonia after hypoxic injury to the infant. They speculated that the ketogenic diet, to be maximally effective, may need to be initiated in the neonatal period, which would require a newborn screening programme.

Treatable does not mean curable. Doctors who report improvement in their patients with a specific treatment have a duty to do this in a careful, detached, and scientific manner, and include long-term follow-up (van der Knaap and Kevelam 2014). As evidence of the enduring nature of the belief that early treatment makes a difference, we need go no further than to Machiavelli who, over 500 years ago, at a time when there was almost nothing in the way of effective treatment wrote: ‘for it happens in this as the physicians say it happens in hectic fever, that in the beginning of the malady it is easy to cure but difficult to detect, but in the course of time, not having been either detected nor treated in the beginning, it becomes easy to detect but difficult to cure’ (Machiavelli, The Prince 1513).
In anti-NMDA receptor encephalitis, antibodies are directed against the NMDAR. More than 90% of affected patients develop at least three of the following groups of symptoms within 1 month of disease onset: psychiatric disturbance, memory problems, speech disorder, seizures, dyskinesias, decreased level of consciousness, autonomic instability and hypoventilation (Armanigue et al. 2012; Titulaer et al. 2013). Facial dyskinesia can be a particular feature. There may be semi-periodic movements where the mouth opens and closes as though gulping, and the tongue protrudes (Kleinig et al. 2008). In young children the presentation can be with status epilepticus with the subsequent development of severe dyskinesias (Matoq et al. 2015). In a review of 577 patients, the MRI of the brain was abnormal in only 33% of patients. Abnormalities in the 

In auto-immune encephalitis, antibodies against cell surface neuronal proteins are diagnostic biomarkers. The antibodies target receptors and cell surface proteins involved in synaptic transmission, plasticity or neuronal excitability (Armanigue et al. 2012). Although the clinical manifestations can be severe, there may be a very good response to immunotherapy, and therefore it is important to try to recognise the nature of the encephalitis without undue delay. The spectrum of symptoms includes movement disorders, psychotic behaviour, memory loss, seizures and autonomic dysfunction.

a In the first column the condition is listed. In the second column, some brief diagnostic clues are given for those conditions not discussed in the text.

NMDAR, N-methyl-D-aspartate receptor.
CSF (79%) and in EEGs (90%) were more frequent (Titulaer et al. 2013).

Initial treatment of anti-NMDAR encephalitis usually consists of high dose corticosteroids, intravenous immunoglobulin and/or plasma exchange. However, because these treatments fail in 30–40% of the patients, rituximab is increasingly being used in combination with intravenous immunoglobulin and steroids (Dale et al. 2014). Rituximab and cyclophosphamide, alone or combined, are often used in adults. Because of the potential adverse effects of cyclophosphamide in children (including malignancies, infertility and premature gonadal failure), most paediatricians use cyclophosphamide only when the above treatments have failed. In these cases, cyclophosphamide is often effective. Approximately 80% of patients with anti-NMDAR encephalitis have substantial or full recovery with therapy. Early diagnosis and aggressive treatment seems more likely to produce a good outcome in this condition. However, as with other causes of auto-immune encephalitis, the retrospective and uncontrolled way that data has (by necessity) been collected, carries the possibility of bias (Nosadini et al. 2015).

There is a separate subgroup of patients with encephalitis and movement disorders who are negative for anti-NMDAR antibodies, and have symmetrical basal ganglia lesions on MRI, or have serum antibodies to the dopamine-2 receptor. This condition has been called auto-immune basal ganglia encephalitis (BGE) (Dale et al. 2012). These patients also respond to steroids and intravenous immunoglobulin (Fig. 19.5).

Mohammad et al. (2014b) compared the movement disorders found in anti-NMDAR encephalitis and BGE. Patients with Sydenham chorea were used as a comparison group. They found that a mixed movement disorder was common in both anti-NMDAR encephalitis and BGE. However, features that were more typical of anti-NMDAR encephalitis were repetitive orofacial movements, and violent thrashing and kicking movements. These movements were labelled ‘stereotypies’ and ‘motor perseveration’ because of their patterned and repetitive or ‘looping’ pattern. In the BGE group, akinesia and tremor were more common. Dystonia and chorea were seen in both anti-NMDAR encephalitis and BGE, and did not appear to be useful in separating the two conditions. As a very broad rule in separating the two conditions, if the child has a parkinsonian picture and bilateral inflammatory basal ganglia changes on MRI, BGE is the more likely diagnosis. If the patient has a hyperkinetic movement disorder and a normal MRI scan, then anti-NMDAR encephalitis is more likely.

**HASHIMOTO ENCEPHALOPATHY**

Hashimoto encephalopathy is an encephalopathy associated with positive anti-thyroid antibodies, and is generally corticosteroid-responsive. There are a large number of potential presentations including stroke-like symptoms, tremor, myoclonus, transient aphasia, sleep and behaviour abnormalities, hallucinations, seizures and ataxia (Armangue et al. 2012). In a survey from the United Kingdom that identified eight children, one had myoclonus and another tremor (Gayatri and Whitehouse 2005). The difficulty with this disorder is that the prevalence of anti-thyroid antibodies in children has not been well studied, and a response to steroids in an encephalopathic child is non-specific. Armangue et al. (2012) warn that it is not uncommon for patients with auto-immune disorders such as anti-NMDAR encephalitis to be initially misdiagnosed as Hashimoto encephalopathy, because of the presence of raised anti-thyroid antibodies.

**GLUCOSE TRANSPORTER DEFICIENCY SYNDROME**

In glucose transporter deficiency syndrome (GTDS) there is an abnormality of transport of glucose across the blood–brain barrier. It is usually caused by abnormal function of the enzyme GLUT1 which is encoded by the gene SLC2A1. As well as the primary mediator of glucose transport across the blood–brain barrier, GLUT1 also mediates glucose transport into and out of astrocytes, and into erythrocytes. Once an easily understood condition, GTDS has become increasingly complex with the recognition of a wide range of clinical manifestations. This is not surprising as there remains considerable uncertainty over the mechanisms of utilisation of glucose in the brain by neurons and glia. The metabolic pathways are complex with, for example, lactate once seen as a waste product of metabolism, being now regarded as not only an energy source but a signalling molecule (Benarroch 2014).

The early reports of GLUT1 deficiency described severely affected children with early-onset epilepsy, marked developmental delay, microcephaly and spasticity (De Vivo et al. 1991). Over time, it has become clear that movement disorders can be a feature of GTD, especially paroxysmal exertional dyskinesia (PED) (Suls et al. 2008). Many subsequent reports have described a combination of multiple forms of epilepsy, and different movement disorders in affected patients. A not uncommon situation is infantile onset epilepsy giving way to childhood-onset movement disorders (Alter et al. 2015).

Pons et al. (2010) found that dystonia and chorea were relatively common in patients with GTDS, as were intermittent ataxia, a spastic-ataxic gait and intention tremor. Dystonic tremor involving the limbs and voice has been reported (Roubergue et al. 2011). Hully et al. (2015) in a comprehensive review of French patients found that movement disorders were observed in all of 24 cases where adequate clinical information was available. Dystonia was found in 83% and chorea in 25%. Ataxia was found in 88%. The abnormal movements mostly affected the bucco-facial areas. Abnormal eye movements were found in 75% of patients, and included strabismus, paroxysmal rotatory or disorganised eye movements and abnormal saccades. In a further, retrospective review of 133 patients with GTDS, using family interviews and medical record reviews, abnormalities of eye movement were the second most common initial symptom after seizures (Akman et al. 2016). Manifestations included eye rolling, eye...
fluctuating, eyelid droopiness, frequent eye blinks, strabismus, opsoclonus, and limitation of upgaze.

Hully et al. (2015) found that focal seizures were the most prominent seizure type during the first year of life in GTDS. Subsequently, between 1 and 2 years, atypical absences (38%) and myoclonic seizures (52%) became more frequent. Myoclonic seizures tended to be associated with a worse long-term outcome.

The movement disorders of GTDS may worsen with fasting or infection. The presence of an exertion-induced movement disorder is a very strong clue to the diagnosis. Both DYT18 (PED) and DYT9 (paroxysmal choreoathetosis with episodic ataxia and spasticity) have been found to be due to SCL2A1 mutations (Klein 2014). In paroxysmal exertional dyskinesia (PED), typically after 5–30 minutes of vigorous walking, leg dystonia develops. (Other causes of PED include dopamine deficiency disorders such as GCH1 deficiency [Dale et al. 2010]. See Chapter 16 for a full review.)

Other periodic manifestations of GTDS include paralytic (especially hemiparesis), lethargy, confusion and migraine (Pearson et al. 2013). Haemolytic anaemia can also occur but is uncommon (De Giorgis and Vegiotti 2013). Prognathism may be a gestalt clue (De Giorgis and Vegiotti 2013).

The diagnosis of GTDS rests on paired CSF-serum glucose measurement and/or detection of SCL2A1 mutations. There can be problems with both and unfortunately, the diagnosis is not always straightforward.

Initial reports of GTDS described a low CSF glucose level of below 2.2mmols/L but higher levels were subsequently reported, especially in milder cases. (Even the units of glucose measurement vary and can cause confusion. In this chapter the values will be expressed in mmol/L. (To convert: 1mmol/L = 18mg/dl.) De Vivo’s group suggested that the laboratory hallmark is a CSF glucose which is usually less than 2.2mmols/L, but sometimes can be as high as 3.2mmols/L (Pearson et al. 2013). The CSF/blood glucose ratio is also used, but again there are different views about what is abnormal. In most cases the ratio is less than 0.4 but the cut off for normality has variously been set as between 0.45 and 0.6 (Leen et al. 2013a).

One of the difficulties in analysing CSF glucose and the CSF/blood glucose ratios was the lack of standardised data for age-related normal values. In response, Leen et al. (2012) using data obtained from between 4000 and 8000 patients, published standardised age-related data for CSF glucose, CSF/plasma glucose ratio and CSF lactate. They found that in normals, CSF glucose values were relatively lower in the first year of life. Between 6 and 11 months of age, the 10th centile value was 2.2mmols/L. Between 12 months and 9 years of age it was 2.6mmol/L, and from 10 to 17 years it was 2.7mmol/L. It became higher with increasing age.

Leen et al. (2013a) then analysed the CSF data of 157 patients with genetically proven GTDS, derived from 42 articles in the literature. The CSF glucose levels were below their 10th centile for age in all patients, and below the 5th centile for 143 of 147 patients (97%). The CSF to blood glucose ratio was below the 10th centile for 139 of 152 patients (91%), and was below the 25th centile for all patients with GTDS, except for one patient with an isolated paroxysmal exertion-induced dyskinesia. The CSF lactate level was never elevated in patients with GTDS.

The authors concluded that the typical GLUT1 deficiency syndrome profile was a CSF glucose level at or below the 10th centile, in combination with a CSF to blood glucose ratio at or below the 25th centile, and a CSF lactate level at or below the 10th centile. Apart from patients diagnosed with GTDS, this profile was found in only 0.9% of CSF samples present in their database. In addition, during a 2-year period their laboratory had received 104 requests for SLC2A1 mutation analysis on patients with a documented normal CSF glucose, and none had the mutation. The authors concluded that lumbar puncture should be the first step in the diagnostic workup of patients suspected of having GTDS, and that SLC2A1 mutation analysis should only be done when the CSF findings point to the diagnosis.

It is generally recommended that the lumbar puncture should be performed after a 4–6 hour fast with the blood glucose measured first, so that an elevated level caused by the stress of the procedure, does not add further difficulty with the interpretation of the CSF/plasma glucose ratio. Leen et al. (2013a) noted that the equilibration of glucose between plasma and CSF takes approximately 2–4 hours, and in their study with clinically relevant levels of hyperglycemia (i.e. plasma glucose 7.8–25mmol/L), the CSF glucose was linearly correlated with plasma glucose.

The genetics of SLC2A1 mutations is complex. In the study of Hully et al. (2015), in 58 patients there were 46 different mutations and 33 were novel. Most were point mutations or small one base insertions or deletions, including 29 missense, ten frameshift, four splicing and ten nonsense mutations. Overall, de novo heterozygous mutations in the SLC2A1 gene are the most common genetic finding in GTDS. Dominant inheritance occurs with Brockmann et al. (2001) reporting GTD affecting five members over three generations. Recessive inheritance has also been reported (Klepper et al. 2009). Not all patients who appear to have GTDS have been found to have SLC2A1 mutations (Klepper 2013).

Traditionally, treatment of GTD is with the ketogenic diet, which is a significant undertaking for the child and family, and not without complications. Other methods have been tried. Leen et al. (2013b) reported four patients with GLUT1 deficiency aged between 15 and 30 years who made a remarkable response to the modified Atkins diet. In a short-duration study, triheptanoin, an odd-chain triglyceride, has been shown to markedly decrease the non-epileptic paroxysmal manifestations of GTD (Mochel et al. 2016). It is of interest that, on multiple occasions, both adult patients with GTD and dystonic tremor described by Rouburgue et al. (2011), refused treatment with either carbamazepine or the ketogenic diet. As discussed above use of the ketogenic diet may not be able to prevent intellectual disability.
GTDS exemplifies problems that the clinician faces with potentially treatable conditions. It can present with almost any neurological symptom imaginable, including movement disorders, unusual eye movements, seizures and developmental delay. A history of fluctuating symptoms raises the possibility of GTDS, but these symptoms are commonly reported, and GTDS is rare, with an estimated frequency of $SLC2A1$ mutations in the Danish population of one in 83,000 (Larsen et al. 2015). Diagnosis requires the relatively invasive approach of a lumbar puncture, and/or genetic testing which is not readily available to most clinicians, and may be expensive and not always conclusive. Analysis of glucose uptake into erythrocytes has also been used in highly specialised laboratories (Yang et al. 2011), but this has not come into widespread use.

The clinician is left in a difficult situation as the diagnosis of GTDS can come to mind with a large number of children, yet very few, if any, will have it. Hopefully, in the future, this situation will improve with more readily available and sophisticated genetic testing. For the present, early-onset absence or myoclonic seizures, movement disorders especially PED, and intellectual difficulties are presentations where the diagnosis of GTDS should be suspected. In the retrospective review of Akman et al. (2016) only nine of 133 patients (7%) had first events reported after the age 2 years. This information may be helpful when the presentation is with epilepsy, but may not be as useful when it is with a movement disorder.

**CEREBRAL FOLATE DEFICIENCY**

In cerebral folate deficiency (CFD) low levels of 5-methyltetrahydrofolate (5MTHF) are found in the CSF in the presence of normal folate metabolism outside the nervous system (Ramaekers and Blau 2004). Two forms of CFD have been identified (1) Mutations in the folate receptor 1 ($FOLR1$) (Steinfeld et al. 2009) and (2) CFD due to autoantibodies to the folate receptor (Ramaekers et al. 2013).

We will discuss CFD due to mutations in $FOLR1$ gene first. In 2009, Steinfeld et al. reported an inherited brain-specific folate transport defect that was caused by mutations in the folate receptor 1 gene ($FOLR1$), coding for folate receptor alpha. Three patients carrying $FOLR1$ mutations developed a progressive movement disorder, psychomotor decline, and epilepsy with onset in the second year of life. All had low MTHF levels in their CSF and they responded to treatment with folinic acid (a 5-formyl derivative of tetrahydrofolate). MRI revealed profound hypomyelination. Cario et al. (2009) also described a brother and sister with $FOLR1$ mutations, with the older brother more seriously affected. Pérez-Dueñas et al. (2010) reported a boy with homozygous $FOLR1$ mutations adding more detailed clinical information. Progressive ataxia developed in the second year of life, with a broad-based gait, instability and jerky tremor in the upper limbs. At the age of 26 months, he had continuous and generalised choreic movements, and multiple, asynchronous myoclonic jerks which prevented him from standing or walking. Tonic-clonic seizures and cognitive decline were also features. Folinic acid (30mg/day) completely controlled the seizures within a month, and significantly reduced the myoclonic jerks and chorea. Consistent with the timing of the onset of symptoms, MRI showed diffuse abnormalities of the myelination of the white matter of the cerebral hemispheres, but with preservation of the myelin that had been deposited early in life.

Grapp et al. (2012) found mutations in $FOLR1$ in ten patients who presented in a similar fashion to the previously described cases. There was developmental regression, often with autistic features, seizures and ataxia. MRI revealed profound cerebral hypomyelination and cerebellar atrophy. Inheritance was autosomal recessive. The age at onset was mainly in the first 2 years of life. The seizure disorder was severe with frequent myoclonic, atonic and tonic-clonic seizures, as well as episodes of status epilepticus. Two older patients, aged 13 and 15 years, respectively, had a severe polyneuropathy. One mildly affected patient showed a very good response to folinic acid treatment.

Although rare, $FOLR1$ mutations need to be considered in children with the combination of regression, seizures, ataxia and movement disorders. Particular clues are (1) onset in the second year of life, and (2) extremely low CSF concentrations of 5MTHF, separating this from the more common non-specific reduction seen in multiple different conditions (Pérez-Dueñas et al. 2010; Grapp et al. 2012). For example, in the patient described by Pérez-Dueñas et al., the CSF concentrations of 5MTHF was 2nmol/L with a normal range of 48–127nmol/L.

The other form of CFD is due to autoantibodies. Ramaekers et al. (2013) have described a number of clinical syndromes due to autoantibodies to the folate receptor. In the infantile form, onset is from around the age of 4 months with marked irritability, sleep disturbance, poor developmental progress, deceleration of head growth, ataxia, dyskinesia and spastic paraplegia. Seizures develop in about one-third. The full-blown clinical picture does not manifest until the age of 2.5 years. In undiagnosed cases, visual disturbance begins around the age of 3 years and leads to progressive visual loss, while progressive hearing loss occurs from the age of 6 years. Other presentations include (1) a spastic ataxic syndrome after the age of 1 year without cognitive impairment; (2) infantile autism with and without other neurological deficits; and (3) progressive dystonia or schizophrenia in adolescence or early adulthood.

Elevated levels of folate receptor autoantibodies have been reported in as many as 50–75% of children with autism spectrum disorder (ASD) (Frye et al. 2013; Ramaekers et al. 2013). Frye et al. (2013) found that folate receptor autoantibodies were present in 75% of 93 children with ASD, but only a third of these children improved when given folinic acid orally. Complicating the picture is that higher levels of milk intake have been found to be associated with an increased risk of having folate receptor autoantibodies, but without clear abnormalities of folate function (Berrocal-Zaragoza et al. 2009).
A difficulty with the diagnosis of CFD is that there are many causes of low CSF MTHF levels including perinatal asphyxia, infection and conditions such as Rett syndrome (Pérez-Dueñas et al. 2011). Pérez-Dueñas et al. (2011) found that low CSF 5-MTHF levels were relatively common, and most often represented a non-specific manifestation of neurological dysfunction, rather than a disorder of folate transport or metabolism. Mangold et al. (2011) came to the same conclusion believing low CSF 5-MTHF levels frequently represent a final common pathway of different mechanisms that impair CNS metabolism, rather than a specific disorder. Willemsen et al. (2005) have also expressed similar doubts. Therefore, at the time of writing there is uncertainty over the incidence and boundaries of CFD caused by autoantibodies. Nevertheless, it is a potentially treatable condition that needs to be kept in mind.

The recommended treatment of CFD is folic acid in doses at 0.5–3mg/kg/day (Ramaekers et al. 2013), with the doses of 3–5mg/kg/day suggested for mutations in the FOLR1 gene (Steinfeld et al. 2009). Supplementation with folic acid is contraindicated as it may exacerbate the CSF 5MTHF deficiency (Hyland et al. 2010). If a low CSF 5MTHF has been found, even if it is thought to be a non-specific finding, it seems prudent to consider a trial of treatment with folinic acid.

BIOTINIDASE DEFICIENCY

Biotin is a cofactor for the human carboxylases, and biotinidase cleaves biotin from biocytin allowing it to be recycled. With biotinidase deficiency there is a variable inability to recycle biotin. There is resultant dysfunction of: (1) pyruvate carboxylase resulting in accumulation of lactic acid and alanine; (2) propionyl-CoA carboxylase, (3) 3-methylcrotonyl-CoA carboxylase, and (4) acetyl-CoA carboxylase which result in the accumulation of multiple organic acids (Wolf 2011). Many countries have newborn screening programmes for the early detection of biotinidase deficiency. It also does not typically cause a movement disorder, but it may cause basal ganglia calcification (Schulz et al. 1988), and radiological abnormalities of the caudate, putamen and basal ganglia (Wolf 2011). It is a condition where early diagnosis and treatment can make a great difference, and therefore it will be discussed here briefly. There are a wide range of clinical manifestations of biotinidase deficiency including respiratory problems (stridor, apnoea and hyperventilation), feeding difficulties, early-onset seizures which are difficult to treat (tonic-clonic, myoclonic or infantile spams), hypotonia, ataxia, cognitive deficits, immunodeficiency, optic atrophy and sensorineural hearing loss (Wolf 2011, 2013). The presence of alopecia, often combined with atopic and seborrhoeic dermatitis, is a particular clue, but is not always present. Older individuals may present with sudden visual loss, optic neuropathy and spastic paraparesis and may be thought to have multiple sclerosis or neuromyelitis optica (Bottin et al. 2015). The patient described by Bottin et al. (2015) was an athletic young adult who had previously been completely normal.

Metabolic findings in biotinidase deficiency include increased lactate in blood and CSF and increased serum ammonia. There may also be a compensated metabolic acidosis. There are increased quantities of organic acids in the urine, including, in particular, elevated 3-hydroxyisovalerate, which strongly points to the diagnosis (Wolf 2011). However, metabolic abnormalities are not always found, especially in young children. Treatment is with biotin 5–10mg orally per day. Higher doses have been used.

THIAMINE TRANSPORTER-2 DEFICIENCY

Thiamine transporter-2 deficiency (TTD) (previously known as biotin responsive basal ganglia disease) is a recessive disorder that should be suspected when there are recurrent episodes of subacute encephalopathy, especially when combined with MRI lesions in the caudate and putamen. It was first reported by Ozand et al. (1998) in ten patients of Middle Eastern origin, but it has been found to affect multiple ethnic groups (Debs et al. 2010; Yamada et al. 2010). Typically, onset is around the age of 3–4 years. The episodes may be provoked by a viral illness. Manifestations include confusion, eye movement disorders, dystonia, ataxia, feeding difficulties and seizures. Untreated, the child may die or be left with generalised dystonia and epilepsy. The typical MRI findings include abnormalities of the central part of the head of the caudate, and part or all of the putamen (Ozand et al. 1998; Alfadhel et al. 2013). However, the abnormalities may be widespread, and include abnormal signal change bilaterally in the thalamus, globus pallidus, white matter, brainstem and cortex (Alfadhel et al. 2013; Kevelam et al. 2013).

Over time other presentations of TTD have been found including onset of intractable seizures in the first year of life, combined with symmetrical bilateral abnormalities of the caudate, putamen and thalamus (Yamada et al. 2010); a Leigh-like syndrome in infants (Kevelam et al. 2013; Ortigoza-Escobar et al. 2014); adults with seizures and a picture of Wernicke's encephalopathy with bilateral MRI abnormalities in the medial thalamus and periaqueductal region (Kono et al. 2009); and a 15-year-old girl presenting with rapid onset prosis, progressive ophthalmoplegia and fatigue, whose MRI revealed bilateral signal changes in the caudate nuclei and putamen, combined with periaqueductal abnormalities (Fassone et al. 2013). Another child presented at age 4 years with paroxysmal dystonia that went on to become a generalised dystonia (Ortigoza-Escobar et al. 2014).

In the original paper of Ozand et al. (1998), most children responded very well to biotin. However, there was one child who did not make a good response. Another child was given
thiamine as part of a ‘vitamin cocktail’ (the dose was not given in the paper), and did not appear to have a beneficial response. Subsequent studies have established that the condition is caused by mutations in SLC19A3, encoding hTHTR2, one of two enzymes that transport thiamine into the brain (Zeng et al. 2005). Hence the name thiamine transporter-2 deficiency (TTD) is appropriate.

SLC19A3 only transports thiamine, and it is not clear why biotin is beneficial in some children. Lack of biotin reduces the expression of SLC19A3 (Vlasova et al. 2005). Tabarki et al. (2015) have suggested that high dose biotin may increase the activity of the multiple carboxylases for which it is a cofactor, resulting in an overall improvement of the energy production system, which is impaired in thiamine deficiency. It has become clear that biotin alone should not be given to children with TTD. In the study of Alfadhel et al. (2013), six of the 18 patients had recurrent crises when treated with biotin alone, but after the addition of thiamine, the crises stopped (Alfadhel et al. 2013). In a subsequent study of children with TTD, ten were given biotin plus thiamine, and ten were given thiamine alone (Tabarki et al. 2015). The mean age was 6 years in both groups. There was no difference in outcome between the two groups in the number of recurrences, the neurological sequelae, or the brain MRI findings. The only difference was the duration of the acute crisis which lasted 2 days in the first group and 3 days in the second. Given that biotin may have an additive non-specific effect, an approach would be to give both thiamine and biotin at the time of initial presentation, and thiamine alone after a month or so. The dose of thiamine is between 10–40mg/kg/day (Ortigoza-Escobar et al. 2014) with Tabarki et al. using 40mg/kg/day for all 20 children. The dose of biotin that has been used has varied between 1–12mg/kg/day.

Ortigoza-Escobar et al. (2014) have recommended that a trial of thiamine should given to every child presenting with acute dystonia. Because of the diversity of clinical presentations this should be extended to any child who, on clinical or radiological grounds, has a picture suggestive of Leigh syndrome (Fig. 19.9) or Wernicke encephalopathy. Probably both thiamine and biotin should be used acutely. While awaiting genetic confirmation the finding of extremely low levels of free-thiamine in the CSF may be a useful clue to the diagnosis (Ortigoza-Escobar et al. 2016).

**GLUTARIC ACIDURIA TYPE 1**

(GLUTARIC ACIDEMIA TYPE 1)

Glutaric aciduria type 1 (GA-1) is an autosomal recessive disorder of amino acid metabolism caused by the deficiency of glutaryl-CoA dehydrogenase activity. The typical biochemical findings are the accumulation of glutaric acid, 3-hydroxyglutaric acid, glutaconic acid and glutaryl carnitine in the blood, urine, CSF and brain tissue (Funk et al. 2005; Köller et al. 2011). Untreated, approximately 90% of patients will sustain severe neurological damage in an acute encephalopathic crisis which is often precipitated by febrile illnesses, immunisation, or surgery (Kölker et al. 2011). In the review by Köller et al. (2007) of 185 symptomatic patients, most had had crises, and these occurred at a median age of 9 months (range 1–37 months). Ninety-five per cent of the crises occurred by 2 years of age.

Following such crises there is destruction of the caudate and putamen and severe damage to the child, who is left permanently incapacitated with dystonia and other movement disorders, and sometimes spasticity. Intelligence may be preserved. Treatment after a crisis is usually not effective, and the emphasis is on trying to diagnose the condition before these occur. Many countries have newborn screening programmes for this reason.

Macrocephaly is an important clue to the diagnosis of GA-1. It may be present at birth, or there may be rapid head growth in the first few months of life (Kyllerman et al. 1994). In the review by Köller et al. (2007), of a total of 279 patients found to have GA-1 by various methods, more than 70% had macrocephaly. There may also be non-specific features such as irritability and slight delay in reaching milestones. Benign macrocephaly (known by many names including benign enlargement of the subarachnoid spaces) is common whereas GA-1 is rare. The presence of widening of the anterior temporal and sylvian CSF spaces is typical of GA-1, and has been given many names including temporal hypoplasia, frontotemporal atrophy and a ‘batwing’ appearance (Harting et al. 2009). This appearance is not specific, and can be seen in otherwise normal infants (Amit et al. 1990). However, given the consequences of delayed diagnosis, screening for GA-1 should be performed if there is any doubt.

The combination of macrocephaly, the characteristic widening of the opercula, and basal ganglia lesions, has been regarded as pathognomonic for GA-1 (Kyllerman et al. 1994; Brismar and Ozand 1995). The widening of anterior temporal and sylvian CSF spaces was felt to be evidence of early-onset damage in GA-1, before any crises occurred. However, in patients diagnosed before symptom onset and treated, these findings can regress (Harting et al. 2009). The widening of the extra-cerebral spaces may predispose to the development of subdural haematomas (Osaka et al. 1993), and a misdiagnosis of child abuse.

Apart from the crises, there are other presentations of GA-1. Kyllerman et al. (1994) found that a slowly progressive dyskinetic, dystonic disorder, or a motor incoordination syndrome with attentional problems, developed in 25% of cases. Strauss et al. (2007) identified six children in whom hypotonia of the trunk was recognised between 2 and 3 months of age, independent sitting was delayed, and a movement disorder emerged gradually between 4 and 6 months of age. They were found to have abnormalities of the caudate and/or putamen in what was described as an ‘insidious’ onset.

Onset beyond the first 3 years of life, and in adults, has also been described with GA-1. Fernández-Alvarez et al. (2003) described a 16-year-old girl with GA-1 who presented with a 3-year history of hand tremor with dystonic posturing of the left arm, and some mild developmental
problems. She did not have a large head, but MRI scan revealed bilateral injury to the putamen and diffuse white matter changes more prominent frontally (Fig. 19.10). White matter abnormalities are a common finding in late-onset GA-1, and it is usually the MRI abnormalities that point to the diagnosis. (For a review, see Fraidakis et al. 2015.)

As well as the three most important radiological signs of GA-1 (widening of the operculum, abnormalities of the caudate and putamen and diffuse white matter changes), there may be other abnormalities. These have been summarised by Harting et al. (2009) in a study of 38 patients. Delayed myelination, may be present early on. Harting et al. also found that abnormalities of the globus pallidus were present in half the patients. These occurred in combination with striatal changes following a crisis, or as isolated lesions in patients without crises. Other structures involved were the substantia nigra (16%), dentate nuclei (11%) and thalamus (5%).

Treatment of GA-1 is the domain of metabolic specialists and will only be briefly mentioned. It consists of a low lysine diet with lysine-free, tryptophan-reduced acid supplements, carnitine supplementation and emergency treatment of any illness that has the potential to provoke a crisis (Kölker et al. 2007).

CEREBROTENDINOUS XANTHOMATOSIS

Cerebrotendinous xanthomatosis (CTX) is a recessive disorder due to a mutation in the gene CYP27A1 resulting in a deficiency in the enzyme sterol 27-hydroxylase. This plays a key role in the conversion of cholesterol to bile acids (Cali and Russell 1991). Elevated levels of cholestanol are found in the plasma. The development of signs is highly variable, and neurological symptoms may not appear until the second or third decade. The early clinical course may be characterised by mild to moderate developmental delay, and intractable diarrhea. In the second stage of the disease, there are bilateral cataracts, sometimes associated with optic atrophy, xanthomas and neurological deterioration (Cruysberg et al. 1995). Neurological problems include ataxia, pyramidal signs, dementia, epilepsy and polynuropathy. There may also be premature atherosclerosis and osteoporosis. Movement disorders such as parkinsonism, oromandibular dyskinesia and myoclonus are usually seen in adults with CTX (Alcalay et al. 2009; Lagarde et al. 2012; Rubio-Agusti et al. 2012). A slowly progressive spinal syndrome may also be seen in adults (Verrips et al. 1999).

MRI findings can be helpful in suggesting the diagnosis of CTX. The earliest and most frequent MRI abnormality is high signal intensity of the dentate nuclei on T2-weighted images (Barkhof et al. 2000). Other grey matter nuclei, including the globus pallidus, substantia nigra and inferior olive can also be involved. MRI may also demonstrate the Achilles tendon swelling. Treatment is with chenodeoxycholic acid which strongly decreases the levels of toxic intermediary bile acids. Early recognition and treatment reduces the risk of permanent neurological sequelae (Yahalom et al. 2013). Mignarri et al. (2014) have developed a ‘suspicion index’ to aid in the diagnosis of CTX, which gives a weighting to the signs described above.

WILSON DISEASE

Wilson disease is an autosomal recessive condition caused by mutations in the ATP7B gene (Patil et al. 2013). This encodes a copper-transporting P-type ATPase involved in both the incorporation of copper into caeruloplasmin, and biliary copper excretion. ATP7B mutations result in an absent or non-functional ATPase with defective synthesis of caeruloplasmin, and defective biliary copper excretion. Copper accumulates in the liver, the brain, and multiple other tissues producing an extraordinary range of clinical features. More than 500 different mutations have been described in the Wilson gene, with 380 having a confirmed role in the pathogenesis of the disease (European Association for the Study of the Liver [EASL] 2012).

In childhood, Wilson disease usually presents with liver disease. The signs of liver disease are not specific, and it is recommended that ‘any liver disease of unknown origin should be considered as Wilson disease until proved otherwise’ (EASL 2012). Liver disease carries the risk of sudden deterioration and fulminant hepatic failure. Other presentations include haemolysis (Czlonkowska 1972), which may be followed by liver failure (Saito 1987). There are many unusual manifestations of Wilson disease. These are described in the recent EASL review (2012). They include gigantism, renal disease including aminoaciduria, nephrolithiasis, hypercalciuria and nephrocalcinosis, and other problems such as cardiomyopathy, myopathy, chondrocalcinosis and osteoarthritis, hypoparathyroidism, pancreatitis, infertility and repeated miscarriages.

Traditionally the neurological presentation of Wilson disease has been subdivided into four different forms: (1) akinetic-rigid, (2) ‘pseudosclerosis’ dominated by tremor, (3) dystonic, and (4) ataxic. However, such is the variability of symptoms that it has been said that every patient with Wilson disease has their own unique movement disorder. In a review from Brazil of 119 patients with Wilson disease, with a mean age at symptom onset of 19.6 years, the following symptoms were observed: dysarthria (91%), gait disturbance (75%), risus sardonicus (72%), dystonia (69%), rigidity (66%), tremor (60%) and dysphagia (50%) (Machado et al. 2006). Less frequent manifestations were chorea (16%) and athekstis (14%). Seizures (4%) and pyramidal signs (3%) were not commonly seen.

Risus sardonicus results from dystonic involvement of the facial and oral muscles, producing retraction of the upper lip and mouth opening. It is well demonstrated in
the illustrations that go with Wilson’s 1912 paper, and may be accompanied by a generally apathetic facial expression. (Risus is the Latin word for laughter, and sardonicus refers to Sardinia. An explanation of this term favoured by Wilson is that it derived from eating the Sardinian ranunculus. Pausanias, in the second century AD, wrote of Sardinia: ‘The whole island if free of lethal drugs except one weed; the deadly herb looks like celery, but they say if you eat it you die of laughing’ (Giddens 2009). Risus sardonicus is also used to describe the facial expression in tetanus and strychnine poisoning.)

The classic tremor of Wilson disease is a high amplitude proximal tremor, seen when the fingers are held close to the nose, with the shoulders abducted and elbows flexed, giving a ‘wing-beating’ appearance. Other tremors seen in Wilson disease include a rest tremor, intention tremor, and an action tremor when trying to write or drink from a cup (Hoogenraad 1996).

The wide range of potential manifestations of Wilson disease is illustrated by the report of a 9-year-old child of presenting with transient hemiparesis and encephalopathy (Carlson et al. 2004), and a 22-year-old man who developed oxcarbazepine-responsive paroxysmal kinesigenic dyskinesia after treatment started (Micheli et al. 2011).

Wilson disease can also present as a primarily psychiatric problem such as deteriorating school performance, combined with personality and behaviour changes. Zimbren and Schilsky (2014) reviewed the recent literature on Wilson disease, and found nine children aged 16 years or younger where the initial presentation was with psychiatric symptoms. These included psychosis, suicide attempts, mania, severe depression and obsessive compulsive disorder. Psychiatric symptoms commonly develop during treatment and may be related to the treatment, the progression of the disease, or to the emotional impact of suffering from a chronic disease.

If the diagnosis of Wilson disease is suspected, there must always be a search for the presence of Kayser–Fleischer rings which are caused by deposition of copper in Descemet’s membrane of the cornea. These are almost always found when Wilson disease presents with neurological or psychiatric problems (Patil et al. 2013). However, they are not specific for Wilson disease, and may appear in other causes of liver disease. A rarer ophthalmological complication is the presence of sunflower cataracts.

Initial investigations in the diagnosis of Wilson disease include the measurement of serum copper and caeruloplasmin. The concentration of caeruloplasmin is usually between 0.2–0.4g/L in typically developing individuals. In Wilson disease, it is usually lower than 0.1g/L (EASL 2012). The serum copper is usually decreased in proportion to the decreased caeruloplasmin in the circulation. Free copper is usually elevated. Wilson disease patients with neurological symptoms usually have some degree of liver disease at presentation (EASL 2012). Urinary excretion of copper is a very useful test, and in children baseline copper excretion of greater than 40µg/24 hours is highly suggestive of Wilson disease (Patil et al. 2013). (In adults the number is greater than 100µg/24 hours.) The 24-hour urinary copper excretion can also be used in monitoring the effect of treatment.

Caution needs to be exercised in the interpretation of these tests. Caeruloplasmin levels can be low with other causes of liver disease, with malabsorption such as in coeliac disease, in familial aceruloplasminemia, and in heterozygotes for Wilson disease (EASL 2012; Patil et al. 2013). With acute liver disease, the caeruloplasmin can be in the normal range. If there is no liver disease, the 24-hour urinary copper excretion may be in the normal range in Wilson disease.

Approximately 20% of Wilson disease heterozygotes have decreased levels of serum caeruloplasmin (EASL 2012). This can cause diagnostic difficulties if the child, for example, has a mild non-specific tremor. In this setting, if the MRI scan and 24-hour urinary copper are normal, and there are no Kayser–Fleischer rings, then Wilson disease is unlikely. Urinary copper excretion is higher in heterozygotes than in controls but it rarely exceeds the normal values (EASL 2012).

Kim et al. (2006) reviewed the MRI findings of 50 patients with Wilson disease. The mean age of the patients was 10.2 years, with an age range of 3–16 years, meaning the patients represented a paediatric population. There were three groups based on the initial MRI findings. In Group 1 there were 23 children where the MRI was normal. In Group 2 there were 15 children where the MRI showed increased signal intensity in the globus pallidus on T1-weighted images. T1-weighted abnormalities were also seen in the putamen, midbrain and caudate nucleus. There were no abnormalities on T2-weighted imaging. In Group 3 there were 12 children. Ten (83%) showed increased signal on T2-weighted images of the putamen followed by eight with increased signal in the caudate nucleus (67%), seven in the globus pallidus (58%), six in the thalamus (50%), five in the midbrain (42%) and one in the pons (8%).

There is an impression that the T1-weighted changes are associated with liver disease, and the T2-weighted changes are due to brain injury, but the situation is complex. Kim et al. (2006) found that neurological symptoms were present in four of the 23 patients in Group 1; two of the 15 in Group 2; and 11 of the 12 patients in Group 3. Six patients in Group 3 showed reversion of the high-signal-intensity lesions on T2-weighted images after therapy, suggesting to the authors that the changes were due to focal gliosis or oedema.

Diffuse white matter hyperintensity can also be seen in MRI of patients with Wilson disease (Barbosa et al. 2007). Whether this has a parallel with white matter changes seen following herpes simplex encephalitis discussed above, where damaged neurons are thought to release antigens promoting secondary immunological injury, as far as the authors are aware has not been investigated. In adults with Wilson disease, brainstem changes can give rise to the ‘sign of the giant...
conditions, whole blood manganese levels are grossly elevated and manganese accumulates in the brain. Children typically present with dystonia between the ages of 2 and 15 years. There may be parkinsonian features with a poor response to L-dopa. Intellect seems to be preserved. MRI of the brain shows a typical appearance on T1-weighted sequences with hyperintensity of the globus pallidus, putamen, caudate, subthalamic and the dentate nucleus with sparing of the thalamus and ventral pons (Tuschl et al. 2012). Other clinical features of SLC30A10 mutations include liver impairment with raised transaminases, unconjugated hyperbilirubinemia, polycythemia and depleted iron stores. In contrast, patients with SLC39A14 mutations do not develop polycythaemia or liver disease, and it appears that manganese does not accumulate in the liver in this disorder. Treatment with disodium calcium edetate infusions can produce clinical and radiological improvement in both conditions (Stamelou et al. 2012b; Tuschl et al. 2016).

**MANGANESE TRANSPORTER DEFICIENCY**

Autosomal recessive mutations in the genes SLC30A10 and SLC39A14 cause two distinct forms of manganese transporter deficiency (Tuschl et al. 2012, 2016). In both conditions, whole blood manganese levels are grossly elevated and manganese accumulates in the brain. Children typically present with dystonia between the ages of 2 and 15 years. There may be parkinsonian features with a poor response to L-dopa. Intellect seems to be preserved. MRI of the brain shows a typical appearance on T1-weighted sequences with hyperintensity of the globus pallidus, putamen, caudate, subthalamic and the dentate nucleus with sparing of the thalamus and ventral pons (Tuschl et al. 2012). Other clinical features of SLC30A10 mutations include liver impairment with raised transaminases, unconjugated hyperbilirubinemia, polycythemia and depleted iron stores. In contrast, patients with SLC39A14 mutations do not develop polycythaemia or liver disease, and it appears that manganese does not accumulate in the liver in this disorder. Treatment with disodium calcium edetate infusions can produce clinical and radiological improvement in both conditions (Stamelou et al. 2012b; Tuschl et al. 2016).

**RADIOLGICAL FINDINGS IN BASAL GANGLIA DISEASE**

In children with movement disorders, the MRI of the brain can be extremely helpful in making a diagnosis. A person highly skilled in MRI interpretation can be of untold value in this setting. As discussed above, there are a number of conditions where a specific diagnosis is suggested by the MRI scan appearance alone, including PKAN, BPAN, manganese transporter deficiency and cerebrotendinous xanthomatosis. Added to these is Alexander disease where there are abnormalities of the white matter and basal ganglia with contrast enhancement (van der Knaap et al. 2001) and MEGDEL (3-methylglutaconic aciduria with sensori-neural deafness, encephalopathy and Leigh-like syndrome) where there is a distinctive putaminal ‘eye’ in the second stage of the disease (Wortmann et al. 2015).

Even when the MRI findings are not diagnostic, certain patterns of involvement may be helpful in narrowing down the differential diagnosis. Conditions that should be considered based on particular patterns on the MRI scan, can be found in Tables 19.15–19.21 (pp. 1071–1072). Characteristic examples are provided in Figures 19.3–19.13 (pp. 1073–1075).

**BASAL GANGLIA CALCIFICATION**

There are numerous causes of basal ganglia calcification. Livingston et al. (2013) have outlined a systematic approach including the following adjectives to describe the appearance of the calcification: (1) spots, (2) lines, (3) rock, (4) blush, (5) gyriform/band-like and (6) reticular. The detection of calcification using MRI scan is improved by the use of techniques such as gradient-echo and susceptibility-weighted imaging. Nevertheless, CT remains a more sensitive test (La Piana et al. 2016).

Fahr syndrome is a well-known, but confusing term, probably best replaced by ‘Primary Familial Brain Calcification’. Clinical manifestations are varied, and include psychiatric features, movement disorders, ataxia, headaches and seizures. Onset can be from childhood to the adult years. Three genes have so far been found to cause the syndrome:

1. SLC20A2 (sodium dependent phosphate transporter 2),
2. PDGFB (platelet-derived growth factor beta), and

Aicardi-Goutières syndrome is a condition with multiple genetic causes as discussed above. In a review of 110 patients with AGS, calcification was found in the basal ganglia in 77% of patients, in the white matter in 74% and in the dentate nucleus in 15% (La Piana et al. 2016). Severe calcification was associated with TREX1 mutations, and early age at onset. Other common findings in this study were cerebral atrophy (92%) and leukoencephalopathy (99%). Early features include temporal lobe swelling, followed by atrophy with temporal horn dilatation, and global cerebral atrophy (Vanderver et al. 2015).

Table 19.21 lists causes of basal ganglia calcification. A more detailed list can be found in San Antonio and Arzimanoglou (2005).

</tbody>
</table>

Subthalamic nucleus (STN) changes are usually seen in association with other brain abnormalities and are not an isolated finding. See Bosemani et al. (2014) for detailed review.
### Table 19.19 Abnormalities of the dentate nucleus of the cerebellum

#### Conditions where dentate abnormalities can be prominent
- Langerhans cell histiocytosis
- Cerebrotendinous xanthomatosis
- Maple syrup urine disease (in neonatal form, swelling of dentate nuclei, brain stem and corticospinal tracts)
- Succinic acid semialdehyde dehydrogenase deficiency (dentate nuclei may be swollen)
- Metronidazole toxicity (plus involvement of splenium of corpus callosum)

#### Conditions where dentate abnormalities are usually associated with multiple other brain abnormalities
- Mitochondrial disorders (see Fig. 19.9)
- Glutaric aciduria type 1 (widening of anterior temporal and sylvian CSF spaces is an important clue)
- L-2 hydroxy glutaric aciduria
- Aicardi-Goutières syndrome
- Peroxisomal disorders
- Krabbe disease
- Merosin-negative muscular dystrophy
- Neurofibromatosis type 1 (presumed hamartomas)
- Alexander disease
- Dentate abnormalities can also be seen following multiple intravenous injections of gadolinium based contrast agents (on unenhanced T1 images; globus pallidus can also be involved)
- Glut-1 deficiency (Hully et al. 2015)
- Vigabatrin effect

See McErlean et al. (2010).

CSF, cerebrospinal fluid.

### Table 19.20 Delayed myelination

This is common in children with delayed development but if severe, the following should be considered.

- HABC syndrome: hypomyelination and atrophy of basal ganglia and cerebellum (typically delayed myelination and cerebellar atrophy are detected, but absent putamen is overlooked) (Fig. 19.11)
- Pelizaeus-Merzbacher disease
- 18q-syndrome
- Cerebral folate deficiency (*FOLR1* mutations)
- Allan-Herndon-Dudley syndrome

HABC, hypomyelination with atrophy of the basal ganglia and cerebellum.

### Table 19.21 Causes of basal ganglia calcification

- Primary familial brain calcification (Fahr syndrome)
- Infections: cytomegalovirus, toxoplasmosis, HIV, tuberculosis, cysticercosis
- Inflammation: lupus erythematosus
- Genetic auto-inflammation (AGS)
- Tumours, including calcified gliomas of the basal ganglia
- Endocrine disorders: hyperparathyroidism; hypoparathyroidism & pseudohypoparathyroidism
- Post-hypoxia
- Toxins: chemotherapy/radiation in treatment of leukaemia
- Mitochondrial disorders including *POLG1* mutations
- Cerebral folate deficiency (mutations in *FOLR1*)
- Biotinidase deficiency
- Carbohydrate deficient glycoprotein syndrome
- Cockayne syndrome
- Dihydropteridine reductase deficiency
- PKAN and associated NBIAs including BPAN
- Krabbe disease
- Carbonic anhydrase 11 deficiency syndrome.
- Neurofibromatosis type 1

PKAN, pantothenate kinase-associated neurodegeneration; NBIAs, neurodegeneration with brain iron accumulation syndromes; BPAN, beta propeller associated neurodegeneration.
Chapter 19 Basal Ganglia Diseases and Movement Disorders

Figure 19.3 (a) Axial T2 weighted images show asymmetric **increased signal in the globus pallidus and putamen** on both sides, with caudate involvement on the left, in a 2-year-old child with a **mitochondrial M14487TC mutation**. (b) Axial T2 weighted image showing bilateral increased signal in the substantia nigra and putamen in the same child. (Courtesy Dr Biju Hameed, Bristol, UK.)

Figure 19.4 Axial T2 weighted image of a 3-year-old child with **fucosidosis**, showing the typical findings of bilateral symmetric hypointensity of the globus pallidus and diffuse hypomyelination in the white matter. (Courtesy Dr Damien Grattan-Smith, Atlanta, USA.)

Figure 19.5 Axial T2 weighted image of a 4-year-old child with **basal ganglia encephalitis** demonstrating symmetrical increased signal and swelling of the caudate and putamen on both sides. The globus pallidus is spared.

Figure 19.6 (a) Axial T2 weighted image shows bilateral hypointense signal in the substantia nigra in a 15-year-old girl with **PLA2G6 associated neurodegeneration**. (b) Axial T2 weighted image shows bilateral hypointense signal in the globus pallidus in the same patient. (Courtesy Dr Biju Hameed, Bristol, UK.)
Figure 19.7 Axial T1 weighted image of a neonate with bilirubin encephalopathy (kernicterus), demonstrating increased signal in the globus pallidus bilaterally. (Courtesy Dr Biju Hameed, Bristol, UK.)

Figure 19.8 Coronal T1 weighted image of an 11-year-old boy with congenital porto-systemic shunt and chronic liver disease. There is increased signal intensity in the globus pallidus bilaterally. This is thought to be related to manganese deposition. (Courtesy Dr Damien Grattan-Smith, Atlanta, USA.)

Figure 19.9 In a 20-month-old child with Leigh syndrome: (a) Axial T2 weighted image shows bilateral destructive changes in the putamen. (b) Axial T2 weighted image shows bilateral increased signal in the subthalamic nucleus. (c) Axial T2 weighted image shows increased signal in the dentate nuclei of the cerebellum. (d) Axial Diffusion Weighted Index image also demonstrates increased signal in the dentate nuclei of the cerebellum indicating recent involvement. (Courtesy Dr Biju Hameed, Bristol, UK.)
Figure 19.10  Axial FLAIR image demonstrates bilateral putaminal atrophy in a child where no definite underlying diagnosis was made. (Courtesy Dr Damien Grattan-Smith, Atlanta, USA.)

Figure 19.11  Coronal T2 weighted image of a 12-year-old child with hypomyelination with atrophy of the basal ganglia and cerebellum (HABC) demonstrating cerebellar atrophy and delayed myelination. The characteristic absence of the putamen is often overlooked. (From Manual of Neurological Signs, Morris JGL, Grattan-Smith P, Oxford University Press, 2013.)

Figure 19.12  Axial T2 weighted image of a 4-year-old child who developed chorea following herpes simplex encephalitis (HSE). The destructive changes following HSE are obvious and there is a diffuse increase in signal in the white matter that was not present in the scans performed prior to the development of the chorea. (From Manual of Neurological Signs, Morris JGL, Grattan-Smith P, Oxford University Press, 2013.)

Figure 19.13  Axial FLAIR image of a child with Acute Necrotising Encephalopathy due to an RANBP2 mutation, showing bilateral increased signal in the thalamus and external capsule.

Tics and Gilles de la Tourette Syndrome

Robert Ouvrier and Russell C Dale

Tics
(Gilles de la) Tourette Syndrome
Tics and Gilles de la Tourette Syndrome

Robert Ouvrier and Russell C Dale

TICS

Tics are involuntary, purposeless contractions of functionally related groups of skeletal muscles; involuntary noises; or involuntary utterance of words. Motor tics are brief, rapid, sudden, unexpected, repetitive and stereotyped. Although they can be voluntarily suppressed for variable periods of time, they cannot be resisted indefinitely. They often predominate in facial, head and shoulder muscles. Typical movements include eye blinking, contractions of neck or shoulder muscles, sniffing or snorting. Tics are the most frequent abnormal movements in childhood and may be seen in 20–30% of otherwise healthy children. Several large case series have been reported (Shapiro et al. 1988; Fernandez-Alvarez and Aicardi 2001).

Tics have a premonitory compulsory component, and a sensory ‘urge’ – indeed tics are sensorimotor phenomena rather than motor phenomena alone. Vocal tics are less common but may be of more serious significance than simple motor tics. The most common vocal tics include throat clearing, squeaking, sniffing and other utterances. Behavioural disturbances, especially attention-deficit–hyperactivity disorder (ADHD) and obsessive–compulsive disorder (OCD) are frequently associated. They are often equally as, or more, disturbing than the movements (Jankovic and Fahn 1986).

In the most recent DSM-5 classification (APA 2013), the term ‘transient tic disorder’ (lasting less than 12 months) has been replaced by ‘provisional tic disorder’ since it is not possible to confirm the ‘transience’ of the tics until at least 12 months after commencement of the tics. After 12 months of tics, the label Persistent (Chronic) motor or vocal tic disorder is applied. If at least one vocal tic has been present during a chronic tic disorder, Tourette syndrome is diagnosed.

Tics are probably caused by some disturbance of the motor system, especially the cortico-striato-thalamo-cortical circuits and the dopaminergic system. Other movement disorders may co-exist with tics, including stereotypies. Sometimes it is hard to differentiate complex tics from compulsions – this is particularly challenging with touching tics or ‘evening-up’ tics, which often have a compulsive element.

Tics and Tourette syndrome are common disorders, and when counselling families it is important to make them aware that tics affect one in 20 boys at some stage in their childhood, and that Tourette syndrome affects one in 200 children. Genetic factors in tic disorders have long been recognised but no single mechanism has been established and environmental factors are probably important. It is very likely that tics and Tourette syndrome have multiple disease mechanisms, as is now recognised in autism. It is likely that complex genetic and environmental factors will contribute.

Management of simple tics does not necessarily require attempts at suppressing abnormal movements, as the condition is benign and often mild. Psycho-education is important for the family. It is important for family, friends and teachers to know that the tics are ‘brain symptoms’ – they are not the child’s fault, and the child ‘cannot help it’. Sometimes, ‘tic breaks’ from the classroom can be helpful, for the child to leave the classroom briefly to release some tics that have been building.

Parents often describe a burst of tics at the end of the day after school, which is probably due to the child suppressing tics during the day – such suppression can be tiring, and the child may also be emotional and irritable due to the mental energy required. Such suppression should not be encouraged, but is commonly observed. Psychological approaches have become fashionable and are popular with parents as they are non-pharmacological. ‘Tic reversal’ and other psychological approaches have been shown to be effective, but require trained personnel to deliver such therapies, and require the child to be motivated, which is not always true in young children who often are not very aware of their tics (which is good).

If the child is distressed or bullied or is disrupting his classmates, active treatment may be instituted with clonidine. Generally, neuroleptics should be reserved for significantly impaired individuals, given the high rate of side effects, particularly appetite increase, weight gain and consequent metabolic effects. Neuroleptics with dopamine receptor blockade are generally considered to be more effective, such as risperidone and aripiprazole. Haloperidol should only be used if other neuroleptics fail. Many other agents have been tried and were reviewed by Fernandez-Alvarez and Aicardi (2001).

Treatment of associated disorders is as important as that of the tics. Indeed, screening for ADHD, anxiety disorder and OCD is essential, as these disorders are often more impairing, and more treatable than the tics themselves. The best treatment...
of ADHD remains the most important role. Tourette syndrome is often familial (which could be due to genetic or environmental influences) but twin studies have revealed concordance rates in monozygotic twins of 50–70% in contrast to 9% in dizygotic twins. A complex inheritance with a single diagnostic methodology (Eysturoy et al. 2015). As with other disorders, the movement disorder represents only part of the condition, which in many cases also features other psychiatric manifestations, especially ADHD and OCD symptoms.

**Aetiology**

Genetic factors play an important role. Tourette syndrome is often familial (which could be due to genetic or environmental influences) but twin studies have revealed concordance rates in monozygotic twins of 50–70% in contrast to 9% in dizygotic twins. A complex inheritance with a single major gene and multiple additional factors has been proposed (Walkup et al. 1996) but no single locus has been established (Pascher et al. 2004; Keen-Kim and Freimer 2006). More recently, studies of the dopaminergic and serotonergic pathways, have yielded inconsistent results, although the involvement of \( DRD2, MAO-A \) and \( DAT1 \) has been supported by independent findings. Further study of gene and chromosomal aberrations in Tourette syndrome aetiology has implicated multiple genes, with \( SLITRK1 \) being the most prominent example (Paschou 2013). Deletions of 16p13.11, 22q11 and of \( NRXN1 \) have also been recorded in some cases (McGrath et al. 2014).

Tourette syndrome is three to four times more frequent in boys. Although psychological events may trigger the onset of the symptoms and modulate the evolution, their role is only secondary. The mechanism of Tourette syndrome is unclear. No pathological basis is known, although magnetic resonance imaging evidence of decreased volume of the basal ganglia, especially the striatum, has been reported. A role of dopamine transmission is likely, given the genetic and pharmacological evidence.

**Clinical Features**

The criteria for the diagnosis of Tourette syndrome include: (1) both multiple motor tics and one or more vocal tics must have been present at some time during the illness although not necessarily concurrently (coprolalia and echolalia are often lacking in otherwise typical cases); (2) the tics occur many times daily, nearly every day or intermittently throughout a period of more than 1 year without a tic-free period of more than 3 months; (3) they cause significant impairment in everyday life; (4) onset is before 18 years; (5) the disturbance is not the effect of substances (e.g. excitants) or of a general medical condition.

Comorbid manifestations are present in more than half of cases. Some disturbances may result from the personal and social consequences of the condition. OCD is observed with variable severity in about 30% of the patients. ADHD is also common, as well as a variety of behavioural and psychiatric problems that may be responsible for as much distress as the abnormal movements.

**Differential Diagnosis**

The disorder should be separated from polymyoclonus and chorea, especially Sydenham chorea. In reality, the most common diagnostic challenge is differentiating tics from stereotypies and compulsive behaviours. If there is a very abrupt, infection-associated onset, then paediatric auto-immune neuropsychiatric disorders associated with streptococcal infections (PANDAS) (Snider and Swedo 2004) should be considered (see Chapter 12). PANDAS also causes multiple tics and other abnormal movements and psychiatric manifestations especially OCD. Antibodies to basal ganglia neurons have been reported in such cases and are thought to cross-react with streptococcal antibodies (Church et al. 2003; Singer 2004). More recently, it has been recognised that the abrupt onset of OCD or tics is not always streptococcus-associated, and the term ‘paediatric acute neuropsychiatric syndrome’ (PANS) is used instead. The most notable differentiating factor of PANDAS and PANS versus ‘idiopathic’ OCD and Tourette syndrome is the acute abrupt and dramatic onset seen in PANDAS/PANS, and then the potential for complete remission, which is not typically seen in OCD/Tourette syndrome, which more typically ‘waxes and wanes’. This observation has led to therapeutic attempts using antibiotics, corticosteroids, intravenous immunoglobulin and plasma exchange, although these treatments should be restricted to clear cut cases of PANDAS and PANS, and preferably treated by physicians familiar with these rare entities and more typical OCD/Tourette cases.
Treatment of Tourette Syndrome

In many cases of Tourette syndrome, no specific treatment is required. The best approach is to make a correct diagnosis and inform the parents and child that Tourette syndrome is not a psychological problem and that the tics do not indicate an underlying severe psychiatric or neurological disorder but that ADHD, OCD and anxiety disorders can occur and can be treated. It is important to stress that peak severity of the tics tends to occur at around 10–12 years and that improvement or remission may well occur later.

Behavioural and psychological approaches are increasingly popular and have been shown to be effective including tic reversal therapy (Piacentini et al. 2010). Clonidine may also be effective. In severe cases, dopamine receptor antagonists are indicated. Pimozide is often used because at the low doses (1–4mg/day) that are often effective, it has relatively few side effects (Comings 1990). Several Cochrane Reviews indicate that treatment with haloperidol (which should only be used if risperidone fails), risperidone or pimozide is more effective than placebos, although such agents did have significant side effects (The Cochrane Library 2007). Treatment of associated psychiatric disorders is as important as that of the tics.

In resistant cases electrical deep brain stimulation has been effective (Larson 2008; Schrock et al. 2015).

Outcome

In a majority of cases the outcome is relatively favourable as the tics often tend to become less prominent and/or patients learn to live with this problem. Long remissions are not rare.

The word paroxysm is derived from the Greek paroxysmos to sharpen or irritate, and a paroxysmal neurological disorder is one where there are recurrent events of neurological dysfunction. There are many benign forms of paroxysmal movement disorder which occur in otherwise typically developing children.

The widespread availability of smartphones means that parents are now able to video events, and this can be of immense value in making a diagnosis. Nevertheless, the history remains the most important single aspect of the diagnostic process. The parents (or witnesses to the event) and the child (if old enough) should be systematically taken through what happened. What was the child doing when the event occurred? What was the first sign of something going wrong? How did the event evolve? Was there alteration of consciousness? Is there anything that reliably stops the events? How long did it last? After it was over, what was the child like? How long before he/she was back to normal?

These are just some of the questions that need to be asked. The parents and child may perceive these questions as an interrogation, or wasting time, when the emphasis should be on what investigations need to be done. The importance of the history needs to be explained to them at the beginning of the appointment, so that they can understand its value, and as accurate a history as is possible can be obtained.

In reviewing the various disorders discussed in this chapter, we were struck by how often the initial description was clear, and confined to a well-defined and easily recognised group of children. Subsequent reports often described a much broader clinical phenotype, not uncommonly with a resultant loss of clarity. For this reason, we make frequent reference to the original papers.

**BENIGN NEONATAL SLEEP MYOCLONUS**

In benign neonatal sleep myoclonus (BNSM) non-epileptic myoclonic jerks begin in the neonatal period. This condition was first described by Coulter and Allen in 1982. The jerks are confined to sleep and stop with arousal. They are never seen in the fully awake state, but may appear in the transition from sleep to wakefulness (Kaddurah and Holmes 2009).

The myoclonic jerks take on many forms and can be unilateral or bilateral, synchronous or asynchronous. They may appear as short clusters that shift sides. In some infants, repeated multifocal jerks continue for 30 minutes or more (Kaddurah and Holmes 2009). The jerking can be violent and the infant may be thought to have generalised tonic–clonic seizures, or even status epilepticus (Turani et al. 2004). The fact that the events are confined to sleep is often not appreciated, and the story of an otherwise well newborn infant having multiple daily seizures, unresponsive to antiepileptic drugs, raises the possibility of BNSM. The absence of facial myoclonus has been cited as a clue to the diagnosis, but mild facial and head myoclonus was found in two of 18 infants with BNSM on video-EEG monitoring (Kaddurah and Holmes 2009).

Rocking the infant, repetitive sounds, holding the limbs and antiepileptic drug therapy have been noted in various reports to make the myoclonus worse (Coulter and Allen 1982; Daoust-Roy and Seshia 1992; Alfonso et al. 1995; Maurer et al. 2010).

In BNSM, the EEG is normal in both the awake and sleep states. The origin of the myoclonus is uncertain. In the study of Daoust-Roy and Seshia (1992), polygraphic recordings showed electromyography (EMG) bursts of greater than 100ms making a cortical form of myoclonus unlikely. Fokke et al. (2011) used sophisticated neurophysiological techniques to study a single infant, and felt the myoclonus arose from a generator in the cervical cord. The myoclonic jerks can appear during all stages of sleep, but are least common during rapid eye movement sleep (Resnick et al. 1986; Daoust-Roy and Seshia 1992).

A positive family history of BNSM has been noted in multiple reports including one family where there were five affected siblings (Vaccario et al. 2003). Afawi et al. (2012) looked at three families with apparently dominant inheritance, and did not find linkage with the KCNQ2 and KCNQ3 potassium channel genes that are mutated in benign familial neonatal seizures.

No treatment is necessary for BNSM. If antiepileptic drugs have been used, these should be stopped. In a review of the
Shuddering attacks were described in great detail by Vanasse et al. (1976) who suggested the events represented ‘an expression of the mechanism of essential tremor in the immature brain’. Although a well-known entity, a PubMed search in December 2016 revealed only six articles specific to shuddering attacks in the literature in English. In a study of 666 children with paroxysmal non-epileptic events referred for video-EEG monitoring, 7% had shuddering attacks (Bye et al. 2000). In a more recent review of paroxysmal non-epileptic events recorded by video-EEG monitoring in 31 children, four of 38 recorded episodes were shuddering attacks (Chen et al. 2015).

With shuddering attacks, the episodes usually last less than 5 seconds (Holmes and Russman 1986). They seem to be a combination of body stiffening and trembling. Typically the head, shoulders and arms are involved, and the movements are symmetrical. The neck may be flexed forwards and the arms abducted, but the exact posture varies. There may be facial grimacing. Parents may describe the episodes as if water was poured down the child’s back, or the child was shivering with cold. The episodes can be very frequent, up to 100 times per day. They may settle down for several weeks only to reappear. There are a large number of listed provoking factors including excitement, fear, anger, frustration and embarrassment (Vanasse et al. 1976). The episodes can also occur spontaneously. During the episodes the child does not have alteration of consciousness, and ictal and interictal EEGs are normal. An EMG recording of an episode showed a similar frequency to essential tremor (Kanazawa 2000).

Onset of shuddering attacks is often in the first year of life, but may not be until 2–3 years of age (Vanasse et al. 1976; Kanazawa 2000). Even later onset has been reported, with patient 3 in the Holmes and Russman study being 6 years old when the events started. The events not uncommonly continue into childhood. In 12 successive children followed by Jan (2010), complete cessation of the episodes was noted by between 3 and 7 years (mean 5.6 years) of age. Patient 3 in the Vanasse et al. (1976) study was still having events at 9 years of age.

In the study of Vanasse et al. (1976), all six children had a tremor and, in four, it was ‘rather marked’. Essential tremor was found in a parent in five of the children. These findings have not been replicated in subsequent studies, and the current view is that shuddering attacks are not a manifestation of essential tremor. Vanasse et al. (1976) also observed that three of the children had tics, and tics were probably also present in two others. Noting the clinical overlap between shuddering attacks and benign myoclonus of early infancy, Kanazawa (2000) suggested both should be subsumed under the term ‘shuddering attacks in infancy’.

There is also an overlap between shuddering attacks and stereotypes. Patient 3 of Vanasse et al. (1976), at 9 years of age ‘became aware and ashamed of these episodes and tried to restrain herself, hide under the table or go out of the room’. As will be discussed below, rather than having multiple different names for the benign movement disorders of childhood, it seems simpler to use the umbrella term ‘benign polymorphous movement disorder of infancy’ which accurately conveys the diversity of potential presentations.

Shuddering attacks do not respond to antiepileptic drugs. Patient 6 of Vanasse et al. (1976) had a reduction in episodes after being given stimulant medication for hyperactivity. Propanolol was reported to help another child (Barron and Younkin 1992). It seems likely that these are non-specific effects that may have related to a change in the child’s morale, or other non-specific factors, rather than a direct effect of the particular medication. As with many of the benign movement disorders of young children, shuddering attacks may be associated with learning and other difficulties. These should be addressed, but the shuddering attacks themselves simply require explanation.

Benign myoclonus of early infancy (BMEI) was first described by Fejerman and Lombroso in the 1970s (Fejerman 1976; Lombroso and Fejerman 1977), and by Fejerman and others in multiple subsequent reports culminating in a review of 102 cases (Caraballo et al. 2009). Although the term myoclonus was originally used, many different types of movement have been described with this condition. Pachatz et al. (1999) performed video-EEG and polygraphic studies on five infants. The events varied in intensity from single subtle jerks, to obvious spasms. Typically, there were tonic spasms of the limbs with associated shuddering like movements of the trunk. EMG of the tonic limb spasms revealed durations as long as 2 seconds. The EEG was normal during the spasms.

In the large review by Caraballo et al. (2009), age at onset ranged from 1 to 12 months, with a median age of 6.2 months. Multiple different events were recognised including myoclonus, spasms and brief tonic contractions, shuddering, atonia and negative myoclonus, and combinations of these movements. An important diagnostic feature, (recognised from the earliest descriptions of BMEI), was that in 87 infants (85.2%), the events only occurred while the infant was awake. In 15 (14.8%), the events occurred while the infant was
awake, but also in sleep and drowsiness. Multiple events per day were common, and in 45 (44.1%) of the 102 infants, the movements appeared in clusters. The events stopped between 6 and 30 months of age.

With BMEI, episodes may be provoked by excitement or frustration. There is no developmental delay or regression, and the neurological examination is normal, as are ictal and interictal EEGs. The children are normal at long-term follow-up. Because of the wide variety of movements that can be seen in this condition, and Dr Fejerman’s 40-year involvement in its evolution, Dalla Bernardina (2009) has suggested the term ‘Fejerman syndrome’ be used rather than BMEI.

### BENIGN POLYMORPHOUS MOVEMENT DISORDER OF INFANCY

The great difficulty in dealing with the benign paroxysmal movement disorders of infancy is that there is an extremely broad repertoire of possible movements and considerable overlap between the various recognised entities. Parents told that their child has a particular condition, may be confused when they read about it, and find that their child seems to have atypical features. Rather than trying to force a child into a particular diagnostic group, that in reality is not a good match for the symptoms, it seems sensible to use an overarching term that acknowledges the wide variety of unusual movements that can occur in young children. Fernández-Alvarez (2015) has suggested the use of the terms ‘polymorphic, benign, non-epileptic, paroxysmal, infantile movements’ in this setting. The umbrella term ‘benign polymorphic movement disorder of infancy’ (BPMDI) is useful, as it conveys the variety of manifestations in a way that is easily understood.

Fernández-Alvarez (2015) lists the main characteristics of BPMDI:

1. Paroxysmal events, sometimes in clusters, separated by 3–4 minutes;
2. Short duration;
3. No alteration of consciousness;
4. May appear daily and multiple times per day;
5. Usually triggered by excitement, frustration or postural changes;
6. Normal development and normal neurological examination;
7. Normal ictal and interictal EEG;
8. Onset in the first year of life, mainly between 4 and 7 months; and
9. Self-limited.

Obviously not every feature will be found in every child.

Another characteristic of benign movement disorders as a group, is that they can usually be stopped, at least momentarily, by calling the child or making an unexpected intervention. Sometimes calling the child is enough, but a strong tickle associated with a loud noise may be needed. If the event usually lasts say 3–4 seconds, or comes in a cluster, and is consistently and abruptly stopped by such interventions, then this is good supportive evidence of its benign nature.

### BENIGN PAROXYSMAL TORTICOLLIS

The name torticollis comes from the Latin words *tortus* (twisted) and *collum* (neck). With torticollis, the head is usually tilted to one side and rotated with the chin pointing to the other side. Torticollis is a common manifestation of cervical dystonia in adults.

Benign paroxysmal torticollis of infancy (BPTI) was first recognised in 1969 by Snyder, who described 12 affected
children. Snyder noted that the onset was most often between 2 and 8 months of age. There were recurrent attacks of torticollis, which could last from 10 minutes to 14 days, but most often the episodes lasted 2–3 days. The head turn was to either side. Snyder found that there could be two to three attacks per month, and the children were normal between episodes. Seven of the 12 children were unwell with vomiting, pallor and agitation at the onset of the attacks. However, the other five appeared ‘perfectly content unless the mother attempts to straighten the head, whereupon the baby cries and opposes the attempt’. At follow-up, the episodes had stopped spontaneously in eight of the children, mostly at around 2–3 years of age. In one child where the episodes were of 10 minutes duration, the episodes stopped at 10 months. In another, whose episodes could last 30 minutes to 7 days, the events did not cease until she was 5 years old. Older children would complain that the ‘house was turning’ during an episode, and in four children the mother noted ataxia during the event.

Snyder performed caloric testing on all 12 children (in half, after the episode had stopped). Ice water applied to the ear canal failed to induce nystagmus in all but three children. Snyder concluded the underlying cause was labyrinthine dysfunction.

Subsequent reports added other features. As well as torticollis, lateral curvature of the trunk and retrocollis could occur in the episodes (Chutthour 1974). Affected siblings were reported (Lipson and Robertson 1978). The episodes could occur with a striking regularity, with the parents able to predict the day of the next episode (Sanner and Bergström 1979). Hanukoglu et al. (1984) noted a female predominance and that most occurrences commenced early in the morning. However, Drigo et al. (2000) in a larger cohort of 22 children, found that there were ten females and 12 males, and the symptoms occurred on awakening in only half of the children. Drigo et al. also noted that in only 27.3% of cases was the head always turned to the same side, and half of the children also had tortipelvis. Further, they described two children whose episodes were very similar to those described by Catalaete and Barron (1993) (discussed in the Unusual Benign Movement Disorders of Infancy section). The events lasted only minutes and were characterised by a sudden onset with an abrupt turning of the head and eyes to one side, rapid blinking, flexing of the upper limbs and tears. One of the authors (EF-A) has seen onset of BPTI in the neonatal period.

This diversity of presentations led Drigo et al. (2000) to suggest that BPTI could be subdivided into two forms: (1) a more common, ‘periodic’ torticollis that lasts several hours or days; and (2) a rarer short-lived and ‘paroxysmal’ form, lasting only minutes, and accompanied by ocular signs that are usually not seen in the ‘periodic’ form.

Rosman et al. (2009) described ten personal cases of BPTI and reviewed 103 cases from the literature. Five of the ten children in their series had gross motor delay, and three had fine motor problems. These tended to improve with the resolution of the episodes of BPTI, but three children were left with ongoing motor problems. In their literature review, they found that there was no effective symptomatic treatment of the inci-
dences. They also found that in contrast to Snyder’s original paper, in most subsequent reports caloric and audiometric testing were normal. Yaghini et al. (2016) have described four children with BPTI who responded well to topiramate.

When performed on children with BPTI, EEG and neuro-imaging studies have been normal. Kimura and Nezu (1998) performed surface EMG recordings during an episode of torticollis, and concluded it was a dystonic phenomenon. The view of many authors is that that BPTI is an early manifestation of migraine, or a part of the periodic syndromes of childhood.

Children who may have BPTI need to be carefully assessed. The differential diagnosis is wide and includes seizures, vertigo, gastroesophageal reflux, Sandifer syndrome, dystonic reaction to drugs, ocular abnormalities such as fourth cranial nerve palsies, and posterior fossa and craniocervical junction abnormalities such as atlanto-axial instability, Arnold-Chiari malformation and posterior fossa tumours (Tomczak and Rosman 2012).

Drigo et al. (2000) noted that with BPTI features such as its episodic nature, the trigger factors, the familial association with migraine and the lack of anatomical lesions, raised the possibility of a channelopathy as an underlying cause. Subsequently a father and son with BPTI who had mutations in the CACNA1A gene were reported (Giffin et al. 2002). Cuenca-León et al. (2008) reported another patient with CACNA1A mutation who presented with BPTI as a neonate, and when older, developed benign paroxysmal vertigo of childhood, and subsequently hemiplegic migraine. Roubertie et al. (2008) reported a two-generation family with CACNA1A mutations where various affected family members presented in different ways including with benign paroxysmal tonic upgaze, benign paroxysmal torticollis, and episodic ataxia. Vila-Pueyo et al. (2014) (discussed in the Unusual Benign Movement Disorders of Infancy section) reported two further cases of BPTI with loss of function mutations in the CACNA1A gene, and suggested it may be an age-specific manifestation of defective neuronal calcium channel activity. Dale et al. (2012) have reported a child with a PRRT2 mutation who initially had BPTI, and then developed infantile seizures.

Given the wide variety of reported manifestations, with some children ill during the occurrences where others are untroubled, with episodes that can last minutes or days, and the reports of both CACNA1A and PRRT2 mutations causing similar features, it appears that BPTI is a clinical syndrome of multiple different aetiologies.

**BENIGN PAROXYSMAL VERTIGO**

The term benign paroxysmal vertigo of childhood (BPVC) was coined by Basser in 1964. He described 17 children (ten girls and seven boys), who had sudden episodes of vertigo. The
onset of the episodes was in the first four years of life, except in two children aged 7 and 8 years, respectively. The attacks were brief, lasting usually less than a minute, and rarely more than a few minutes. The child was well before and after the event and there was no alteration of consciousness during the event. The onset was sudden and ‘in a severe attack the child remains perfectly still, unable to move, stand or even sit without support’. In a less severe episode the child typically ‘clutches the mother or her clothing until the attack ceases’. Pallor was frequently seen, and in some children there was also nystagmus during an attack. Older children described intense vertigo during the episodes. For example: ‘Everything around me is spinning’; or ‘The house is falling over’. The interval between episodes varied, typically being 4–6 weeks, but it could be as short as days or as long as 6 months to a year. The attacks ceased spontaneously, usually after several years, but sometimes after only months.

Basser felt that BPVC might be a form of vestibular neuritis, but it was later suggested that it may be an early manifestation of migraine (Fenchel 1967). Subsequent studies have not clarified the underlying cause. Lindskog et al. (1999) reviewed 19 patients with BPVC. The age at onset was between 5 months and 8 years, and the symptoms disappeared within 3 months to 8 years. At follow-up the patients were aged between 18 and 24 years. One woman initially had BPTI then developed BPVC, and as an adult had migraine. However, overall, only 21% of the group developed migraine. None had persistent vertigo, or a balance disorder. Lindskog et al. concluded that BPVC has a favourable outcome, but is not a precursor of migraine.

Drigo et al. (2001) described 19 patients. Six patients had previously presented with episodes of BPT. Three patients went on to develop migraine, and five developed a ‘periodic syndrome’ with recurrent abdominal pain and cyclic vomiting, leading the authors to also suggest that BPVC is related to migraine. Krams et al. (2010) felt that BPVC might have a worse long-term prognosis than previously reported, but included in their group patients who had episodes of vertigo lasting as long as 7 days, which is not typical of the syndrome described by Basser. Batuecas-Caletrío et al. (2013) followed 27 patients for at least 15 years, and found that 33% went on to develop migraine. Most recently Marcelli et al. (2015) found that ten of 15 children with BPVC developed migraine, and or recurrent vestibular symptoms. The other five patients had never had a headache in their life. In this study, abnormalities on neuro-otological examination were found in three patients during the interictal period, and in four of six children evaluated ‘during migraine attacks, vestibular or dizziness spells, even without clinically evident balance issues’. Both peripheral and central vestibular abnormalities were found.

Although there is a relative paucity of reports of BPVC in the literature, the personal experience of the authors is that it is not an uncommon problem. In an otherwise normal child who has the typical clinical features described by Basser, there are few conditions that realistically come into the differential diagnosis, and investigations may not be necessary.

### Transient Idiopathic Dystonia in Infancy

Transient idiopathic dystonia in infancy (TIDI) was first reported by Willems in 1986. There has been a subsequent paucity of reports. At the time of writing, the most recent reference found in a PubMed search was by Calado et al. in 2011. The term ‘transient dystonia’ has also been applied to low birthweight infants, who show increased muscle tone in the first year of life that subsequently resolves (Drillien 1970; Sommerfelt et al. 1996). It is obviously important not to confuse the two conditions.

The onset of TIDI is usually in the first 6 months of life. There is dystonic posturing of an upper limb and sometimes the trunk or a leg. The typical arm posture is forearm pronation with hyperflexion of the wrist. When prone with the head elevated from the bed, the affected arm may be rotated, and rests on the dorsum of the hand. If the infant is prone and lying flat on the bed, the arm may be extended backwards. When sitting, the arm may hang down with the fist closed, and the arm internally rotated. The dystonic posturing is often unilateral. It may be bilateral, although often with one side more affected (Deonna et al. 1991). Typically, the dystonic posture disappears with intentional movement; for example, when the infant reaches out to grasp an object. This is the key diagnostic feature separating TIDI from other dystonias. A fine tremor involving the tongue, or trunk and extremities has been noted in some cases (Willems 1986; Calado et al. 2011). Angelini et al. (1988) described infants who had more abrupt paroxysmal episodes of dystonic posturing.

Two of Willems’s patients were siblings, and, in the study of Calado et al. (2011), father and child were affected. Motor and intellectual development is usually normal in TIDI. Deonna et al. (1991) reported a slight delay in two of eight infants.

The posturing usually stops before the age of 2 years. Some cases seem to have more prominent dystonia and a more prolonged clinical course; for example, patient 4 of Willems had Achilles tendon surgery at 2 years of age.

Decreased perfusion of the basal ganglia and left temporomesial cortex on single-photon emission computed tomography (SPECT) and decreased glucose metabolism in the basal ganglia and cerebellum on positron emission tomography (PET) have been reported in one patient (John et al. 2000). Worsening of the dystonic posturing apparently induced by cisapride, a 5-HT receptor antagonist, has been described (Angelini et al. 1996). Beltran and Coker (1995) have suggested the possibility of fetal cocaine exposure having a role.

Whether TIDI is a transient form of dystonia, or simply transient posturing that resembles dystonia is unclear, and
as with so many of the transient disorders of infancy, it is likely that reported cases are a heterogeneous group.

How far to pursue investigations in an infant who appears to have TIDI is a difficult question. In a child who otherwise seems normal, and in whom the dystonic posturing completely disappears with movement, no investigations may be necessary. Screening for metabolic disorders, in particular glutaric aciduria type 1, and for GLUT-1 deficiency can be considered. An MRI of the brain will require sedation or anaesthesia, and the yield is likely to be low. As always, discussion with the family is important in coming to a decision as to how far to proceed.

**INFANT MASTURBATION (SELF-STIMULATION OR GRATIFICATION EPISODES)**

The first difficulty with this condition is the word used to describe it. 'Masturbation' is straightforward but carries the stigma of centuries of disapproval. (For example, Stedman's Medical Dictionary [1961] has the following entry: 'masturbate [L. masturbor]. To excite the genital organs by unnatural means; to practice self-abuse'.) Nechay et al. (2004) found: 'Parents prefer the term gratification (or even benign idiopathic infantile dyskinesia) to infantile masturbation as there is less social stigma attached to these terms'. However, 'to gratify' means 'to give pleasure', and not everyone will be happy with this. 'Paroxysmal hyperkinetic motor syndrome of infancy' has been suggested by Phillips and Seshia (2013), 'to avoid cognitive biases such as confirmation, diagnosis momentum etc.' Both 'benign idiopathic infantile dyskinesia' and 'paroxysmal hyperkinetic motor syndrome of infancy' lack specificity and would require explanation whenever they were used, given the multiple hyperkinetic dyskinesias of infancy. In addition, the process of replacing a term that is regarded as carrying a stigma, with another word that seems less offensive, carries with it the implication that there is something wrong (or to be ashamed about) with the activity. We feel 'self-stimulation episodes' (SSE) is an acceptable term as it is not as blunt as masturbation, but at the same time should not cause confusion.

Although discussed in Still's paediatric textbook first published more than 100 years ago (Still 1909), SSE continue to be a diagnostic problem for those unaware of the characteristic clinical features. (It is usually only in girls that there is a diagnostic difficulty.) SSE can be mistaken for epileptic seizures (Livingston et al. 1975), abdominal pain (Fleisher and Morrison 1990) and paroxysmal movement disorders (Mink and Nell 1995; Yang et al. 2005). Typically, when an infant is supine, the legs are tightly opposed and the feet crossed at the ankles. There may also be mechanical pressure over the supra-pubic or pubic area. Pelvic thrusting may be prominent. If in a high chair or a child car seat, the infant may press against the restraints. Irregular breathing, facial flushing, sweating, irritable cries, and grunting may give an impression that the child is in pain. The episodes can last minutes to several hours. A fixed and glazed look raises the possibility of altered consciousness, but the episode can be usually stopped immediately by picking up the child. This may produce annoyance, and resumption of the activity as soon as the child is put down again.

Still, and many others since, postulated that the behaviour begins after an episode of local vulval irritation, which sensitises the child to pleasurable sensations arising from genital stimulation. Some young girls have as many as 40–50 episodes per day (Rödöö and Hellberg 2013).

There are a small number of follow-up studies of children with SSE. Bakwin (1973) described three girls. One continued to perform the movements at 4 years of age. Another stopped at 6–7 months, and there had been no recurrence up to the age of 8 years. The third child at 12 months carried a large rag doll with her constantly. She repeatedly threw the doll to the floor, and would rhythmically press her body against it. By 4 years, she rarely exhibited the behaviour, and when last seen she was a medical student. In a more recent study, 12 of 19 girls followed up for an average of 8 years, had stopped the episodes after a mean duration of 66 months (Rödöö and Hellberg 2013).

In a child with the typical clinical features of SSE, no investigations are necessary. It is important to explain to the parents that it is a normal behaviour, more pronounced in some children, and with no worrying long-term consequences. Distracting the child towards more interesting activities may help. Many parents are relieved that their child does not have a serious underlying condition, and may regard the activity with a sense of humour. However, even in this apparently enlightened age, some parents feel upset and ashamed, and may need additional counselling (Franić and Franić 2011). It should be emphasised that SSE cause no harm to anyone, and are natural in a young child. Coercive measures to stop the activity are likely to be bad for both the child and the parents.

**STEREOTYPIES**

The word stereotypy was used in the medical literature as long ago as 1907, when it appeared in Meige and Feindel’s textbook *Tics and their Treatment* (Edwards et al. 2012). However, from the beginning there has been a struggle to provide a clear and easily understood definition of what the word means. Stereotypies have been studied in great detail in animals (Ridley and Baker 1982). When left alone in a cage, monkeys will develop repetitive behaviours, known as cage stereotypies, which usually include pacing backwards and forwards, circling, backwards somersaults and jumping on all fours. Deprivation stereotypies occur when a young animal is separated from its mother at an early age. Rather than pacing backwards and forwards, these animals develop body-rocking, head rolling, self-clasping and self-injurious behaviours such as head banging, self-biting and eye-poking. Once deprivation stereotypies develop, they are very difficult to disrupt. It is felt that cage stereotypies are the response of a normal nervous system to perform the movements at 4 years of age. Another stopped at 6–7 months, and there had been no recurrence up to the age of 8 years. The third child at 12 months carried a large rag doll with her constantly. She repeatedly threw the doll to the floor, and would rhythmically press her body against it. By 4 years, she rarely exhibited the behaviour, and when last seen she was a medical student. In a more recent study, 12 of 19 girls followed up for an average of 8 years, had stopped the episodes after a mean duration of 66 months (Rödöö and Hellberg 2013).

It should be emphasised that SSE cause no harm to anyone, and are natural in a young child. Coercive measures to stop the activity are likely to be bad for both the child and the parents.
system to an abnormal environment. Deprivation stereotypies, on the other hand, reflect an abnormal nervous system, the result of the early separation and isolation.

Repetitive and rhythmic behaviours are part of normal human development (developmental stereotypies). A study of 20 normal infants during their first year of life revealed a great quantity, and variety, of rhythmical and highly stereotyped behaviours (Thelen 1979). These were most prominent between 24 and 42 weeks of age. At that time, some infants spent as much as 40% of the time they were observed, engaged in such behaviours. Thelen observed 47 distinct movements in the 20 infants. Between 2 and 4 years of age, compulsive-like behaviours are also common in typically developing children (Evans et al. 1997). It is when a single behaviour begins to dominate, and persists, that it comes to attention.

Stereotypies such as hand-flapping have long been recognised as a feature of children with autism and intellectual disability. They are common in Rett syndrome, where a characteristic feature is that children under the age of 10 years, while performing hand stereotypies, tend not to look at their hands (Temudo et al. 2007). In a parallel to the animal data, there is also a high incidence of stereotypies in children placed in institutions at an early age (Bos et al. 2010).

Stereotypies occurring in children without major neurological or behavioural problems received little attention until the paper of Tan et al. (1997). Ten children were described, seven of them being boys. A large variety of movements were seen, the most common being arm flapping and leg shaking. In some children, there was hand posturing that seemed ‘almost dystonic or choreoathetoid’. Facial grimacing was also seen. The movements appeared in multiple different situations including when the child was excited, stressed, concentrating, bored or unoccupied. (With the now widespread availability of smartphones a common scenario is a video of the child performing a stereotypy while strapped into a child car seat.) Tan et al. found that stereotypies usually first appeared early in life with a median age at onset of 12 months. Eight of the patients had additional problems such as mild intellectual disability, speech problems and attention-deficit–hyperactivity disorder (ADHD). Follow-up was available to a maximum age of 11 years in nine children, and the stereotypies had completely stopped in only two. Not uncommonly, the child, when older, restricted the movements to the privacy of his own room.

Subsequently, Mahone et al. (2004) using the term complex motor stereotypies (CMS) described 40 children confirming the clinical features described by Tan et al. (1997). As well as CMS, 25% of their group had comorbid ADHD, and 20% had a learning disability. A family history of stereotypies was identified in 25%, tics in 33%, ADHD in 10%, and mood-anxiety disorder in 38%. Only two children had complete resolution of their stereotypies after a duration of 11 and 12 years, respectively.

Oakley et al. (2015) followed 49 children (31 boys and 18 girls) with stereotypies who, when reviewed, were aged between 9 and 20 years. The duration of follow-up was between 6.8–20.3 years. Only one had stopped performing the stereotypies. However, in most the duration and frequency of the episodes was diminished compared with when they were younger. Further, ‘all denied any current functional impairment related specifically to their movements’. There was a family history of CMS in 39%. Most patients (92%) in the series had at least one comorbid disorder, including elevated levels of anxiety (73%), ADHD (63%), obsessive compulsive disorder (35%) and tics or Tourette syndrome (22%). Neuropsychological testing performed on 57 children with CMS, revealed that on IQ tests, although they were consistently in the average range, they did not perform as well as a comparison group (Mahone et al. 2014). One-third of the CMS group also showed signs of developmental motor co-ordination disorder.

Sometimes during stereotypies, the child can engage in intense imaginative play (Robinson et al. 2014). Reported themes included computer games, cartoons and/or films, fantasy scenes, circus tricks or jokes, and film scenes that included family members. The child may be so immersed in the imaginative play, that they may appear to be in a trance, and the possibility of focal dyscognitive seizures arises. Calling them may have no effect, but a sudden unexpected tickle will usually bring an immediate response and stop the event, making a seizure unlikely.

Movement-related cortical potentials (MRCPs) were studied in ten patients with CMS (Houdayer et al. 2014). MRCPs were not present before the stereotypy indicating that these have a different nature than voluntary self-paced movements. This was not interpreted as indicating that stereotypies are involuntary, as MRCPs can be also absent with tics, and present in patients with conversion disorder where the movements are thought to be involuntary (Houdayer et al. 2014). Magnetic resonance spectroscopy using a 7T magnet compared 18 children with primary CMS, and 24 typically developing controls (Harris et al. 2016). Compared with the controls, children with CMS had lower levels of GABA in the anterior cingulate cortex and striatum suggesting possible GABAAergic dysfunction within corticostriatal pathways. Interpretation of the results of such sophisticated methods of investigation will need to take account of the statement that many children with CMS make – they like doing the movements.

Stereotypies can be classified as transient or persistent. When persistent they are subdivided into: (1) primary when development is essentially normal, and (2) secondary when they are seen in children with autism, intellectual disability or sensory deficits.

Edwards et al. (2012) argue that with stereotypy ‘the meaning of the term has become so blunted by shifts in meaning that it no longer has sufficient precision to be a useful clinical categorical tool’. There is no doubt that it is difficult to avoid cumbersome definitions of stereotypies. Tan et al. (1997) suggested: ‘involuntary coordinated, patterned, repetitive, rhythmic, non-reflex, non-goal directed motor activity that is carried out in exactly the same way during each repetition’. Wolf and Singer (2008) use the following: ‘repetitive, rhythmic movements that have a predictable pattern and location, seem purposeful but serve no obvious function, tend to be prolonged,
and stop with distraction’. Edwards et al. (2012) felt that the following should be preferred: a non-goal-directed movement pattern that is repeated continuously for a period of time in the same form and on multiple occasions, and which is typically distractible’. Although Edwards et al. claim that such a definition would exclude tics, it would seem to apply very well, for example, to an isolated blinking tic.

It is likely that no simple definition will be found to describe CMS in childhood. The main differentials are complex tics and compulsions. It is not possible to separate these three conditions on the characteristics of the movement alone. Additional difficulties arise because the boundaries are also not always absolutely clear. Both tics and stereotypies can occur in the same patient, and there is often a compulsive element to tics. However, some broad rules usually allow a confident diagnosis to be made. The typical picture of a stereotypy is (1) the movements start early in life, usually in the first 2 years; (2) the same movement persists over time but with some elaboration; (3) although there may be facial grimacing, this is usually in association with arm movements, rather than occurring in isolation; and (4) the child will often say they like doing the movement.

In contrast to tics (1) the movements typically start later, often at around 4–5 years of age; (2) commonly the initial tics are simple in form, such as blinking or facial grimaces, and it is only after several years that more complex movements appear; (3) with tics the movements change over time; for example, blinking may be the first tic, this then subsides, and shoulder shrugging appears, which is then followed by episodes of opening the mouth widely etc.; and (4) the child says they have to do the tic, or they do it because the body part feels stiff, or sore, or itchy.

These criteria will separate tics from CMS most of the time, but there will always be problems; for example, in some children the first tic to appear is a complex movement, and occasionally tics appear in young children. The diagnosis of a compulsion relies on the child saying that the movement is done to ward off harmful events, which they may be reluctant to reveal. However, compulsions are less common than either tics or stereotypies, and usually appear in children well beyond the age of 1–2 years.

Many children with tics say they do not have a premonitory sensation or a need to perform the movement, but when present these features strongly point to the diagnosis of a tic. Enjoying the movement is a very useful pointer to it being a stereotypy. (A father of a child with stereotypies remembered doing them himself as a child, and explained that, when he felt excited, to suddenly add in an arm flap gave him such a thrill that it was ‘almost like taking a drug’.) Distractibility is not a particularly useful differentiating sign, as it is found in both CMS and tics.

The general view on stereotypies has been that there is no effective treatment. However, Specht et al. (2016) used an instructional DVD to assess parent guided therapy. The aim was to make the child more aware of when the stereotypies were occurring. The child was requested to perform the stereotypy for 30 seconds, followed by 60 seconds of rest. This was done five times in succession, twice a day, ideally in front of a full-length mirror. Specht et al. found a reduction in various scores of stereotypies of 15–24%. This assessment was done by the parents, who also administered the treatment. In addition, there was a steep drop out rate. Of the initial 81 participants, 54 provided data at 1 month, 38 at 2 months, and 29 at 3 months.

One approach to stereotypies is to argue that they are a harmless activity that the child enjoys, and treatment is not necessary. In the study of Specht et al. (2016), parental concern seemed to be the driving force behind treatment: ‘Parents express considerable concern regarding disruptions and stigmatization’. In a previous study the same group had noted: ‘These movements are readily suppressed by sensory stimuli or distraction and are of little concern to the patient, whose daily activities are rarely affected’ (Mahone et al. 2004). Hedderly (2016) has observed that after stopping the stereotypies ‘children can express relief, reporting a sense of freedom from the compulsion to perform them’. However, it is unlikely that treatments that only reduce the number of stereotypies will bring such benefits.

The decision as to whether behaviour-based therapies should be used for CMS, will, in the end, hinge on the attitudes of the parent and the treating doctor, with hopefully the child having a say. Parents often worry that the child will be teased, which occurred in 23% of patients in the Mahone et al. study of 2004. However, once other children start asking about CMS, often the child restricts the movements to times when they are alone. If the child is being teased and cannot control the movements among other children, it is a setting where behavioural techniques may be more effective. If the parents perceive the movements as a physical manifestation of joy in their child, they usually are less concerned about them. Some parents find the attention the CMS bring to the child in public upsetting, even if the child is oblivious to it. In this situation it can be explained to the older child that people do not understand their movements, and it would be best to keep them quiet until they get home. One of the potential disadvantages of behavioural therapies to ‘control’ CMS, is that the message for the child is that the movements are ‘bad’, and need to be stopped, even if they enjoy them. If the behavioural therapy fails to control the movements, then the child may be worse off than before, feeling guilt that the movements continue.

The presence of CMS should be seen as a marker for potential problems with learning and attention, which will have a much greater impact on the child’s life than CMS (Oakley et al. 2015).

**PAROXYSMAL TONIC UPGAZE**

In 1988 Ouvrier and Billson described four children with an unusual syndrome they called ‘benign paroxysmal tonic upgaze
of childhood’. The typical features included (1) onset in early life; (2) periods of constant or variably sustained tonic conjugate upward deviation of the eyes; (3) downbeating saccades in attempted downgaze; (4) normal horizontal eye movements; and (5) frequent relief by sleep. The children typically adopted a chin down posture at the times of the upward eye deviation. They were otherwise normal apart from mild ataxia, persistent in one child, and in another appearing at times of illness. There was no deterioration during follow-up which was as long as 15 years. Over time, the abnormal eye movements improved, although two children continued to have minor problems. Investigations including neuroimaging, EEGs and metabolic studies were normal. One patient who died accidentally, had a normal brain post-mortem. In another patient, the mother reported improvement with L-Dopa therapy, but this was never independently verified (Ouvrier and Billson 2005).

Ouvrier and Billson concluded: ‘An otherwise normal neurologic and ophthalmic examination coupled with normal neuroimaging of the brain in children with this striking eye movement disorder is sufficient to justify the prediction of a favorable outcome’. At further follow-up, two of the patients were found to have cognitive difficulties (Ouvrier and Billson 2005).

Subsequent reports indicated that structural abnormalities of the brain could be found in children with episodes of paroxysmal upgaze. These included bilateral periventricular leukomalacia (Sugie et al. 1995), hydrocephalus associated with a vein of Galen malformation (Hayman et al. 1998), a pinealoma (Spalice et al. 2000) and demyelination (Senbil et al. 2009). Ataxia was also noted in multiple different reports (Campistol et al. 1993; Guerrini et al. 1998; Lispi and Vigevano 2001). In a study of 16 children only three had normal development and neurological findings (Hayman et al. 1998). This study included patients with rhizomelic short stature and microcephaly. More recently, episodes of tonic upward eye deviation in children have been associated with chromosomal abnormalities (Joseph et al. 2005), Beckwith–Wiedemann syndrome (Skalicky and Billson 2008), and CACNA1A mutations (Roubertie et al. 2008; Blumkin et al. 2015). Ataxia was present during episodes in 15 of the 46 cases. Five children had persistent co-ordination problems, and borderline motor delay. In seven children, the episodes occurred when the children were unwell with a febrile illness, or following immunisation. In 26 children the episodes stopped between 1 and 48 months. The clinical features of the events were as described in the initial report, with Salmina et al. adding the useful phrase ‘eyes up, chin down’ which captures the characteristic posture.

The term ‘paroxysmal tonic upgaze (PTU) plus’ has been suggested for children who have structural and other abnormalities associated with episodes of tonic upgaze (Zafeiriou 2015). Even if neuroimaging is initially normal, other clinical features help to separate patients with ‘PTU plus’ from Ouvrier–Billson syndrome. For example, of the three children described by Blumkin et al. (2015) with CACNA1A mutations, two had significant motor delay. The other child had ataxia, pyramidal signs, and after the age of 2 years, episodic coma associated with seizures and autonomic symptoms.

Seizures come into the differential diagnosis, but are usually easily separated from PTU. Oculogyric crises need to be considered, as the episodes of upgaze are not clinically distinguishable from brief episodes of PTU. Oculogyric crises occur in treatable conditions such as tyrosine hydroxylase deficiency, where severe neurological abnormalities may be completely reversed with L-Dopa therapy, and it is therefore of the greatest importance that they be recognised. (For a full discussion, see Chapter 19.)

No treatment of PTU has been shown to be consistently effective. L-Dopa appears to have helped some children (Campistol et al. 1993). Antiepileptic drugs have been tried but without clear success. No clear explanation has been found for the eye movement disorder, but one possibility is abnormal cerebellar dysfunction, particularly of the flocculus (Hills et al. 2013).

**PAROXYSMAL TONIC DOWNGAZE OF INFANCY**

Downward deviation of the eyes in infants may be a sign of serious underlying pathology such as hydrocephalus or kernicterus, but it may also appear in otherwise typically developing children.
Of 19 infants with the ‘setting sun’ sign described by Cernerud (1975), eight had increased intracranial pressure requiring surgical intervention, two had transient signs of increased intracranial pressure which resolved spontaneously, and nine infants showed no signs of illness at all. The sign was elicited by abruptly changing the infant from a vertical to a supine position, or suddenly removing a light source (the ‘eye-popping’ reflex of Perez). Hoyt et al. (1980) examined 242 healthy neonates and found that five had tonic downward deviation of the eyes while awake. This settled after 6 months, and the infants were otherwise normal.

Yokochi (1991) described 13 children with spastic quadriplegia or diplegia, intellectual disability and commonly cortical visual impairment, who had paroxysmal episodes of downward deviation of the eyes lasting several seconds. In five infants these episodes stopped by the age of 2 years. Subsequently brief episodes of tonic downward deviation were described as a benign transient phenomenon in five infants born between 22 and 28 weeks’ gestation (Kleiman et al. 1994). Wolsey and Warner (2006) described two infants who had episodes of downward eye deviation beginning at the age of 5 months, lasting seconds to minutes. During the episodes, one infant had stiffening of the arms and legs, and the other had grasping, flailing upper extremity movements, and reflexion of the head. The infants were otherwise normal and the events stopped after 6–12 weeks. There was no alteration of consciousness, and investigations such as EEG and MRI of the brain, were normal.

Simonsz et al. (2009) presented a series of infant boys who presented with tonic downgaze, and a chin-up head posture at the age of 3–5 months. They were normal neurologically, and had normal imaging findings. By 2–3 years the inability to maintain upgaze had disappeared. The underlying cause was congenital stationary night blindness.

Although paroxysmal tonic downgaze can be a benign and transient phenomenon, investigations are required including neuroimaging, and careful ophthalmological examination and follow-up. In considering this diagnosis it is important to be aware of the ‘eye-popping’ reflex described by Perez (1972) and discussed by Cernerud (1975) and Wolsey and Warner (2006). In this reflex, there are brief (3–10 seconds) episodes of downward deviation of the eyes associated with lid retraction, appearing after a light source is removed, or following a sudden change of illumination from light to dark. Perez found this reflex to peak between 14 and 18 weeks of age, where it was present in 80% of 308 infants studied.

**SANDIFER SYNDROME**

In 1964, Kinsbourne described five children with contortions of the neck associated with a hiatus hernia. The name Sandifer syndrome has subsequently been used for this condition on the suggestion of Sutcliffe, as a number of the described patients had been under Sandifer’s care, and ‘this was already a specific clinical entity and first appreciated by the late Dr. Paul Sandifer’ (Webb and Sutcliffe 1971). (Sandifer had died suddenly, at the early age of 56 years in 1964.)

Kinsbourne felt the contortions seemed to be voluntary trick movements aimed at relief of discomfort. The positions adopted by the children were extraordinary and captured in photographs. As an example, case 2 was a 7-year-old boy: ‘When the boy was standing or lying he would overextend his neck and rotate his head to one or other side. His preferred posture for reading was lying supine on his bed with his head hyperextended over the edge and holding his book above him’. With case 4 there was ‘continuous obtrusive head rolling from side to side along the arc of a circle centred upon the vertical axis of the body. These movements attended all his activities and resulted in the occasional adoption of bizarre postures. Thus, he might sit with his head turned sideways beneath the arm-rest of the chair’.

The five patients were boys aged between 4 and 14 years. They all had a hiatus hernia and associated gastro-oesophageal reflux (GOR) of sufficient severity that all but one had iron deficiency anaemia. The movements were most evident immediately after eating, and were not present in sleep. The bizarre postures upset the parents, but the children seemed untroubled by them. Three of the children said they helped to relieve abdominal discomfort. After successful repair of the hiatus hernia, the movements were completely abolished, and did not reappear.

The initial reports of Sandifer syndrome reflected the patients described by Kinsbourne. For example, a ‘Picture of the Month’ (Gellis and Feingold 1971), showed an emaciated boy adopting a head down posture with rotation to the left in both the lying and standing postures. A similar picture was described in children with GOR, but without an accompanying hiatus hernia (Ramenofsky et al. 1978). With the advent of pH monitoring and other sophisticated techniques for detecting GOR, a less severe clinical picture has been described. Werlin et al. (1980) reported five infants under the age of 8 months, with three less than 17 days of age, who had GOR and abnormal movements. The movements consisted of body shaking or stiffening, at times in association with apnoea. Recently the diagnosis of Sandifer syndrome has been made in a 6-month-old girl who had twisting of the neck to one side that persisted for 7 days, after which the abnormal position moved to the other side (Cafarotti et al. 2014). Feeding seemed to have no relationship with the neck posture. Treatment with ranitidine resulted in a cessation of all symptoms. The clinical picture in these later cases is obviously very different from the original description.

A basic difficulty is that GOR is very common in children especially in infants. It has been estimated that between 30% to 67% of children have GOR (Berman 2015). There are also doubts that pharmacological therapy of GOR is effective (Tighe et al. 2014). Unusual movements are particularly common in young children, as is GOR. If symptoms settle after anti-reflux treatment is given, this does not establish
that GOR was responsible for the symptoms. As discussed above, there are many potentially serious causes of torticollis in children, and the diagnosis of Sandifer syndrome has been considered in children with a retained foreign body in the oesophagus (Smallpiece and Deverall 1982), Chiari malformation (Berthet et al. 2014) and cow’s milk protein allergy (Bamji et al. 2015).

Treatment of Sandifer syndrome obviously involves the expertise of gastroenterological colleagues, but is by no means always straightforward. A 4-year-old boy failed medical therapy and then had laparoscopic fundoplication followed by laparoscopic pyloroplasty, without relief of his abnormal side-to-side head movements (Wasserman et al. 2010). The movements persisted until a naso-jejunal feeding tube was inserted.

Restricting the diagnosis of Sandifer syndrome to children who have pronounced abnormalities of neck movement and posturing, where GOR is severe and is clearly demonstrated to be the cause, is an approach that might be considered. Irrespective of what criteria are used, the diagnosis of Sandifer syndrome should always be made with great caution.

### PAROXYSMAL DYSKINESIAS

The term paroxysmal dyskinesias is particularly applied to three conditions: (1) paroxysmal kinesigenic dyskinesia (PKD); (2) paroxysmal nonkinesigenic dyskinesia (PNKD); and (3) paroxysmal exercise-induced dystonia (PED). Although there are many other conditions where there are recurrent episodes of hyperkinetic movements such as tics, stereotypies, and the episodic ataxias, traditionally these are not considered when paroxysmal dyskinesias are discussed. Paroxysmal dyskinesias are classified as primary where the cause is usually genetic and of dominant inheritance, and secondary when the cause is an identifiable disorder such as hypoparathyroidism or multiple sclerosis.

### HISTORICAL FEATURES

A review of the historical features of the paroxysmal dyskinesias is helpful in understanding the clinical manifestations of the different conditions, and the at times complex terminology and classification systems that have appeared in the literature. To avoid confusion, the current notations PKD, PNKD, and PED will be used except when directly quoting from previous papers.

### PAROXYSMAL KINESIGENIC DYSKINESIA

The first known description of paroxysmal dyskinesias was in 1892 by Shuzo Kure of a Japanese man with PKD. (See Ebrahimi-Fakhari et al. 2015 for illustrations from the original paper.) Subsequent reports often regarded PKD as a form of reflex epilepsy. The most detailed of these, and which is beautifully described the clinical features of PKD, was by Lishman et al. (1962, p. 104), where seven patients were described. So precise is their description that it is reproduced it here:

‘The attacks usually begin in childhood and occur frequently. They are constantly precipitated by sudden movement and are more likely to occur after a period of rest. Movement of the legs more often than the arms initiates them. An element of surprise or “startle” seems important. In many cases a state of tension, anxiety or self-consciousness makes them more likely. Conversely, subjective preparation for movement and slow initiation of action tend to reduce or abort them. The attacks themselves consist of tonic spasm which may involve the whole body, but is more commonly localised to the limb in which they start or confined to one side. In three cases the movements had a writhing character reminiscent of torsion spasm. Clonic movements were absent. A sensory aura was not uncommon. Whenever present it began in the limb in which the movement would start and spread briefly before spasm supervened. In any given case the pattern of attack was generally stereotyped, though attacks might be arrested before fully developed. Consciousness was never lost, though in some cases there was evidence of transient clouding. Attacks could sometimes be voluntarily induced, provided the provoking movement was abrupt and forceful.

Lishman et al. (1962) did not give a detailed account of treatment, but phenytoin, when used, seemed to be effective. Phenobarbitone gave variable results.

Kertesz (1967) introduced the term paroxysmal kinesigenic choreoathetosis emphasising the provocation by movement, the short duration of the episodes, the good response to phenytoin and the familial occurrence, but speculated that the inheritance was recessive. (Subsequently it became clear that the inheritance is autosomal dominant with reduced expressivity.) In 1969, Kato and Araki described a 14-year-old girl whose episodes of PKD responded well to carbamazepine, and this has become the most commonly used medication. In 1997, Szepetowski et al. described four families where benign infantile convulsions were inherited as an autosomal dominant trait, together with variably expressed ‘paroxysmal choreoathetosis’. Eight patients had infantile convulsions followed by the later development of choreoathetoid movements. There was strong linkage evidence for the abnormal gene to be present in the pericentromeric region of chromosome 16.

It was long assumed that PKD would be found to be caused by a channelopathy (Berkovic 2000). In 2011, using a combination of exome sequencing and linkage analysis, Chen et al. found that mutations in the gene for proline-rich transmembrane protein 2 (PRRT2) was the cause of PKD.
PAROXYSMAL NONKINESIGENIC DYSKINESIA

In 1940, Mount and Reback described a 23-year-old man with ‘familial paroxysmal choreoathetosis’. The family history stretched back over 100 years to the patient’s great-grandfather, who died at the age of 87. In all, there were 28 affected individuals (18 males and ten females). From the pedigree provided, inheritance was autosomal dominant.

The index patient had both minor and major episodes with the major episodes lasting as long as 2 hours. He found that if he drank a cocktail after dinner, he was certain to have an episode. On days when he drank coffee, tea, alcohol or coca cola, he was more likely to have attacks. Fatigue, concentration and ‘exposure’ also seemed to be precipitating factors. On average he had one ‘large’ and two ‘small’ episodes a day. During the minor incidences he had no difficulty in speaking, but during the large attacks his speech was dysarthric and at times he was anarthric. The large episodes were characterised by choreoathetoid, ballistic and dystonic movements. In a severe episode if he attempted to walk, dancing movements occurred in the lower limbs, sometimes throwing him off balance. There was no alteration of consciousness. He found that the episodes ceased more quickly when he lay down. If he was able to go to sleep, even for a few seconds, the episode was over when he awoke.

In 1968, Richards and Barnett described another large family with PNKD from Canada. They noted that it was a less common condition than PKD, and the two were often confused in the literature. In contrast to paroxysmal kinesigenic choreoathetosis, they suggested it be called paroxysmal dystonic choreoathetosis, or Mount and Reback syndrome. In 2004, Rainer et al. identified missense mutations in the myofibrillogenesis regulator gene (MR-1) in 12 affected individuals in two unrelated PNKD kindreds.

PAROXYSMAL EXERCISE-INDUCED DYSTONIA

In 1977 Lance described two families. The first had the typical features of PNKD. The second family consisted of a man who died at 58 years of age, his then 44-year-old daughter, and her 23-year-old daughter. These individuals developed dystonia which mainly affected the legs after exercise. The dystonia was never precipitated by sudden movement, but by steady exercise such as walking ‘a mile’ (1.6 kilometres). The incidences were also brought on by other forms of exercise, such as a game of tennis or strenuous housework. The 23-year-old woman noted that her episodes started with a sensation of heaviness of the legs and cramping of the feet, followed by inversion of both feet, and writhing movements at the ankles. The duration of exercise required to provoke her episodes was variable. On some days an episode could start after walking only 200 metres, but on other occasions she could walk 8 kilometres without any trouble. The episodes usually lasted between 5 and 30 minutes.

Adapted from Lance (1977).

Paroxysmal nonkinesigenic dyskinesia (PNKD), paroxysmal exertion induced dystonia (PED) and paroxysmal kinesigenic dyskinesia (PKD) have been added to the original.

CLASSIFICATION SCHEMES

Lance (1977) discussed these two families and in addition reviewed the literature of PKD, which was clearly the most common form of paroxysmal dyskinesias, as he was able to identify 100 cases. A modified form of his classification scheme can be found in Table 21.1.

Demirkiran and Jankovic (1995) subsequently suggested the generic term paroxysmal dyskinesia replace the previously used choreoathetosis, as the incidences could be choreic, ballistic or dystonic and in some episodes there was more than one movement disorder. They proposed a more complex classification scheme incorporating phenomenology, duration of episodes and aetiology. Psychogenic disorders were included as a secondary cause of PNKD, and some of the clarity provided by the Lance scheme was lost in this attempt to cover all possible presentations. Bruno et al. (2004) included the control of the events by phenytoin or carbamazepine as part of the defining criteria for the diagnosis of PKD.

CLINICAL AND GENETIC FEATURES OF THE PAROXYSMAL DYSKINESIAS

PAROXYSMAL KINESIGENIC DYSKINESIA AND THE SPECTRUM OF PRRT2 MUTATIONS

A large number of reports followed the identification of PRRT2 mutations as a cause of PKD by Chen et al. (2011). Ebrahimi-Fakhari et al. (2015) found that 1444 patients with 70 different PRRT2 mutations had been reported over a 4-year period. The vast majority of cases were familial in origin, and almost 80% carried the same c.649dupC frameshift mutation. Ninety-five per cent of patients fell into the diagnostic spectrum of benign familial infantile convulsions, infantile convulsions followed by PKD, or PKD alone.

Benign Familial Infantile Convulsions

PRRT2 mutations are also responsible for benign familial convulsions (BFIC). Typically there are afebrile seizures that begin between 3 and 12 months of age, and remit after 1–2 years. Usually there are clusters of focal dyscognitive, or secondarily generalised tonic–clonic seizures. Heron et al. (2012) identified heterozygous mutations in PRRT2, in 14 of 17 families (82%) affected by BFIC, indicating that PRRT2 mutations are the most frequent cause of this disorder. Heron et al. also found PRRT2 mutations in five of six (83%) families affected by infantile convulsions and choreoathetosis (ICCA) syndrome. Steinlein et al. (2012) reported similar results with BFIC. Zara et al. (2013) identified 21 families with 78 individuals affected by BFIC who had PRRT2 mutations. Five individuals from three families developed PKD in childhood or adolescence. Carbamazepine was only used as treatment in a few of the families in these reports. As BFIC is a self-limiting condition, it is difficult to make strong recommendations, but unless there is a risk of Stevens–Johnson syndrome it would seem reasonable to use carbamazepine for BFIC, if treatment seems warranted. Febrile seizures have also been reported in patients with PRRT2 mutations (Marini et al. 2012; Scheffer et al. 2012). In their review Ebrahimi-Fakhari et al. (2015), felt the association of PRRT2 mutations with febrile seizures was ‘more coincidental than causal’.

Other Manifestations of PRRT2 Mutations

PRRT2 mutations have been found to cause some cases of paroxysmal hypnogenic dyskinesia (PHD) (Liu et al. 2016). In this condition there are unprovoked dystonic, choreoathetoid and ballistic episodes during sleep. In the Liu paper, two of five children with typical PHD, with onset of events between 2 months and 3 years, were found to have PRRT2 mutations. PRRT2 mutations have also been associated with migraine (in particular hemiplegic migraine), ataxia, absence seizures and benign paroxysmal torticollis (Dale et al. 2012; Gardiner et al. 2012; Marini et al. 2012; Riant et al. 2012). There is a report of a boy with a PRRT2 mutation and hemiplegic migraine, whose episodes stopped completely after he was treated with carbamazepine (Dale et al. 2014). It appears that hemiplegic migraine is the most common primary diagnosis in PRRT2 mutation carriers who do not have BFIC or PKD (Ebrahimi-Fakhari et al. 2015).

Homozygous mutations of PRRT2 are associated with a much more severe phenotype. Manifestations include intellectual disability, episodic ataxia, absence seizures and cerebellar atrophy (Najmabadi et al. 2011; Labate et al. 2012; Delcourt et al. 2015). Delcourt et al. (2015) noted that three or more forms of paroxysmal neurological disorder could occur in the same patient, and the episodes tended to persist.

The mechanism by which mutations in PRRT2 cause these various manifestations is unknown. PRRT2 has been shown to interact with the synaptic protein SNAP25 and it seems likely that the problems relate to abnormalities of synaptic neuro-
transmission (Ebrahimi-Fakhari et al. 2015; Gardiner et al. 2015).

Secondary Causes of Paroxysmal Kinesigenic Dyskinesia

There are a number of conditions that have been described as secondary causes of PKD. These include hypoparathyroidism, pseudohypoparathyroidism, birth injury, head injury, multiple sclerosis, hypertonatremia, thyrotoxicosis and insulin-dependent diabetes (Nardocci et al. 1989). In a familial case of PKD with the typical features, including immediate cessation of events with carbamazepine, investigations may not be necessary. However, in a sporadic case it seems sensible to organise neuroimaging, and blood tests including measuring calcium, thyroid function tests, and fasting blood glucose level. Other investigations would relate to the clinical setting, as would treatment.

Seizures, in particular those arising from the supplementary motor area, can have similarities to PKD, having both an aura and movement-induced events, in particular limb spasm (Falconer et al. 1963). However, usually there are more unprovoked events than typically are seen in PKD. There may also be secondarily generalised seizures.

PAROXYSMAL NONKINESIGENIC DYSKINESIA

Bruno et al. (2007) published a wonderfully detailed analysis of the clinical features of patients with PNKD with MR-1 mutations. They described 49 patients (27 males and 22 females) from eight kindreds. Neurological examination was normal in all between episodes except for a child with presumably coincidental cerebral palsy. The onset of the events ranged from age 3 months to 12 years (with an average of 4 years). In 16 patients (33%), the episodes started before the age of 1 year. Forty-one per cent of patients reported premonitory sensations preceding an episode. In most, this was a sense of stiffening or numbness of a limb, but in 20% it was more a sense of anxiety. The events were most often a combination of dystonia and chorea, but 12% reported dystonia only. Speech involvement occurred in 45% of patients. Less common problems included blepharospasm, risus sardonicus and diplopia at the height of an event. Typical episodes lasted 10 minutes to 1 hour, but this could range from several minutes to 12 hours. Most patients had a period in their life where they were having at least weekly occurrences. With age, the frequency of episodes tended to decrease. Six per cent reported only a small number of events in their life, with one patient only ever having one episode.

Reflecting the initial report, a striking feature was precipitation of episodes after drinking caffeine and alcohol. This was seen in almost all patients. Emotional stress also seemed to lower the threshold for the incidences. In 70% of patients, going to sleep could abort the episode. Contrary to the impression from the previous literature, most patients who took benzodiazepines, either during, or to prevent an episode felt they were helpful. Headaches, including migraine, were a common additional symptom with these patients. Penetration of the MR-1 mutation was extremely high, with only one very young patient being asymptomatic.

Bruno et al. (2007) also looked at patients from six other kindreds with PNKD, who were MR-1 mutation-negative. They had a much more variable clinical picture in terms of onset, precipitants, clinical features, and response to medication. Exercise was the most common trigger, reported in 68% of the patients.

There may be multiple different genetic abnormalities responsible for patients with PNKD who are MR-1 mutation-negative. There are two reports of PNKD caused by mutations in KCNMA1 (Du et al. 2005; Zhang et al. 2015), and it is likely other abnormalities will be found in the future. Zorzi et al. (2008) reported three patients with overlapping PNKD and PED phenotypes who had glucose transporter deficiency. All had microcephaly and intellectual disability, and two had seizures, features that are not seen in MR-1 mutation positive patients.

Although the episodes of PNKD can be disruptive to life, they are rarely life-threatening. However, Zittel et al. (2015) reported the case of a MR-1 mutation positive 19-year-old girl, whose mother had died at the age of 37 years from suffocation due to laryngeal dystonia during a PNKD episode. The episodes in this girl did not respond well to clonazepam, but there was a marked improvement when acetazolamide was added. The authors suggested this should be considered early in the treatment of patients with PNKD.

Other medications that have been reported to help in individual cases of PNKD include haloperidol, levetiracetam, valproate and anticholinergics (Mink 2015). Carbamazepine is generally ineffective. There are several reports of adults with PNKD responding to deep brain stimulation of the globus pallidus, but no reports of children.

Episodes of PNKD can be misinterpreted as psychogenic in origin, and as in many movement disorders, there may be associated psychiatric difficulties. This is exemplified by the paper of Walker (1981), who described two siblings who had both come under psychiatric care because of suicide attempts, and were found to be the children of the patient described by Mount and Reback.

PAROXYSMAL EXERCISE-INDUCED DYSTONIA

Twenty years after the initial description by Lance (1977), Bhatia et al. (1997) reported eight new sporadic cases of PED, and reviewed the literature. There were, including their own patients, only 20 cases reported. Five patients came from two families, and the other 15 were sporadic. It was suggested the term ‘paroxysmal exercise-induced dystonia’ be used, rather than dyskinesia as dystonia was the dominant movement disorder.
In 2008, mutations in *SLC2A1*, which encodes GLUT1, the main transporter for glucose across the blood–brain barrier, were found to be a cause of PED. Suls et al. (2008) studied a five-generation family and identified a heterozygous missense mutation in *SLC2A1* in 22 affected family members. Three other nuclear families with a similar phenotype were found to have frameshift and missense mutations in *SLC2A1*. From a total of 25 affected individuals from these four families, 19 had a history of PED (76%), and 14 of epilepsy (56%). In the 19 patients with PED, median age at onset was 8 years with a range of 3–30 years. PED was characterised by choreoathetosis, dystonia, or both, with the legs involved in all patients. In ten patients (55%), only the legs were involved. In six (33%) the legs and arms were involved, but with the legs more affected. In two of these six, there was also facial involvement. In the five-generation family, eight of the 19 individuals had PED without epilepsy.

Suls et al. (2008) found that in their cohort, epileptic seizures appeared mainly as generalised tonic–clonic seizures or absences, with the absence having an onset at around 2 years of age, much earlier than is seen with classic absence seizures. One patient had myoclonic seizures, and two patients also had partial seizures. Most mutation carriers were of average intelligence, or had mild intellectual disability, with no difference between patients with PED alone, and those with epilepsy. Compared to patients with classic GLUT1 deficiency, there was a less pronounced decrease in fasting cerebrospinal fluid (CSF) glucose to serum glucose concentration ratio, reflecting the milder phenotype.

Weber et al. (2008) described a three-generation family with PED due to *SLC2A1* mutations, accompanied by epilepsy, mild developmental delay, reduced CSF glucose levels and haemolytic anaemia. They also screened four other families in whom PED was combined with epilepsy, developmental delay, or migraine, but not with hemolysis, and identified two additional *SLC2A1* mutations. The age at onset of the dyskinesia varied between 10 and 15 years (mean 13 years). Stress, exertion and fasting provoked the appearance of dyskinesia.

Schneider et al. (2009) screened ten patients with PED and found that two had *SLC2A1* mutations. One had previously suffered childhood absence epilepsy and, at the time of review, she also had hemiplegic migraine. The other patient only suffered from PED. The authors proposed that *SLC2A1* mutations can present with a spectrum of severity with microcephaly, intractable seizures, and intellectual disability at one end, and isolated PED at the other. Afawi et al. (2010) described a family with *SLC2A1* mutations, including two members who had PED alone, two with epilepsy alone, and one person who had both. The PED appeared when the patients were between 10 and 15 years of age (mean 13 years), and the onset of epilepsy was between the ages of 13 and 30 years (with a mean of 19 years). The seizures were tonic–clonic in three individuals, and myoclonic with myoclonic status in one.

Ramm-Pettersen et al. (2013) reviewed the response of six patients with *SLC2A1* mutations and PED to dietary treatment. They were mostly adolescents, and three had mild intellectual (disability). In the one patient given the ketogenic diet, the PED episodes stopped. The other were given the modified Atkins diet and, in three, the episodes stopped, but they remained a problem in the two others. Being on the ketogenic diet in particular, but also the modified Atkins diet, is no small undertaking, and in mildly affected patients with PED as their only symptom, a careful discussion of benefit versus risk is obviously important. There is a report of patients with dystonic tremor due *SLC2A1* mutations refusing treatment with either the ketogenic diet, or antiepileptic drugs (Roubergue et al. 2011).

In patients with PED, the presence of seizures strongly raises the possibility that *SLC2A1* mutations are the underlying cause. The seizures may have an early onset, or be delayed until adolescence, and be relatively mild. (A more detailed discussion of glucose transporter deficiency can be found in the Treatable Movement Disorders Section in Chapter 19.)

PED appears to be a heterogeneous condition. Multiple other causes have been identified besides *SLC2A1* mutations. These include a mother and son where PED was due to GTP cyclohydrolase deficiency (Dale et al. 2010), early-onset Parkinsonism in adults (Bozi and Bhatia 2003), moyamoya disease (Lyoo et al. 2007), pyruvate dehydrogenase deficiency in a girl who responded to thiamine therapy (Castiglioni et al. 2015) and an ECHS1 mutation in a 15-year-old girl who had mild pallidial changes on MRI (Olgiati et al. 2016). Other causes will no doubt be found in the future.

**APPROACH TO PAROXYSMAL DYSKINESIAS**

Although paroxysmal dyskinesias can be a confusing subject, the approach suggested by Lance provides a very useful starting point. If the patient has short-lived attacks, often provoked by sudden movement, then PKD is likely. If the attacks are dystonic, affect particularly the legs, last longer and come on after sustained exercise, then PED is the probable diagnosis. When there are prolonged episodes, then PNKD needs to be considered, especially when the episodes are provoked by the consumption of caffeine or alcohol.

**PSYCHOGENIC PAROXYSMAL DISORDERS**

The huge topic of psychogenic disorders is discussed in Chapter 32. The following from Kinsbourne (1964, p. 1058) illustrates some of the difficulties. ‘When a patient presents with a disorder of movement and posture, it is natural in the first instance to think of neurological disease, such as of the basal ganglia. If the clinical features are not those of a recognised neurological syndrome, the possibility of a psychogenic disorder may then arise. But sometimes both these explanations prove incorrect.’

Disorders of Visual and Oculomotor Functions

Carey Matsuba

The visual system plays an important role in the exploration and analysis of the external world. Proper functioning of this system requires the integrity of an extremely complex neuronal network easily disturbed by a vast number of central nervous system (CNS) disorders, making it important to review this system through the components from ocular structures to the retinal transmission of the visual information through the optic nerve to the occipital cortex. This transmission can be impeded or disturbed by many pathological processes that may in turn influence oculomotor function. Clinical and electrophysiological analysis of the visual system disorders is a sensitive means of exploring the CNS function and abnormalities of oculomotor movements and constitutes an essential part of the neurological examination.

VISUAL IMPAIRMENT

OVERVIEW AND DEFINITIONS

Visual impairment has historically been defined by two features: a reduction in visual acuity and/or loss in visual field. The World Health Organization defines visual impairment as seen in Table 22.1, however, the definition has particular challenges in the paediatric population. The primary challenge is that in young children vision function changes with maturity and therefore there are no standard criteria for childhood visual impairment. In addition, the measurement of visual acuity and visual fields in children can be challenging to the clinician. Many children with a visual impairment may go undiagnosed for this reason while for others nonocular causes of a reduction in visual acuity or field loss are occasionally not considered in the realm of visual impairment. In ICD-10 neurological causes of a reduction in visual acuity or loss in visual field are not explicitly included in the aetiologies of a visual impairment. Both of these conditions would be coded generically as H54.7 (Table 22.2).

It should be noted that this traditional definition of visual impairment differs from problems with visual function. All too often children with developmental difficulties may be incorrectly diagnosed as having a visual impairment, such as children with reading disorders or poor visual-motor coordination. Alternatively, some children may have colour blindness or lack of stereopsis. Although physiologically these are common visual dysfunctions, these conditions alone do not meet the criteria of visual impairment.

Despite limitations in diagnosis and problems with definition, the aetiology of visual impairment encompasses multiple conditions which can occur in isolation or in conjunction with a systemic condition. Estimates of prevalence greatly vary, in part related to the difficulties in diagnostic criteria and challenges with assessment; in developed countries about one or two out of 1000 children will meet the criteria of visual impairment (Gilbert et al. 1999). The age at diagnosis of visual impairment varies depending upon the underlying aetiology, presence of co-existing conditions and access to appropriate assessments. Most children with visual impairment should theoretically be identified early, as the most common causes of visual impairment are present in the first year of life. For example, cortical visual impairment, the most common aetiological condition, has been associated with perinatal injury, structural brain anomalies and metabolic disturbances. Similarly, the most common optic nerve disease leading to visual impairment, optic nerve hypoplasia, as well as structural eye diseases, can be typically identified in the first days to months of life: the typical presentation not only involves challenges with visual attention but also comorbid health and neurodevelopmental difficulties. The combination of abnormalities leads to the earlier detection of most conditions leading to visual impairment: given this early presentation there are no systematic screening programmes for visual impairment.
The visual pathway comprises the eye, optic nerve, optic radiations and occipital cortex. Any abnormality within the pathway can lead to a reduction in visual acuity and/or visual field loss. It is important to note that this chapter focuses on conditions causing a non-reversible reduction in visual acuity or loss in visual field and hence common ophthalmological issues such as refractive error, strabismus and colour vision abnormalities are not specifically discussed, however these conditions are often present in conjunction with aetiological causes of visual impairment.

The visual pathways are an intricate organised system. Often the systems are divided into two areas, the anterior pathway comprising of the eye and optic nerve as well as the posterior pathway comprising of the optic radiations and occipital cortex. This division is important as anterior pathway conditions can be directly visible by ophthalmological evaluation, whereas the posterior pathway is hidden. In many conditions there can be aberrations in both pathways.

Visual function relies on the combined development of the eye and brain. Although structurally the eye is formed at the time of birth the myelination of the optic nerve fibres and brain continues well after this event (Magoon and Robb 1981; Atkinson 2000; Kiorpes and Movshon 2004); as this occurs visual capabilities of the child increase to adult levels.

### Ophthalmological Assessment for the Non-Ophthalmologist

The ophthalmological assessment is a key component in the evaluation of visual impairment. A full ophthalmological examination includes a fundoscopic examination, evaluation of visual acuity and visual field testing however such examinations can be difficult in infants, young children and children with developmental disabilities. The assessment should also include identification of the reflex responses such as pupillary light reflex, which is reliably present after 31 weeks of gestation: a blink response to light develops at approximately the same period (dazzle reflex) but a blink to threat is unreliable and late in appearance. Fixation and following are present from very early in life: infants turn their head towards a

Meaning that careful history taking and examination are needed. This evaluation goes beyond a full ophthalmological assessment.

Assessment of children with suspected visual impairment primarily relies on history and observation. Although the child with visual impairment may present at any age, the majority of aetiological causes stem from genetic, prenatal or perinatal causes. Patients with visual impairment are more likely than not to have additional health and neurodevelopmental conditions meaning that particular focus on a complete neurological and developmental history is important.

When observing visual clinical signs, those such as light sensitivity or exotropia can help guide clinicians to possible aetiological causes. Photophobia may indicate a cone disorder, corneal dystrophy or glaucoma while exotropia may be a sign of visual inattention, often present in cortical visual impairment. Clinicians should use the time during information gathering to intermittently observe visual function, including visual behaviours such as head tilt, visual working distance at play: head tilt may indicate the presence of nystagmus, field loss or a problem with the extraocular muscles. In addition to eye alignment and the presence of nystagmus, craniofacial anomalies and pigmentation abnormalities can also be used to assist with diagnostic profile.

</table>
diffuse light from a few days of age. The human face, at a distance of approximately 30cm is the best target for fixation: following in the vertical plane is particularly useful as vertical eye movements are not normally random movements and are, therefore, more reliable than horizontal ones. Nystagmus induced by rotation about the body axis is present in healthy term infants but inhibited within a few seconds by visual fixation, whereas in blind children it may persist for 15 seconds.

The ocular assessment should include inspection of the eye for structural anomalies such as size, presence of coloboma or presence of nystagmus. Extraocular movements are an important component to be assessed: typically extraocular muscles are assessed through alignment. Pupillary responses give a dynamic evaluation of the system and can identify abnormalities in the visual pathways as well as significant differences between the left and right visual pathways.

Stereopsis can be used as a measure of eye alignment but unfortunately can only be measured in children developmentally 2–3 years of age. When measuring stereopsis it is important not to dissociate the child’s vision: dissociation can occur when the examiner covers one eye, breaking stereovision meaning that testing for stereopsis should be undertaken first using one of several common tests such as the Lang stereotests or two pencil test. When a child is not able to perform a stereo testing there are several measures of alignment including simple inspection, the Bruckner’s test, as well as cover and uncover test: the Bruckner’s test (http://www.ophthobook.com/wpcontent/uploads/2007/12/ped-hirschburg.jg) is a simple light reflex test as is the Cover and Uncover test (http://www.aafp.org/afp/1998/0901/afp19980901p691-f5.jpg).

Fundoscopic evaluation may be the most difficult to perform on a child as well as to evaluate for a non-ophtalmologist clinician. Subtle changes particularly in the periphery require indirect ophthalmoscopic evaluation. For the experienced clinician most children will be able to cooperate for direct ophthalmoscopic examination with the assistance of a fixation target. Although a thorough indirect fundoscopic evaluation is often needed, the non-ophtalmologist clinician requires a review of the macula and optic disc.

Refractive errors are common in children with neurological impairments. In the non-verbal or young child refraction can be performed by an ophthalmologist through cycloplegic retinoscopy. The ophthalmologist uses the retinoscope to shine light into the child’s dilated eye and observes the reflection (reflex) off the patient’s retina. While moving the light across the dilated pupil the ophthalmologist observes the relative movement of the reflex and then uses a phoroptor or manually places lenses over the eye (using a trial frame and trial lenses) to “neutralise” the reflex: in this way a refractive error can be measured. Depending on the symptoms such as the presence of strabismus the child could be placed in corrective lenses, optimising their vision.

**Visual Acuity Measurements**

Visual acuity is a measure of one’s ability to see detail. It is a useful measure of total visual pathway function and improves in childhood. At birth, the macula is immature but with time matures during infancy. It is measured by several standard conventions such as 20/20 or 6/6 (Snellen), 1.0 (decimal) or 0.0 logMAR. In practice these measures all relate to a standard based on the comparison of standard visual acuity compared to the individual’s measured acuity. Most clinicians are familiar with matching acuity charts at 20 feet or 6 metres.

There are a number of visual acuity tests that can be used in children including the BUST visual acuity test card, commonly used by the neurologist, however, the use of the near test must be used with some caution. For example, the BUST card uses numbers, meaning that a child would have to be familiar with such units to perform the test. Most early visual acuity tests rely on matching figures such as the HOTV, tumbling E or picture tests. At developmental age 3 years children have started to match and therefore acuity testing could be tried (American Academy of Pediatrics et al. 2003).

In young children estimates of visual acuity are available using preferential looking acuities or electrophysiological procedures (visual evoked potentials) as they may not be able to perform standard matching acuity charts. Visual evoked potential measures have been shown to record better visual acuity measures over preferential looking acuities (Mayer et al. 1995; Salomao and Ventura 1995). Both measures have been normalised in infants and young children, although visual evoked potentials measures tend to report higher acuities than Preferential looking acuities particularly in younger children. This is partially related to higher processing required with visual attention and eye-head coordination in the behavioural testing (Braddick and Atkinson 1988). Similarly, in children with cognitive difficulties letter acuities have been found less than preferential looking acuities (Mayer et al. 1983; Friedman et al. 2002).

**Visual Field Measurement**

As with visual acuity, visual fields mature with time. Term infants have significantly smaller visual fields than older children (Schwartz et al. 1987; Mayer and Fulton 1994), with the visual field increasing through infancy to 4 years: by 18 months of age it can be as large as 90–95% of that in adults.

Visual fields are an important measure of visual function however formal visual field measurements are difficult in young children. In these children estimations of the visual field can be done by confrontation which can be performed by presenting secondary targets in the child’s periphery, while the child is fixating on a primary fixation target, typically the examiner’s face. By observing the orientating response with either head or eye movements a clinician can get an estimation of peripheral field while spurious results can also occur, resulting from other distracting movements. To adjust a wand with a fixation target or light at the end can be used to minimise errors. This technique is not particularly accurate for scotoma or subtle changes in the extremes of the peripheral field, but it can get an estimation of a hemi or quadranopia, with these field deficits being relatively the most common presenting condition of field loss. With maturity a Goldmann kinetic perimetry can be performed in children as young as 4 years (Mayer and Fulton 2005).
Additional Testing for the Non-Ophthalmologist

There are many electrophysiological measures to assess vision and non-ophthalmology clinicians should be familiar with some, such as the electro-oculogram (EOG) used to assess maculopathy primarily due to retinal pigment epitheliopathy. Maculopathies in paediatrics are relatively uncommon. The electroretinogram (ERG) is used to identify cone and rod dysfunction and can be used to assist or confirm the diagnosis of many retinal diseases. Optical coherence tomography (OCT) is an important non-invasive, imaging technique that allows cross-sectional and three dimensional measurements of the retina.

The visual evoked response to flashes is an excellent technique to demonstrate the integrity of the visual pathway without patient cooperation (Baker et al. 1995). A positive cortical wave with a peak latency of 300ms is first demonstrable at 30 weeks’ gestation with the latency then declining by about 10ms each week through the last 10 weeks of gestation (Taylor et al. 1987; Leaf et al. 1995). By about 3 months of age the morphology and latency of the visual evoked responses are relatively mature, but the interpretation of the responses at earlier periods remains difficult. Visual evoked procedures, such as patterns, shifting orientation and sweep are being used that can provide greater information regarding the visual axis.

For central causes of vision loss neuroimaging techniques may be useful in the assessment of children with visual impairment (Flodmark et al. 1990) as they can detect associated cerebral malformations such as structural anomalies along the visual pathways.

Management of Visual Impairment

Once the clinician has diagnosed a visual impairment it is important to consider appropriate management strategies, however, many clinical diagnoses are descriptors of a phenotype. For example, retinitis pigmentosa is an inherited condition caused by mutations occurring in one of several genes which may be clinically indistinguishable. But genetic testing has become more prominent in the investigation of ophthalmological conditions as newer experimental treatments, such as gene therapy, are being studied, seen in Leber's congenital amaurosis (Bainbridge et al. 2008), however, the mainstay of treatment is supportive.

By definition visual impairment is a non-reversible reduction in visual acuity or loss in visual field. It is important to optimise the vision, particularly in regards to refractive error. In many circumstances environmental adaptations, including preferential seating, magnification and optimal lighting, can help with functional vision. In addition, many conditions have associated comorbid health issues. Optimising the health of a child with visual impairment may improve their visual function, the most apparent form of which would be the treatment of refractory seizures.

Following the diagnosis of a visual impairment referral to vision support services early is important, if available. Specialised services can offer information on the condition and disability, with primary caregivers the leads in providing support to the child. Through the assistance of specialised services and/or local and national support groups, developmental, educational, social and cultural issues can be addressed.

The habilitation of children with visual impairment results from skilled, early intervention. As children with visual impairment are at risk of developmental impairments, assessing and supporting all domains of development are important. Often children are best supported through a multidisciplinary team which may include ophthalmologists, paediatricians, neurologists, geneticists, nurses, psychologists, speech-language pathologists, audiologists, physical therapists, occupational therapists, assistive technology specialists, educators as well as orientation and mobility specialists.

There are a number of points to consider in the habilitation of children with visual impairment, the first being to optimise and/or promote vision development. Encouraging visual interaction with the environment can be reduced by severe acuity or field loss, defective eye movements, marked developmental delay or visual attention disorders. When some vision is present opportunities to encourage vision should be undertaken immediately. Initially the presentation of meaningful but simply designed targets should occur: with time and better responses more complex figures can be used. Typically the presentation should be done at a close range often using concrete objects.

Early intervention providers, school educators, technology specialists and mobility specialists are important in the habilitation of children with visual impairment, with these trained individuals planning the curricula and teaching the children. The curriculum includes typical learning objectives but greater detail is needed for concept formation, orientation and mobility, daily living techniques, nonvisual communication in reading, writing, speaking, listening and the use of technical aids. These professionals are also important in explaining the educational environment as impaired accommodation, contrast sensitivity, colour perception, lighting, or eye movements can adversely affect learning. When the visual disorder is progressive the rate of deterioration determines the timing of introduction of Braille and assistive devices. Low vision aids and assistive technologies are more effective when educators are involved in the transition and instructions.

It is beneficial to introduce these services early so children with visual impairment have opportunities to become accustomed to these supports. Older children will benefit from low vision clinics operated by ophthalmologists or optometrists which provide continuity, particularly with low vision aides and technology.

Vision Screening

Paediatric vision screening is primarily used to identify refractive error, strabismus and amblyopia. Amblyopia is clinically defined as a significant reduction in visual acuity, despite appropriate correction of a refractive error (Friendly 1987) and is the most common cause of unilateral vision loss.
Typically the examination reveals factors that lead to amblyopia such as anisometropia, strabismus, monocular form deprivation or a combination of these. Unlike many causes of vision loss amblyopia can be treated, leading to improvements in visual acuity, however, vision screening is not used to identify visual impairment.

**AETIOLOGIES OF VISUAL IMPAIRMENT**

There are vast number of CNS, optic nerve, retinal, and ocular structural disorders that lead to dysfunction of the visual pathways and are often associated with a number of systemic and neurological diseases. The following paragraphs discuss some common conditions that result in a loss of visual field or visual acuity, with the main causes of visual impairment in childhood listed in Table 22.3.

**VISUAL IMPAIRMENT DUE TO CNS CONDITIONS**

**Cortical Visual Impairment**

In adults the term cortical blindness describes the complete vision loss due to bilateral damage to the occipital cortex. However, children who present with damage to the occipital cortex differ from adults, leading to the introduction of the term cortical visual impairment (CVI) due to these children often having partial vision loss (Jan et al. 1987). In the mid-1980s this form of visual impairment was being increasingly identified (Whiting et al. 1985; Roland et al. 1986). The term CVI applies to a reduction in visual acuity due to damage of the occipital cortices, in particular the calacrine cortex. In some children the reduction in visual acuity may primarily result from deep subcortical white matter insults such as periventricular leukomalacia meaning that the term cerebral visual impairment has been commonly used as it is more inclusive.

The early diagnosis of CVI remains essentially clinical with supportive investigations. Children may undergo multiple investigations but the results must be interpreted with caution: visual evoked responses may be deceptive as they may be normal despite profound vision loss (Taylor and McCulloch 1991; Wong 1991). An extinguished ERG can be helpful but may be absent in blindness not due to involvement of the retinal sensory epithelium. Study of optokinetic nystagmus may be helpful for the diagnosis of malingering if special equipment is available but clinical assessment is usually the best option.

CVI is now the most common cause of visual acuity loss in young children in developed countries. Traditionally CVI has been defined as a reduction in visual acuity and/or visual field, however, it has also been used to describe eye movement abnormalities and poor visual attention (Weiss et al. 2001). In the presence of acuity loss it is associated with significant comorbidities including cognitive and motor impairments with causes typically including perinatal hypoxic-ischaemia, especially in preterm infants with periventricular leukomalacia (Ng et al. 1989; Lanzi et al. 1998), infections, hydrocephalus, trauma and structural brain anomalies. Rarer aetiologies include hypoglycaemia, seizures, as well as inflammatory and neurodegenerative conditions. Fortunately, unlike in adults, children with vision loss due to occipital cortex injury often have improvement in their visual acuity over time (Roland et al. 1986).
