The underlying neurological structural abnormality varies, often dependent upon the onset of the injury, preterm versus term as well as type of injury. In preterm children the most common site of injury is to the periventricular white matter. Often, white matter disease can be divided into hypoperfusion and haemorrhagic while profound hypotensive injuries in preterm children may lead to deep grey matter and brainstem injuries. In term children watershed areas are affected, more likely to occur in the frontal and parietal-occipital regions.

FEVR, familial exudative vitreoretinopathy.
Acquired CVI is frequent in children with some degree of vision usually preserved. Many children present with puzzling visual behaviour and can be shown to have field and/or agnostic deficits including difficulties with recognition, orientation and depth, movement and simultaneous perception (Jan et al. 1987; Jan 1993). CVI may be transient or lasting, with transient CVI frequent following head trauma (Eldridge and Punt 1988) which may be a manifestation of epilepsy, migraine or other acute conditions (Barnet et al. 1970) such as hypoglycaemia (Garty et al. 1987).

Lasting acquired CVI can be a complication of infections especially purulent meningitis or herpes encephalitis, of acute hypoxia following vascular collapse, acute dehydration or status epilepticus (Arroyo et al. 1985; Connolly et al. 1991) as a result of infarction in the territory of both posterior cerebral arteries due to their compression while crossing the tentorial edge. Extensive cortical malformations are a less frequent cause (Jan 1993).

The clinical assessment of children with CVI may be difficult. Patients with CVI often have a normal fundoscopic examination with the optic nerve occasionally having some signs of pallor which would be consistent with transsynaptic degeneration of the geniculostriate pathways, occurring in post natal injuries (Jindahra et al. 2009). However, the optic nerve atrophy is not the major cause of a reduction in visual acuity when found. Nystagmus may be present in conjunction with periventricular leukomalacia while strabismus is a common feature.

Visual acuity measurements may be difficult. Often, the use of forced-choice preferential looking acuities may be able to yield estimates of visual acuities while other tools such as Vernier VEPs may be a reliable physiological measure of visual acuities. Although there may be complete loss of vision lasting weeks or months most patients recover some degree of vision (Lambert et al. 1987; Matsuba and Jan 2006). Even though permanent field deficits and low acuity almost always persist, children appear to have greater recovery of visual acuity compared with adults (Matsuba and Jan 2006; Malkowicz et al. 2006; Werth 2008). The clinical features of CVI often make recognition and/or behavioural manifestations and it is occasionally difficult to distinguish CVI from optic ataxia or dyskinetic eye movements where major disturbances in reaching for objects easily suggest blindness (Perenin and Vighetto 1988; Jan et al. 2001).

Until recently there have been no specific treatments for CVI. With the advent of neuroprotective strategies in the neonatal period there is some hope on the horizon, with cerebral hypothermia possibly leading to neuroprotection following neonatal encephalopathy (Gluckman et al. 2005; Azzopardi et al. 2009). Other neuroprotective medications are also being considered but the effect on CVI is still unknown.

**Development of Ventral and Dorsal Visual Pathways**

Vision influences many areas of child development. In the neonatal period, infants develop visual attention. Once attention is developed, the infant will begin to reach to interact with near objects. Subsequently, vision encourages children to explore more distant objects through visuomotor skills. The complex visual and environmental interaction is influenced by multiple comprehensive visual modules with these modules separated into two main cortical pathways, the dorsal and ventral streams (Milner and Goodale 1995). The ventral stream links the occipital and temporal lobes with connections associated with recognition of geometric forms, route finding and visual memory. The dorsal stream runs between the occipital and parietal lobes, subserving the ability to process the whole visual scene: it is mostly concerned with the perception of movement and visuomotor performance.

Interference with these pathways does not necessarily include a reduction in visual acuity or field but can have functional consequences (Goodale and Westwood 2004). It is thought that children with preferential ventral pathway involvement may have difficulties in recognition of objects in the presence of normal visual acuity, while children with damage to the dorsal stream were also found to have an impaired ability to make accurate visually guided movements (Dutton et al. 2004). Dorsal stream vulnerability has been suggested in children with Williams syndrome (Atkinson et al. 2001). Given the complexity of these perceptual difficulties, a more complete systematic evaluation may be useful (Dutton et al. 2010).

**Delayed Visual Maturation**

A healthy term infant typically starts the smiling response at 5 weeks of age followed by the ability to fix and follow at 8 weeks of age. However, some children without a known physiological reason fail to demonstrate these skills, which has led to the term delayed visual maturation (DVM) (Illingworth 1961). There are potentially multiple reasons for this presentation, as most infants with normal ophthalmological and neurological examinations often have a rapid development of normal visual responses. However, DVM is associated with comorbid health and cognitive impairments. In a follow-up study children with a history of DVM often developed normal acuities but over half had a neurodevelopmental impairment (Hoyt 2004).

**VISUAL IMPAIRMENT DUE TO OPTIC PATHWAY DISORDERS**

**Optic Nerve Hypoplasia**

Optic nerve hypoplasia (ONH) is the most common disc anomaly (Table 22.4). It is a developmental defect in the number of optic nerve fibres which may be unilateral or bilateral and may occur as an isolated defect or be associated with other CNS defects, the most common of which is the absence of the septum pellucidum in septo-optic dysplasia (de Morsier syndrome). There are many systemic and teratogenic associations...

ONH is associated with a host of additional conditions. Endocrinological abnormalities related to defective development of diencephalic derivatives are commonly present while infants may have hypoglycaemia in the neonatal period, caused by hypopituitarism, which may lead to seizures. Emergency treatment from the lack of growth hormone is needed in order to avoid sequelae, particularly resulting from the profound hypoglycaemia. The central endocrinopathies can occur in isolation, typically growth hormone deficiency, or in combination affecting both anterior and posterior pituitary glands. Puberty may be precocious or delayed (Hanna 1989).

An early diagnosis of associated cerebral abnormalities is essential considering the endocrinopathies. CT or MRI permits not only the diagnosis of ONH but also the presence of other CNS congenital anomalies such as an arachnoid cyst, hemispheric migrational anomalies, or perinatal injury (Brodsky and Glasier 1993), with the occurrence of bilateral porencephaly or schizencephaly rarely (Menezes et al. 1988).

Neurological deficits can occur in association with ONH. In the presence of structural lesions including thinning or agenesis of the corpus callosum children often have neurodevelopmental problems. Unilateral ONH does not preclude intracranial malformations (Brodsky and Glasier 1993).

Several mechanisms may lead to the formation of ONH, with the condition attributed to a failure of retinal ganglion cell differentiation at 4–6 weeks’ gestation. In animal studies deletion of netrin-1, an axon guidance molecule, led to ONH and other CNS migrational anomalies such as agenesis of the corpus callosum (Denier et al. 1997; Oster and Stretavan 2003). Alternatively CNS injuries that occur at the time of
development may lead to failure of the axons to develop. In this process toxins or associated CNS injury may be implicated, leading to a loss of neurons. There are many conditions that have been associated with ONH-including chromosomal disorders such as trisomy 18 and chromosome 13q-, craniofacial anomalies including Apert’s syndrome and Goldenhar syndrome as well as fetal alcohol syndrome.

Although rare, individuals have been reported to inherit ONH (Hackenbruch et al. 1975; Benner et al. 1990). The \textit{HESX1} gene was isolated in two siblings with ONH, absence of the corpus callosum and pituitary hypoplasia (Dattani et al. 1998). It has also been found as a sporatic mutation (Dattani et al. 2000) and may be accompanied by other homeobox genes such as \textit{SIX3} and \textit{SIX6} or mutations in the \textit{PAI6} gene (Azuma et al. 2003; Bennett 2003).

Other Disc Abnormalities

Some disc abnormalities may interfere with vision or be associated with neurological abnormalities of which they may be the presenting manifestation.

\textbf{Coloboma} of the optic nerve may lead to a visual impairment. Despite the appearance it may be difficult to predict the level of vision (Brodsky 1994) which can occur in isolation or in combination with involvement with the retina, iris, ciliary body and choroid. Typically, coloboma of the optic disc may be isolated inferiorly, appearing as a deep excavation with abnormal emergence of the retinal vessels. Coloboma may be unilateral or bilateral. The condition often occurs as part of the CHARGE (Coloboma of the eye, Heart defects, Atresia of the choanae, Retardation of Growth and development, and Ear abnormalities and deafness), Walker-Warburg and Goldenhar syndromes while the coloboma may be associated with CNS abnormalities which include agenesis of the corpus callosum, in isolation, or as a component of Aicardi syndrome (Chevrie and Aicardi 1986; Aicardi et al. 1987). Isolated cases are sometimes transmitted as an autosomal dominant trait (Savell and Cook 1976). The visual acuity is variable, dependent upon the integrity of the papillomacular bundle.

The morning glory disc anomaly is a congenital, funnel-shaped excavation of the posterior fundus. The disc is enlarged with a white excavated centre, surrounded by an annulus of chorioretinal pigmentation changes. Retinal vessels emerge at the margins of the disc and appear to be increased in number, while the macula may be incorporated into the excavation. Most cases are unilateral (Steinkuller 1980) with visual acuity typically suboptimal, ranging from 20/200 to finger counting. In some individuals there appears to be an association with CNS abnormalities, especially trans-sphenoidal basal encephalocele. Other associated brain anomalies include agenesis of the corpus callosum and posterior dilatation of the lateral ventricles (Pollock 1987). Patients with this anomaly need to have ongoing ophthalmological follow-up as there is a risk of serious retinal detachment or retinal tears.

\textbf{Optic disc drusen} are cystic formations buried in the head of the optic nerve whose precise mechanism of formation is not known but which may be transmitted as an autosomal dominant trait with variable penetrance. Drusen present in children as a swelling of the optic disc that may mimic papilloedema (Santavuori and Erkkila 1976; Katz et al. 1988) and may occur as an isolated abnormality or be associated with various neurological dysfunctions (Santavuori and Erkkila 1976). In adult patients they present at fundoscopic examination as polylobulated cystic formations of distinctive appearance whereas in children they remain buried within the optic nerve head (Fig. 22.2). Therefore, examination of both parents is indicated for any child with pseudopapilloedema as the presence of typical drusen in one of them is of diagnostic importance. Clinically, optic disc drusen develop visual field deficits and on rare occasions central acuity may be lost (Brodsky et al. 1996).

\textbf{Congenital/Hereditary Optic Nerve Atrophy}

Congenital optic nerve atrophy is a relatively common finding in children with neurological disorders. It occurs in most children as a sporadic phenomenon and does not have a high degree of specificity, as it is observed in a number of apparently heterogeneous congenital non-progressive encephalopathies as well as in some early progressive encephalopathies.

Congenital optic nerve atrophy is rarely isolated and often represents part of more complex syndromes that also involve the CNS. Many individuals are affected because of infectious fetopathies such as that caused by rubella virus, brain malformations, sequelae of hypoxic-ischaemic encephalopathy (probably the most common cause) or disorders such as osteopetrosis. In addition there are several hereditary forms which are variably expressed.

\textbf{Leber hereditary optic neuropathy (LHON)} is the most frequent cause of a hereditary optic neuropathy with late manifestations (Moorman et al. 1993). The disease affects males 80–90% of the time but 18% of female carriers have some clinical manifestations. Seventy to 100% of daughters of female carriers are also carriers, while 50–100% of sons of female carriers are affected with transmission always through the female line. Several point mutations of mitochondrial DNA have been shown to be associated with the disease (Yen et al. 2006; Fraser et al. 2010; Koilkonda and Guy 2010; Yu-Wai-Man et al. 2011). Some of these mutations (den Hollander et al. 2006) probably act as primary mutations (‘major mutations’) while others may have only a contributory role (‘minor mutations’). The mechanism of the disease however, remains unknown. Onset is usually in adolescence or early adulthood (Riordan-Eva et al. 1995; Newman 2005) but the age of such may be quite variable, even in the same kinship.

LHON typically presents with blurred central vision in one eye. Similar symptoms usually occur in the opposite eye within a few days or weeks but the interval occasionally occurs in months or years. In about 20% of individuals the onset is simultaneous (Riordan-Eva et al. 1995) with colour vision affected and visual fields typically showing central or centrocaecal defects. Fundoscopic examination at the initial stage shows a peculiar telangiectatic microangiopathy,
especially in the peripapillary region (Nikoskelainen et al. 1983) although this may be present in asymptomatic family members (Nikoskelainen et al. 1982). Fluorescein angiography characteristically shows absence of peripapillary retinal staining (Nikoskelainen et al. 1984) while in symptomatic patients telangiectasias are accompanied by retinal oedema and haemorrhages. In later stages atrophy appears first in the maculopapillar bundle and then in the rest of the retina within 2 months of onset. At this stage a pale disc with narrow vessels is visible (Lopez and Smith 1986) with visual field loss progressing from an enlarged blind spot to a large centrocaecal scotoma and loss of visual acuity usually severe to 6/60 or less. Although there is no specific treatment avoiding agents that might stress mitochondrial energy production may be a possible option in the future (Fraser et al. 2010; Koilkonda and Guy 2010; Yu-Wai-Man et al. 2011).

Hereditary optic atrophy with the characteristics of LHON has been reported in association with neurological symptoms and signs in some families. Associated neurological features have included ataxia and cerebellar manifestations that may suggest multiple sclerosis, dystonia and paraplegia which might result from a special susceptibility of patients with specific mitochondrial mutations associated with LHON like the 11778 mutation to demyelinating disease (Flanigan and Johns 1993; Hanefeld et al. 1994). Both the 11778 and the 3460 mutations in some women with multiple sclerosis with prominent and early optic nerve involvement (Kellar-Wood et al. 1994). Even classic forms may be associated with abnormalities of auditory evoked potentials (Mondelli et al. 1990), suggesting diffusion of lesions to the brainstem in two-thirds of affected individuals.

Individuals with optic atrophy and dystonia are of interest as they may also represent a mitochondrial disease (Novotny et al. 1986; Leuzzi et al. 1992). A ‘typical’ Leber optic atrophy with a mitochondrial myopathy has been described in a patient (Roger 1986) while the relationship between pure and complicated forms is being further clarified by DNA studies.

Several vitamin cocktails including coenzyme Q10 have been tried in LHON but the success has been limited. Avoiding stress in mitochondrial energy production may be beneficial, which leads to the suggestion of avoiding stresses such as tobacco and excessive alcohol (Kirkman et al. 2009).

There are several other forms of hereditary optic nerve atrophies. Autosomal dominant optic atrophy may occur very early in life, typically within the first or second decade in life which for most individuals has an insidious onset. The degree of vision loss is variable (Caldwell et al. 1971) and there may be limited vision loss in almost half the patients while examination shows disc pallor, especially in the temporal sector of the disc and central or centrocaecal scotomata (Neetens and Martin 1996). There is no angiopathy at any stage of the disorder and this makes it easy to separate dominant optic atrophy and early LHON while the outlook of autosomal dominant optic atrophy is favourable as the condition is stationary in most individuals (Elliot et al. 1993).

Congenital dominant optic nerve atrophy is a rare variant of the more common type, with onset in the first decade of life. Symptoms typically present at 4–6 years at the time of vision screening with reduction in visual acuity variable and visual acuities of 20/200 or worse representing about 15% of individuals. Interestingly, there is significant intrafamilial variation. In addition to a visual acuity, reduction dyschromatopsia occurs along with typically central field deficits. Dominant optic nerve atrophy is believed to be a primary degeneration of the retinal ganglion cells. The long arm of chromosome 3 (3q28–q29) and chromosome 18q have been implicated (Kerrison et al. 1999; Delettre et al. 2002; Fraser et al. 2010; Yu-Wai-Man et al. 2011).

Autosomal recessive optic atrophy is rare and more severe than the dominant form (Moller 1992) and may occur in

---

**Figure 22.2** Drusen of the head of the optic disc in a 4-year-old child. (a) Fundus photograph showing protruding papilla with bending of vessels at its margin. (b) Following fluorescein injection there is no exudation of substance, contrary to what is observed in papilloedema.
the presence of parental consanguinity. It presents at birth or before age 3 years with this later presentation possibly the result of young patients not indicating their vision loss. An ERG is necessary to exclude Leber congenital amaurosis (Repka and Miller 1988). Visual acuity is severely affected such that children may appear to be blind with a sensory nystagmus. Visual fields invariably show some constriction.

Optic atrophy and diabetes mellitus occur together in a progressive syndrome that may also include deafness, diabetes insipidus and other neurological disturbances known as DIDMOAD or Wolfram syndrome (Grosse Aldenhoven et al. 1991; Barrett et al. 1995). This syndrome seems to be transmitted as an autosomal recessive trait. There is great variation in clinical presentation, leading to some speculation that the condition reflects several defects leading to a common clinical presentation (Fraser et al. 2010; Yu-Wai-Man et al. 2011). The diabetes is usually the first manifestation, followed in the second decade of life with vision and hearing loss. Anosmia is also present in some patients while tremor, ataxia, nystagmus, ptosis, brainstem atrophy and central apnoea have been reported in many individuals.

Optic nerve atrophy is also a feature in a vast number of neurological diseases and syndromes (Iserl and Boltshauser 1981). For example, it is present in at least 20% of individuals affected by Friedreich ataxia (Pinto et al. 1988) but is not the presenting manifestation, whereas this may be applicable with other ‘spinocerebellar degenerations’.

A number of hereditary optic nerve atrophies are associated with neurological or systemic features, with such conditions rare and typically present in the first decade with vision loss or other neurological sequelae: associated comorbid conditions include hearing loss, motor impairments, including ataxia, and cognitive impairments (Newman 2005). One such condition is complicated optic nerve atrophy of Behr syndrome (Landrigan et al. 1973), which includes spastic diplegia and ataxia in association with early onset optic nerve atrophy, which is probably heterogenous (Thomas et al. 1984). A syndrome of optic atrophy, movement disorder and spastic paraplegia, associated with 3-methyl-glutaconic aciduria, has been delineated (Costeff et al. 1993). Dystonia and pyramidal tract signs in the lower limbs are frequent features (Elpeleg et al. 1994); recessively inherited optic atrophy is a hallmark of progressive encephalopathy with peripheral edema, hypsarhythmia and optic atrophy (PEHO) syndrome (see also Chapter 10).

Compressive Optic Neuropathies

Compression on the optic nerve on one or both sides is a frequent feature of tumours of the diencephalon and less commonly, of the hypophysis. In a significant proportion of individuals optic neuropathy is the presenting manifestation and here it is important to make an early diagnosis and not accept a wrong diagnosis of demyelinating and vascular optic neuropathy.

Craniohypophyngiomas and optic nerve gliomas are the most common causes of compression neuropathy but hypophyseal tumours may rarely be the cause (Reid et al. 1985). The onset of visual symptoms may be acute and unilateral while classic features of bitemporal hemianopia as well as any neurological finding can be absent. Small children may present with nystagmus and as a result any child with new onset nystagmus should be investigated for the possibility of a chiasmal tumour, even in the presence of a normal fundusscopic examination. Growth retardation is often present and an important clue suggesting the possibility of diencephalic disease. Neuroimaging, especially MRI, is essential for a precise diagnosis and should be performed whenever there is doubt about the origin of the optic nerve disorder (Eidelberg et al. 1988).

Increased Intracranial Pressure and the Optic Nerve

Children with increased intracranial pressure may present with transient or permanent visual symptoms. Visual field loss is more common over visual acuity loss in children developing papilloedema with field deficits including enlarged blind spot, nasal field defects especially inferonasal, disk-related arcuate scotomata and global constriction. Other ophthalmic presentations are double vision and strabismus secondary to abducens palsy, retro-orbital pain and photophobia especially in prepubertal children. Following prompt diagnosis and treatment resolution of disk swelling and improvement of visual function is expected in patients with mild to moderate papilloedema.

All individuals suspected to be affected by increased intracranial pressure must undergo ophthalmological assessment. Dilated fundoscopy allows careful assessment of the optic nerve head and fundus photography can be used to monitor changes over time. Assessment of thickening of the peripapillary retinal nerve fibre layer by OCT is useful while early visual loss is best detected by visual field assessment. Visual fields can be used not only to diagnose but also to monitor progress and treatment with the goal of the latter to relieve symptoms and preserve vision.

Toxic and Nutritional Optic Neuropathies

A large number of chemicals, especially drugs, can be the cause of optic neuropathy (Sipeti and James 1983). Isoniazide, ethambutol, streptomycin, chloramphenicol, penicillamine, quinine, ergot derivatives and chlorpropamide are among the most important incriminated agents. The halogenated hydroxquinolines have been responsible, especially in Japan but also less commonly in occidental countries for an optic neuropathy associated with peripheral and spinal involvement (Behrens 1974). This subacute myelo-optic neuropathy has substantially regressed since the dangers of these drugs have been publicised. Prolonged use of Linezolid, used in the treatment of Gram-positive infections, is associated with reversible optic neuropathy (Rucker et al. 2006) while intra-arterial chemotherapy has been implicated as the origins of some optic atrophy.
Demyelinating Optic Neuropathies

Unilateral and bilateral optic neuropathies will be reviewed more fully in Chapters 11 and 12. Multiple sclerosis is less common in children. The relationship to optic neuritis is also much less than in adults, especially when optic involvement is bilateral, although this remains controversial (Parkin et al. 1984; Kriss et al. 1988; Riikonen et al. 1988). As with adults, T2 lesions on MRI are associated with an increase risk of developing MS (Cakmakli et al. 2009; Absoud et al. 2011). Optic neuritis following specific infectious diseases has been recorded following measles, rubella, varicella (Purvin et al. 1988b; Selbst et al. 1993), Epstein-Barr virus infection (Purvin et al. 1988a) and coxsackie B5 infection (Spalton et al. 1989). Optic neuritis may occur in sinus disease (Awerbuch et al. 1989) and sarcoidosis (Graham et al. 1986; Chapelon et al. 1990).

Typically, children present with vision loss either acutely or over a few days and the loss of visual acuity and visual fields can be profound. In the presence of bilateral disease the pupils may be dilated even under brightly lit circumstances while clinically the optic discs are swollen. The standard treatment remains high-dose steroids.

Vascular Optic Nerve/Retinal Disease

The most common cause of vascular retinal disease is migraine (see also Chapter 17), which may be responsible for monocular loss of vision ipsilateral to the side of the headache. Vision loss constitutes the aura of a migraine and may be partial or total. Rarely, migraines may be characterised by monocular blindness without headache. Vision loss generally clears in a few minutes, but an occasional patient may be left with permanent vision loss. Although patients who develop persistent blindness often have other risk factors for vascular disease vision loss has been reported in some adolescents without such risk factors (Coppeto 1986). Patients with monocular attacks of blindness as a manifestation of migraine (retinal migraine) should be investigated and treated urgently to prevent permanent impairment with treatment of such patients similar to typical migraines, sometimes supplemented by anti-aggregant drugs like aspirin. Transient bilateral loss of vision is often related to migraine in young patients (Tippin et al. 1989) and same applies to post-traumatic transient blindness (Greenblatt 1973).

Central retinal artery obstruction may be the result of emboli to the retinal artery as a result of congenital heart disease (Brown et al. 1981). Other causes include coagulopathies, various types of vasculitis, mitral valve prolapse, cardiolidip antibody syndrome, and cardiac catheterisation (Jackson et al. 1984; Kosmosky et al. 1988). The onset of symptoms is usually abrupt with a sudden unilateral loss of vision that may be partial or complete with altitudinal defects present in a majority of individuals. Ophthalmological examination shows swelling of the optic disc, oedema of the retina and narrowing of the arteries followed by thickening of the arterial wall while haemorrhages may be present. Fluorescein angiography can provide objective confirmation of the diagnosis and accurately shows the topography and degree of ischaemia (Chutorian et al. 2002). Treatment depends on the cause: anticoagulants may be indicated if the source of the emboli is identified while steroids and immunosuppressors are useful for many vasculitides. The outlook for vision depends on the cause of the obstruction and on the location of the obstructed vessels with the prognosis better for obliteration of the peripheral branches than for that of the central artery itself.

It is worth mentioning the ophthalmological finding of the cherry red spot seen in central artery occlusion which appears several hours after the occlusion. In this circumstance the spot is seen because the macula receives blood supply for the choroid below but the surrounding retina is pale as a result of the infarction.

Coats disease is characterised by congenital retinal telangiectasias, aneurysmal retinal vessel dilation and capillary microaneurysms with associated subretinal and intraretinal exudation. Many individuals are affected by Coats disease sporadically but a somatic mutation in the NDP gene has been described (Black et al. 1999). In addition, it can be part of a rare autosomal recessive syndrome of facioscapulohumeral dystrophy, hearing loss and intellectual disability (Taylor et al. 1982; Matsuzaka et al. 1986). Other syndromes including Cornelia de Lange Hallerman-Strieff, and Senior-loken have been associated with this condition (Newell 1994; Schuman 1995; Barakat et al. 2009). Bilateral Coats disease, facial dysmorphism, abnormal hair and nails as well as striking supra- and infratentorial calcification involving the thalami and neighbouring brain areas have been reported as familial disorders (Tolmie et al. 1988; Goutieres et al. 1999) (Fig. 22.3).

VISUAL IMPAIRMENT DUE TO RETINAL DISORDERS

A wide variety of congenital retinal diseases exist, representing a heterogeneous group of children. Often such diseases may be classified as either static, progressive or alternatively according to whether the disease is predominantly rod or cone. For
the majority of conditions such as retinitis pigmentosa, achromatopsia and retinal dystrophies a paediatric ophthalmology text will provide greater detail.

Retinal disorders include genetic, traumatic, inflammatory deficiency and vascular diseases. Several infectious disorders can produce retinitis, especially the exanthematous diseases of childhood (Marshall et al. 1985). Early recognition of retinal conditions may be important in the management: for example, choroidoretinitis may be the first manifestation of subacute encephalitis and remains isolated for several months or even years. This disease should be included in the differential diagnosis of retinal disorders as early treatment is potentially useful (Tomoda et al. 1997).

**Inherited Retinal Diseases**

Leber's congenital amaurosis is an inheritable generalised rod and cone dystrophy that presents early in childhood which may be progressive in some individuals. Leber's congenital amaurosis presents as blindness or very limited vision with nystagmus from birth or the first months of life with children often demonstrating blindisms such as eye pressing. With time the fundus examination may show pallor of the optic discs, thinned retinal vessels, clumps of retinal pigment or white punctate retinopathy or be altogether normal (Schroeder et al. 1987). Extinction of the ERG is an essential diagnostic feature, typically inherited as an autosomal recessive condition (Lambert et al. 1993), while some affected children have hypotonia, seizures and intellectual disability. In the past it was responsible for a larger proportion of congenital blindness, however, this is no longer the case because of other conditions, primarily cortical visual impairment.

These dystrophies are known to occur in association with structural defects of the CNS such as encephaloceles (Vaizey et al. 1977), microcephaly (Cantu et al. 1977) and anomalies of the cerebellar vermis (Dekaban 1975; Weinstein et al. 1984; Marchal et al. 1989; Funakawa et al. 1995). Hypoplasia of the vermis has been found in 10% of the cases (Nickel and Hoyt 1982) while retinal degeneration may also be associated with various renal defects (Proesmans et al. 1975; Godel et al. 1978; Rizzo et al. 1986; Warady et al. 1994) or be a part of complex syndromes (Mainzer et al. 1970; Rizzo et al. 1986).

A similar phenotype has been found in patients with peroxosomal disorders such as Zellweger syndrome as well as in individuals with few other abnormalities suggestive of a peroxosomal defect (Ek et al. 1986). Such heterogeneity probably accounts for the variable frequency with which neurodevelopmental signs are found in infants with congenital retinal degeneration, with figures as low as 3% (Noble and Carr 1978) or as high as 25–37% (Schappert-Kimmijser et al. 1959). A review of 75 individuals affected by Leber congenital amaurosis found 30 different conditions including Joubert syndrome, Zellweger syndrome, infantile Refsum disease, congenital stationary night blindness and achromatopsia (Lambert et al. 1989).

As noted above, many of the conditions associated with Leber congenital amaurosis are associated with intellectual disability however in 'pure (single gene defect) form' neurodevelopmental conditions are rather uncommon. It is transmitted as an autosomal recessive trait (Lambert et al. 1993) and a gene has been mapped to chromosome 17p (Camuzat et al. 1995). Most of the 'non-pure' conditions are probably transmitted as mendelian recessive traits (Alstrom and Olson 1957; Baker et al. 1995; Casteels et al. 1996; Taylor 1997). Structural CNS defects and neurological and cognitive dysfunction are more frequent (Vaizey et al. 1977).

These conditions are genetically heterogenous with multiple genes being identified (den Hollander et al. 2006, 2008). Molecular testing can now identify the gene in over 50% of individuals. With the advent of better diagnostic measures therapeutic interventions are now being considered through gene therapies. Although there appears to be reasonable safety profile the results are variable (Bainbridge et al. 2008).

The presence of a retinal dystrophy, the cherry-red spot is a worrisome finding. It is observed in several gangliosidoses and lipidoses storage disorders such as Tay-Sachs disease and Niemann Pick type A (see Chapter 9) with the appearance due to a relative transparency of the macula. Typically, storage disorders accumulate material within the cell layers of the retina: as the macular is just a thin layer there is less accumulation in this area which allows the redness of the choroid to be observed.

---

Inherited Retinal Diseases

Leber's congenital amaurosis is an inheritable generalised rod and cone dystrophy that presents early in childhood which may be progressive in some individuals. Leber's congenital amaurosis presents as blindness or very limited vision with nystagmus from birth or the first months of life with children often demonstrating blindisms such as eye pressing. With time the fundus examination may show pallor of the optic discs, thinned retinal vessels, clumps of retinal pigment or white punctate retinopathy or be altogether normal (Schroeder et al. 1987). Extinction of the ERG is an essential diagnostic feature, typically inherited as an autosomal recessive condition (Lambert et al. 1993), while some affected children have hypotonia, seizures and intellectual disability. In the past it was responsible for a larger proportion of congenital blindness, however, this is no longer the case because of other conditions, primarily cortical visual impairment.

These dystrophies are known to occur in association with structural defects of the CNS such as encephaloceles (Vaizey et al. 1977), microcephaly (Cantu et al. 1977) and anomalies of the cerebellar vermis (Dekaban 1975; Weinstein et al. 1984; Marchal et al. 1989; Funakawa et al. 1995). Hypoplasia of the vermis has been found in 10% of the cases (Nickel and Hoyt 1982) while retinal degeneration may also be associated with various renal defects (Proesmans et al. 1975; Godel et al. 1978; Rizzo et al. 1986; Warady et al. 1994) or be a part of complex syndromes (Mainzer et al. 1970; Rizzo et al. 1986).

A similar phenotype has been found in patients with peroxosomal disorders such as Zellweger syndrome as well as in individuals with few other abnormalities suggestive of a peroxosomal defect (Ek et al. 1986). Such heterogeneity probably accounts for the variable frequency with which neurodevelopmental signs are found in infants with congenital retinal degeneration, with figures as low as 3% (Noble and Carr 1978) or as high as 25–37% (Schappert-Kimmijser et al. 1959). A review of 75 individuals affected by Leber congenital amaurosis found 30 different conditions including Joubert syndrome, Zellweger syndrome, infantile Refsum disease, congenital stationary night blindness and achromatopsia (Lambert et al. 1989).

As noted above, many of the conditions associated with Leber congenital amaurosis are associated with intellectual disability however in 'pure (single gene defect) form' neurodevelopmental conditions are rather uncommon. It is transmitted as an autosomal recessive trait (Lambert et al. 1993) and a gene has been mapped to chromosome 17p (Camuzat et al. 1995). Most of the 'non-pure' conditions are probably transmitted as mendelian recessive traits (Alstrom and Olson 1957; Baker et al. 1995; Casteels et al. 1996; Taylor 1997). Structural CNS defects and neurological and cognitive dysfunction are more frequent (Vaizey et al. 1977).

These conditions are genetically heterogenous with multiple genes being identified (den Hollander et al. 2006, 2008). Molecular testing can now identify the gene in over 50% of individuals. With the advent of better diagnostic measures therapeutic interventions are now being considered through gene therapies. Although there appears to be reasonable safety profile the results are variable (Bainbridge et al. 2008).

The presence of a retinal dystrophy, the cherry-red spot is a worrisome finding. It is observed in several gangliosidoses and lipidoses storage disorders such as Tay-Sachs disease and Niemann Pick type A (see Chapter 9) with the appearance due to a relative transparency of the macula. Typically, storage disorders accumulate material within the cell layers of the retina: as the macular is just a thin layer there is less accumulation in this area which allows the redness of the choroid to be observed.
Other Hereditary Pigmentary Retinopathies (Retinitis Pigmentosa)

A number of other progressive pigmentary degenerations of the retina can be the cause of progressive visual loss in association with neurological dysfunction (see Fig. 22.4). The major initial symptom is nyctalopia followed after a variable time by concentric narrowing of the visual field and decrease in visual acuity with the disease onset variable. The ERG is abnormal early but fundus examination may remain normal for long periods. If patients present with nystagmus they are more likely to have rod-cone/cone-rod diseases. There are two main groups of pigmentary retinopathy: in one, only the eyes are involved while in the second retinal disease is associated with neurodegenerative disorders. These include individuals affected by Leigh syndrome, the ceroid-lipofuscinoses, abetalipoproteinemia, the mucopolysaccharidoses, several types of cerebellar or spinocerebellar degenerations and genetic syndromes such as the Laurence-Moon, Alstrom-Hallgren and Usher syndromes. Among the isolated pigmentary retinopathies multiple types exist with variable inheritance (X-linked, autosomal recessive and dominant). While there is genetic heterogeneity within each inheritable class: X-linked, autosomal recessive and dominant). While there is genetic heterogeneity within each inheritable class: X-linked, autosomal recessive and dominant. There is an extensive differential diagnosis for hereditary pigmentary retinopathies including, blunt trauma, congenital or acquired infections and medications. The astute clinician will, therefore, need to investigate for non-hereditary aetiologies, particularly in the context of comorbid conditions. Unfortunately, there is no specific medical treatment for patients with retinitis pigmentosa, however the clinician can play an important role in optimising visual function and linking the patient with low vision services. Congenital stationary nightblindness is characterised by nightblindness, variable vision loss and a normal fundus with patients often having high myopia, nystagmus, strabismus and paradoxical papillary responses. Like retinitis pigmentosa, there are multiple modes of inheritance. ERG is helpful as there are typical tracings noted for this condition.

Cone and Cone-Rod Dystrophy

Similar to retinitis pigmentosa, inherited cone and cone-rod dystrophies are a heterogeneous group of conditions characterised by a variable photophobia, a reduction in visual acuity abnormal colour vision and abnormal ERG findings. In most individuals the disease is progressive. There is great variability in presentation and progression with most individuals affected sporadically while in familial conditions autosomal dominant inheritances is most frequent. Other inheritance patterns have been reported.

Achromatopsia

Achromatopsia represents a heterogeneous group of stationary retinal dystrophies. In complete form it is characterised by photophobia, reduced visual acuity and poor colour vision. The incomplete form is less severe while a number of genetic mutations have been identified (Wissinger et al. 2001). The ERG shows a lack of cone responses. This condition is typically stable but slow deterioration has been described (Genead et al. 2011).

Gyrate Atrophy of the Retina

This is a rare familial condition, inherited as an autosomal recessive trait: the gene maps to 10q26 and various mutations are known. It is a slowly progressive disease whose initial manifestations are nyctalopia followed by concentric narrowing of the visual field and loss of vision. Fundoscopic examination shows the classic appearance of spider's web retina covered with chocolate dust (Fig. 22.5). Hyperornithininaemia, characteristic of the disease, is due to deficiency of the enzyme ornithine arinotransferase: this is a pyridoxal-dependent enzyme so a small proportion of individuals respond to pharmacological doses of pyridoxine (Michaud et al. 1995).

COMMON ACQUIRED RETINAL CONDITIONS

Retinopathy of Prematurity

Retinopathy of prematurity (ROP) is still a common cause of visual impairment in children now mostly seen in surviving extremely low birthweight (<1000g) infants. Up to 30% of preterm infants may suffer from visual problems, most...
commonly strabismus (Gibson et al. 1990). These children commonly have neurological and developmental disabilities. ROP is classified based on the four criteria: severity (stages 1–5), location (zones 1–3), extent of retinal involvement (hours) and plus disease (clinical description of activity) (Committee for the Classification of Retinopathy of Prematurity 1984; International Committee for the Classification of the Late Stages of Retinopathy of Prematurity 1987).

The majority of children with ROP undergo complete resolution, typically those with low stages however those with higher stages may have a reduction in visual acuity (Holmstrom et al. 1999). Many children will have some reduction in visual fields (Cryotherapy for Retinopathy of Prematurity Cooperative Group 2001) but the clinical consequence may not be that evident. Many children will have additional ocular consequences including refractive errors and strabismus (Holmstrom et al. 1999).

The mainstay of therapy has been with the use of laser and cryotherapy performed by the ophthalmologist. Anti-VEGF therapies are now being used which minimise the angiogenesis associated with ROP. (Mintz-Hittner et al. 2011).

**Other Retinal Disorders**

There are many retinal conditions that may lead to a loss in visual acuity many of which are associated with neurological disorders. These conditions range from infectious diseases, especially toxoplasmosis (Fig. 22.6) and cytomegalovirus infections, to congenital anomalies such as the retinal ‘lacuna’ of Aicardi syndrome (Fig. 22.7). Fundoscopic abnormalities may also be seen in several metabolic diseases.

**Vitamin E deficiency** has associated retinal involvement with peripheral neuropathy and oculomotor dysfunction often accompanying this condition. **Vitamin A deficiency** is a common reason for vision loss in developing countries: a deficiency of such, rare in Western countries, is usually caused by a combination of malnutrition and malabsorption due to intestinal infections. Clinically there is slow dark adaptation: peripheral fields may be affected as rod dysfunction occurs, while improvement can occur with vitamin A supplementation.

**Vigabatrin** is becoming an important cause of retinal toxicity. In pediatrics, it is a first line treatment for infantile spasms and can be used for other forms of refractory seizures. Infants affected by peripheral field loss associated with vigabatrin were first described in 1997 (Eke et al. 1997) and since then vigabatrin has been correlated to cause concentric peripheral visual field loss thought to be the result of the cumulative retinal dose of the drug (Malmgren et al. 2001). Active surveillance with ophthalmological assessment and visual field testing when possible has been suggested. Other tests such as OCT, VEP, and ERG may be unreliable in assisting in the diagnosis.

**Vitreoretinal Diseases**

There are a number of diseases that result from abnormalities of the vitreous. Vitreoretinal dysplasias result from the maldevelopment of the vitreous and retina. Abnormalities of the vitreous may lead to several congenital anomalies such as persistent hyaloid artery, while in the majority of individuals the hyaloid artery regresses and, therefore, visual impairment does not occur. A less common condition is persistent hyperplastic primary vitreous, caused by the failure of the primary vitreous
Chapter 22 Disorders of Visual and Oculomotor Functions

Vitreoretinal dysplasias can occur in isolation or associated with other comorbid conditions that can involve one or both eyes. Common conditions include Norrie disease, familial vitreoretinopathies, juvenile retinoschisis, trisomy 13 and incontinentia pigmentosa.

Norrie disease is a sex-linked recessive disorder characterised by bilateral retinal folds, retinal detachment, vitreous haemorrhage and bilateral retrolental masses that may be a cause of congenital or early onset blindness in boys. Phenotypes are variable. About 25% of affected males also develop cochlear hearing loss (Liberfarb et al. 1985) and developmental disability is also common. A more severe phenotype has been found in children with large chromosomal deletions (Suarez-Merino et al. 2001) and mutations of the responsible gene can be used in genetic diagnosis (Black and Redmond 1994). Cataplectic episodes may be associated with this condition.

Familial exudative vitreoretinopathy are another group of inherited forms of visual impairment. They are characterised by abnormal retinal vascularisation, exudation, neovascularisation and tractional retinal detachments. There are several modes of inheritance, with the X-linked form leading to severe early onset visual impairment. A variety of molecular genetic studies have been performed, showing the complex nature of the phenotypic presentation (Qin et al. 2005).

Juvenile X-linked retinoschisis is an X-linked disorder characterised by the cystic spokewheel-like maculopathy, with children typically presenting with a reduction in visual acuity or strabismus. Whereas in trisomy 13 the fundoscopic examination identifies disorganisation of the vitreous and retina often other ocular abnormalities are seen including microphthalmos, corneal opacities, cataract and dysplasia of the optic nerve.

Structural Causes of Visual Impairment

There are many structural abnormalities of the eye with the vast majority not primarily presenting to the neurologist, one of the most common conditions being cataracts. Congenital cataracts or lens opacities are a frequent cause of visual defects in children and if identified early can be removed and vision preserved. However, the clinician should be aware of the great association with additional neurological conditions such as the mucopolysaccharidoses, galactosaemia, intrauterine infections, chromosomal aberrations and other syndromes (Kohn 1976). The visual outcomes for the majority are excellent with early treatment but poorer outcomes are associated with delays in diagnosis and/or associated ocular or systemic conditions that may independently lead to visual impairment.

A number of other ocular structural conditions such as anophthalmos, nanophthalmos and microphthalmia are rare. Along with coloboma the group is associated with a variety of chromosomal anomalies, genetic diseases and systematic conditions including the brain, cardiac and renal systems.

Aniridia may present to the neurologist as an abnormality in pupillary response. Aniridia is a structural eye defect. Typically, infants present with nystagmus, hypoplasia of the iris, unresponsive pupils and light sensitivity. Mutations in the PAX6 gene are commonly responsible (Prosser and van Heyningen 1998). Patients may present with a family history of the condition, presenting as an autosomal dominant form: for sporadic patients evaluation for Wilms tumour is required, as the PAX6 gene is located near the WT1 gene (Gronskov et al. 2001). This condition may be also associated with genitourinary abnormalities and intellectual disability, the so called WAGR association. The condition has variable reductions in

Figure 22.7 Aicardi syndrome. (a) Typical ‘lacunae’ in left fundus oculi at age 9 months and (b) at age 4½ years. The size of the ‘lacunae’ has not changed but the amount of pigment has increased. The peripapillary location of the lesions is usual. (Courtesy Dr I McCormick, Children’s Hospital, Vancouver.)
visual acuity and as a result not all patients will have a visual impairment.

**NYSTAGMUS**

Nystagmus (Table 22.5) is typically an involuntary, rhythmic, conjugate oscillatory movement of the eyes (Dell’Osso 1984; Hoyt 1987; Troost 1989) that may occur in any plane and is one of the most common characteristics of children with visual impairment, with the estimated prevalence is 24 in 10,000 (Sarvananthan et al. 2009). It is due to dysfunction of the complex mechanisms that maintain ocular fixation with the clinical description of nystagmus usually based on the direction of the fast component and is termed horizontal, vertical or rotary or any combination of these. The nystagmus may be conjugate or dysconjugate. A long recognised distinction is between jerk nystagmus, in which there is a slow initiating component followed by a fast corrective component and pendular nystagmus in which the oscillations are of equal speed. However the distinction between jerk and pendular oscillations may be difficult and even meaningless as the form of eye movements may change with gaze or other factors. In pendular nystagmus the oscillations are slow in each direction, at least in the primary position of gaze, but may change to jerk nystagmus on lateral gaze. The most common form of jerk nystagmus is gaze evoked nystagmus due to a deficit in the mechanisms responsible for holding the eyes in an eccentric position whose seat is in the posterior fossa. The intensity of jerk nystagmus increases in the horizontal plane when gaze is in the direction of the fast phase (Alexander’s law).

Nystagmus should be differentiated from roving eye movements of blind children with pregeniculate lesions. Such movements are indicative of extremely poor vision or complete blindness and may be replaced by nystagmus when some useful vision develops in infants a few months of age (Jan et al. 1986; Kompf and Piper 1987).

**ACQUIRED NYSTAGMUS**

Acquired nystagmus is usually of the jerk type with a horizontal or horizontal-rotary form with the main causes indicated in Table 22.6. It is important to keep in mind that drug toxicity is a common cause of jerk nystagmus of horizontal or vertical types and certain forms of nystagmus such as seesaw and downbeat nystagmus (Hanegan et al. 1983) are electively caused by certain conditions like chiasmal lesions of a Chiari I malformation.

Nystagmus can be the result of many neurological diseases. New onset acquired nystagmus may present with vertigo, nausea, dizziness and oscillopsia. The type of nystagmus may point to certain aetiological causes meaning that neuroimaging is required to rule out central causes such as demyelinating

Shaking, and head tilt (torticollis) with symptoms appearing usually toward the end of the first year of life or during the second year. All three components need not be present at the same time, and head tilt and nodding movements may be transitory or absent altogether. The nystagmus is constant and may be binocular but is often predominantly or exclusively monocular. Vision is typically normal with head shaking horizontal, vertical or gyral with the rate of 60–120 per minute, while the rate of eye oscillations is around 300 per minute. The nystagmus and head shaking occur in bursts lasting 5–30 seconds in association with fixation. Although infrequent, spasmus nutans is the most common cause of unilateral nystagmus in infants (Weissman et al. 1987) and should be included in the diagnosis of all patients with unilateral nystagmus (Farmer and Hoyt 1984). The cause of the disorder is unknown and the course is benign with resolution in a few months to 2 years, however, patients with ‘sinister’ spasmus nutans due to optic gliomas are have been reported (Albright et al. 1984; King et al. 1986), so that imaging is always indicated, even when the typical picture is present. Retinal disease can also be a cause (Lambert and Newman 1993) and spasmus nutans has been reported in association with unilateral poor vision due to anterior pathway lesions.

**CONGENITAL/INFANTILE NYSTAGMUS**

Congenital nystagmus is usually recognised shortly after birth but it may be later in the latent type which may not be detected until the visual acuity testing. It may be delayed up to several months of age especially when sensory in type, persisting throughout life. There is no widely accepted classification of nystagmus and often congenital nystagmus may be categorised into congenital idiopathic nystagmus, sensory defect nystagmus and neurological nystagmus.

There are numerous causes of congenital nystagmus. It may be genetically determined and can be transmitted as an autosomal recessive, autosomal dominant or X-linked condition (Dell’Ossi et al. 1974). In addition many genetic syndromes such as Down syndrome and Noonan syndrome are associated with nystagmus.

Congenital nystagmus usually oscillates in a constant direction with up to 40 wave forms having been described, most of which are specific for congenital nystagmus. Often the assessment of wave forms requires specialised equipment but such recordings are difficult to calibrate in children (Baker et al. 1995), meaning that clinical examination is essential.

Clinically, congenital nystagmus remains horizontal during vertical gaze rather than converting to gaze-evoked vertical nystagmus (Troost 1989). Head nodding or shaking is present in 6.6–8.0% of children with congenital nystagmus, regardless of the type (idiopathic or sensory) and the mode of inheritance (Jan et al. 1990). It may be a means to improve foveation time and therefore visual acuity. A reduction in visual acuity is seen in about half the children (Dell’Oss et al. 1974; Troost 1989; Jan et al. 1990), but in the presence of ‘sensory’ nystagmus lower visual acuity is common (Jan et al.
1986, 1990). Congenital nystagmus is usually associated with strabismus and other ocular abnormalities (Hertle and Dell’Osso 1999; Abadi and Bjerre 2002). Additional features of congenital nystagmus are described in Table 22.7. A unique feature of congenital nystagmus is the so-called inverted optokinetic nystagmus where the fast components are in the direction of rotation of the drum instead of the opposite, which is normal (Halmagyi et al. 1980).

In patients with albinism nystagmus is commonly seen and often jerk nystagmus may reverse direction. Interestingly, children with albinism have an excess proportion of undescussed retinofugal fibres so that the innermost parts of the nasal fields have a crossed cortical projection. This anomaly can be detected by study of the visual evoked potentials and in some patients by MRI demonstrating a sagittally split chiasma (Apkarian et al. 1995).

Common causes of jerk nystagmus includes vestibular and gaze evoked nystagmus. Vestibular nystagmus is also a common type of jerk nystagmus and may result from involvement of the vestibular end organ or central pathways and nuclei (Daroff et al. 1978). Central causes are usually uniplanar in contrast to peripheral causes which are commonly torsional or multiplanar. Visual fixation typically inhibits peripheral vestibular nystagmus but not central vestibular nystagmus. While in gaze-evoked nystagmus the jerk nystagmus occurs in the direction of eccentric gaze. Posterior fossa structural diseases are commonly implicated. Drugs, particularly anticonvulsants, are also known to lead to the phenomenon.

Patients with Pelizaeus-Merzbacher disease can present with an unique kind of nystagmus that is not seen in other neurodegenerative disease which is a combination of elliptical pendular and upbeat nystagmus (Troost et al. 1991). If observed in the context of supportive clinical history and imaging a presumptive diagnosis can often be made.

In periodic alternating nystagmus the null point shifts position in a cyclic pattern. Periodic alternating nystagmus is typically congenital and benign but has been associated with neurodegenerative conditions such as ataxia-telangiectasia, and vestibulocerebellar lesions (Shallo-Hoffman and Riordan-Eva 2001). In some patients periodic alternating nystagmus may respond to oral baclofen while other less common types of nystagmus are summarised in Table 22.7.

Latent nystagmus occurs when a single eye is covered. It may be ‘manifest latent’ in children with strabismus who are actually viewing with a single eye at a time even though both eyes are open.

**OCULAR OSCILLATIONS DIFFERING FROM NYSTAGMUS**

There are a number of ocular movements that may mimic nystagmus (Table 22.8). Square wave jerks represent an abnormal eye movement and consist of a conjugate displacement of the eyes up to 5 degrees from fixation, followed by a refixation cascade which is often barely visible because of small amplitude.

Although square wave jerks can be seen in normal patients they have been associated with cerebellar disease, progressive supranuclear palsy and multiple sclerosis (Dell’Osso et al. 1975).

Monocular vertical oscillations may also occur in amblyopic patients, know as the Heimann-Bielschowsky phenomenon (Smith et al. 1982). Many other types of ocular oscillations are also recognised.

Opsoclonus is characterised by chaotic, rapid oscillations in all planes of gaze. Opsoclonus is exceptionally observed in newborn infants (Hoyt 1977) and may also be seen in some viral infections as well as in association with neuroblastoma. In children with neural crest tumours or brainstem encephalitis opsoclonus is accompanied by diffuse or focal myoclonus. Ocular flutter and ocular hypermetria may be seen in patients with inflammatory or other disorders of the cerebellum (Cogan 1954).

Ocular motor apraxia (saccade initiation failure) is characterised by abnormal movements of the head and eyes when changes in gaze are being attempted. In complete form initiation of a saccade may take up to one second and the movement is slow and hypometric so that several successive hypometric saccades may be necessary to bring the eyes to the desired position. In fact, refixation is commonly performed by head turning rather than by eye deviation: during head rotation, there may be deviation of the eyes in the opposite direction (contraversion), with secondary realignment of the eyes and head when the new target has been reached (Zee et al. 1977). The anomaly is limited to horizontal saccades while vestibular reflex movements, pursuit (slow) movements and vertical saccades are normal.

For most patients ocular motor apraxia is idiopathic however for some it has been associated with chromosomal abnormalities (Martin Carballo et al. 1993) or with immune deficiency (Narbona et al. 1980). CNS anomalies such as delayed myelination, agenesis of the corpus callosum and cerebellar vermian abnormalities have been reported (Shawkat et al. 1995) which suggests lesional causes of delayed saccades may be more common. A small number of patients with vertical ocular motor apraxia have been described (Ebner et al. 1990; Hughes et al. 1985) with one shown to have had a bilateral lesion at the mesencephalic-diencephalic junction.

Ocular motor apraxia should be distinguished from abnormal eye movements observed in children with very poor visual
Acuities who tend to use head movements rather than saccades for looking at targets (Jan et al. 1986) and in children with severe strabismus and low acuity. Syndromes of ocular motor apraxia with retinal dystrophy are known, with the most common being Joubert’s syndrome. These children have cerebellar vermian anomalies and often develop retinal dystrophies; the syndrome is also associated with renal cystic disease which ultimately leads to renal failure.

Ocular motor apraxia is observed as a specific congenital disease known as Cogan disease and in various CNS disorders including perinatal conditions like cerebral palsy, congenital malformations, neurodegenerative conditions, infections and tumours (Le Ber et al. 2003, 2004). Cogan disease is generally recognised after 6–12 months of age because of the occurrence of head thrusts that may be mistaken for tics or even epileptic seizures. Vertical saccades are normal and cognitive development is usually preserved; however, many children have motor difficulties and challenges with school performance (Rappaport et al. 1987; Marr et al. 2005). The disease is genetically determined in small numbers of patients, probably transmitted as a recessive trait with variability in clinical presentation, with some only having abnormalities with optokinetic nystagmus. The prognosis is generally favourable with a tendency towards improvement or better adaptation (Zee et al. 1977). In addition, older patients tend to use more unobtrusive manoeuvres than head thrusts such as forced blinking which breaks fixation which will allow refixation to occur.

Abnormal eye movements reminiscent of those with Cogan disease may be seen in association with callosal agenesis or vermian aplasia (Bordarier and Aicardi 1990; Leao and Ribeiro-Silva 1995; Kondo et al. 2007). Slowness of saccades has also been reported in Friedreich disease (Kirkham et al. 1979) and other rare spinocerebellar degenerations (Wadia and Swami 1971) including a syndrome of ataxia-ocular motor apraxia (Aicardi et al. 1988). Abnormal eye movements are also observed in children with albinism (Collewijn et al. 1985).

### PUPILLARY CONDITIONS

Although pupillary conditions do not lead to visual impairment they are important in the understanding of many serious neurological conditions such as Horner syndrome.
HORNER SYNDROME
(CLAUDE BERNARD-HORNER SYNDROME)

Horner syndrome comprises of three features (Weinstein et al. 1980): miosis, ptosis and anhidrosis of the face. For patients affected congenitally there is also heterochromia of the irides with deficient pigmentation on the affected side while in some individuals flushing of the face is present (Saito 1990). Instillation of norepinephrine produces little or no dilation.

Horner syndrome is caused by sympathetic denervation, which may be congenital or acquired. It may be due to damage to the brachial plexus, especially the lower roots at birth or to tumours or other injuries that involve the superior cervical ganglion or the sympathetic trunks around the carotid artery. For a small number of individuals the syndrome is transmitted as a dominant trait (Hageman et al. 1992) and can be caused by lesions anywhere from the hypothalamus to the eye.

Horner syndrome should be distinguished from physiological anisocoria that may happen to be associated with mild ptosis of whatever cause, the so-called pseudo-Horner syndrome (Thompson et al. 1982), with the distinction important as Horner syndrome may have serious implications. Raeder syndrome differs from Horner syndromes by absence of facial anhidrosis and evidence of trigeminal involvement and often of other cranial nerves (Mokri 1982) with this syndrome indicating pathology in the region of the cavum of Meckel. For other patients experiencing the syndrome without involvement of other cranial nerves this may be a variant of migraine (Shevell et al. 1993).

ARGYLL ROBERTSON PUPIL AND OTHER RARE PUPILLARY ANOMALIES

Argyll Robertson pupil is classically associated with tertiary syphilis and, therefore, rarely observed in children, however the dissociation of light and near response may occur in other conditions such as pinealomas and other midbrain damage such as encephalitis, diabetes mellitus and some degenerative conditions.

The tonic pupil of Adie is rare in children. Typically it is idiopathic but has been associated with viral infections, ophthalmoplegic migraine and vaccinations (Goldsmith 1968; Aydin et al. 2006; Iannetti et al. 2009). It may be associated with hyporeflexia or areflexia and is thought to result from lesions in the ciliary ganglion with aberrant fibre regeneration.

DISORDERS OF OCULAR MOTOR FUNCTION

IN VolvEMEN of peRIPHERAL OCULAR MOTOR NERVES OR THEIR NUCLEI

The movement of the eyeballs are controlled by the IIIrd, IVth and IVth cranial nerves through the muscles that they innervate. Paralysis of one or several of these muscles results in ophthalmoplegia which may be acquired or congenital and occur isolated or in combination. Such paralysis should be distinguished from nonparalytic strabismus which is a very common condition affecting 3–4% of all children. (For additional information, please refer to Leigh and Zee 2006.)

ACQUIRED OPHTHALMOPLEGIA

Ophthalmoplegia can be due to a large number of causes. Children with acquired ophthalmoplegia may present with double vision, head tilt and strabismus.

Acquired IIIrd Nerve Palsies

Acquired IIIrd nerve palsies are common. The most frequent causes (Table 22.9) are closed head trauma, infections, tumours and vascular causes including migraines (Ing et al. 1992). Typically the IIIrd nerve is damaged through the course taken as nuclear and fascicular IIIrd nerve palsies are rare. If a nuclear IIIrd nerve palsy is present bilateral signs are likely to be present, whereas fascicular palsies tend to be unilateral. The age at onset and underlying cause are determining factors in the prognosis of the disease.

The most common cause of acquired IIIrd nerve palsy is trauma, with traumatic palsies resulting from haemorrhage or oedema into the nerves or muscles or from avulsion or lacerations of these structures (Miller 1985). The diagnosis of traumatic palsy may be difficult, particularly when the trauma has been minimal or not reported or when the paralysis is delayed or there are complications such as secondary orbital oedema, secondary increased intracranial pressure, infections or vascular disorders such as carotid-cavernous fistulae (Marmor et al. 1982). For such individuals neuroimaging investigation is indicated because trauma may be the only precipitating factor or paralysis of a nerve already compromised by a chronic (compressive) lesion.

Infection is the next most common cause, especially meningitis (Miller 1985), encephalitis and abscesses. Partial palsy
may be due to frontal sinusitis (Coker and Ros 1996) while tumours may present as an isolated IIIrd nerve palsy, especially craniopharyngiomas. With brainstem tumours other neurological signs become rapidly obvious: acute painful unilateral IIIrd nerve palsy may represent an ophthalmoplegic migraine, with there typically being a history of migraine. Generally, symptoms start in the first decade and resolve over a period of weeks with steroids possibly reducing the length of symptoms. Relapses can occur, however.

### Acquired IVth Nerve Palsies

Acquired IVth nerve palsies are mainly of traumatic origin (Keane 1993). Avulsion of the superior oblique pulley may explain the relative frequency of the paralysis of this muscle (von Noorden et al. 1986), with the nerve open to injury by inflammation or compression in the long course (Sydnor et al. 1982) taken. Rare causes such as infection, tumours and raised intracranial pressure have also been documented. Nuclear and fascicular IVth nerve palsies typically result from posterior fossa tumours while fourth nerve paralysis is typically unilateral in more than 60% of patients and resolves in two thirds (Sydnor et al. 1982). The signs of acquired IVth nerve palsy are similar to individuals affected congenitally. Symptoms are diplopia with a combined vertical/horizontal separation plus (subjective incyclo) torsion maximal in downgaze, particularly symptomatic in bilateral cases: clinically this may present with difficulties in descending stairs. IVth nerve palsies often clear spontaneously after several months but infrequently they persist or show evidence of aberrant regeneration, the first signs of which may appear by 4–6 weeks following the causal lesion or infection (Walsh and Hoyt 1969; Miller 1985).

### Acquired VIth Nerve Palsies

As with the other oculomotor cranial nerves the most common cause of VIth nerve palsy in infants is trauma but other pathologies including tumour, infection and increased intracranial pressure may also lead to paresis (Table 22.10). Paralysis of the VIth nerve is sometimes observed in newborn infants, probably as a result of birth trauma (de Grauw et al. 1983), and usually disappears spontaneously in a few weeks. Tumours are the most common cause in older children and the nerve is especially sensitive to any cause of high intracranial pressure including pseudotumour cerebri. Meningitis and postnatal trauma can also produce lateral rectus paralysis (Afifi and Menzes 1992). Acquired paralysis of the VIth nerve may be difficult to distinguish from the sudden appearance of a squint due to a decompensation of refractive error or other visual disturbance, often at the time of an acute infectious disorder (Watson and Fielder 1987).
Postinfectious VIth nerve palsy secondary to a viral infection may be diagnosed on the basis of history although the diagnosis is often made without definitive proof. The onset is sudden and the involvement is generally unilateral with the child complaining of diplopia and the paralytic strabismus is observed. Full motility is restored within 6–12 months although a recurrent form has been reported (Afifi et al. 1990; Cohen et al. 1993).

Involvement of the VIth nerve may be a part of the Gradenigo syndrome which commonly occurred as a complication of mastoiditis when the infection reached the apex of the petrous, though individuals suffering from such are now exceptional. The proximity of the cavum trigeminale causes the Vth nerve to also be affected with pain in the face and eye and the facial nerve may be involved in the petrous canal. Gradenigo syndrome can be a consequence of T-cell lymphoma (Norwood and Haller 1990) on rare occasions. The syndrome is now more commonly seen with orbital or retro-orbital disease (Taylor 1997).

**Combined Ophthalmoplegias**

On occasion, ophthalmoplegia may involve a combination of nerves, an example of which is the Miller Fisher syndrome. Miller Fisher syndrome, a variant of Guillain-Barre syndrome, results in ophthalmoparesis of one or a combination of the IIIrd, IVth and VIth cranial nerves with pupil involvement and is associated with the presence of serum anti-GQ1b IgG antibodies. The involvement appears to be primarily in the periphery, although some oculocephalic manoeuvres may suggest a supranuclear component. Typically function slowly recovers spontaneously or following treatment with plasmapheresis with an association observed following Campylobacter jejuni infection, which is thought to induce antiganglioside antibodies (Ang 2001).

Another example of a combined ophthalmoplegia is the Tolosa-Hunt Syndrome (Fig. 22.8). Tolosa-Hunt syndrome is characterised by a dull, persistent pain around the affected eye, ophthalmoplegia and sometimes involvement of the optic nerve, the first and/or second branches of trigeminal nerves and sympathetic innervation of the affected eye (Goto et al. 1989; Gordon 1994). The IIIrd nerve is usually involved first and more severely than the others but all three oculomotor nerves may be affected. The diagnosis requires exclusion of the other known causes of painful ophthalmoplegia such as infection, neoplasm or lymphoma (Spector and Fiandaca 1986). CT may show a high-density area in the orbit and orbital phlebography may show occlusion of the superior ophthalmic vein (Goadsby and Lance 1989). While detailed imaging of the cavernous sinus is now essential in the investigation of apparently isolated and even painless, cranial nerve palsies. The course usually extends over weeks or rarely months, with

</table>
corticosteroid administration valuable in the treatment and frequently having a dramatic effect. The condition is related to orbital pseudotumour (Rohr and Gauthier 1988; Grossniklaus et al. 1995), which may be either acute or chronic, with this so-called sclerosing orbital pseudotumour (Abramovitz et al. 1983) not responding to steroids. Pseudotumour is rarely seen in children and usually associated with displacement of the globe downward and outward as well as with oedema and inflammation of the eyelids, both signs that are not present with Tolosa-Hunt Syndrome. Pseudotumour may be difficult to differentiate from lymphomas and other tumours (Flanders et al. 1989).

Acute rectus muscle palsy as a result of orbital myositis (Pollard 1996) is also closely related to orbital pseudotumour and Tolosa-Hunt syndrome. CT or MRI shows swelling of the affecting muscle, usually the lateral rectus, but occasionally the medial or superior rectus. Muscle involvement has also been observed in Graves ophthalmopathy in infants and adolescents (Uretsky et al. 1989).

Acute rectus muscle palsy as a result of orbital myositis (Pollard 1996) is also closely related to orbital pseudotumour and Tolosa-Hunt syndrome. CT or MRI shows swelling of the affecting muscle, usually the lateral rectus, but occasionally the medial or superior rectus. Muscle involvement has also been observed in Graves ophthalmopathy in infants and adolescents (Uretsky et al. 1989).

The painful ophthalmoplegia of Tolosa-Hunt syndrome may be difficult to distinguish from ophthalmoplegic migraine although involvement of the Vth nerve, increased erythrocyte sedimentation rate and long duration of pain favours the former diagnosis (Kandt and Goldstein 1985). Enlargement of the optic nerve sheath and of the extraocular muscles is also an argument in favour of Tolosa-Hunt syndrome. Treatment with prednisone (1–1.5mg/day) alleviates the pain and ophthalmoplegia, the latter after several days or weeks but recurrences may occur on discontinuation of treatment or in spite of it. Involvement of the facial nerve is not rare (Swerdlow 1980) with some suggesting that Tolosa-Hunt syndrome may be a form of recurrent cranial nerve neuropathy because of the relative frequency of recurrences that may affect the contralateral side and involvement of different cranial nerves (Barontini et al. 1987).

Cavernous sinus thrombosis may resemble Tolosa-Hunt syndrome when it produces unilateral (and sometimes bilateral) ophthalmoplegia however fever and septic signs are usually marked and there is proptosis and orbital congestion. Vigorous antibiotic treatment is urgently indicated before meningeal involvement sets in (Harbour et al. 1984).

CONGENITAL OPHTHALMOPLEgia

Congenital ophthalmoplegia is often not recognised until relatively late or discounted as representing ‘physiological’ or pathological strabismus. For this reason the diagnosis of congenital ophthalmoplegia should not be excluded on the basis of the child having no ophthalmoplegia at birth by history. Photographs can be extremely useful.

Congenital IIIrd Nerve Palsy

This condition is relatively uncommon, being unilateral in the vast majority. All bilateral congenital IIIrd nerve palsies are associated with additional neurological signs due to anomalous brain development, intrauterine injury (vascular, teratogenic or infectious) and perinatal damage are possible causes.

Congenital IIIrd nerve palsy presents with ptosis, exotropia and hypertropia of the involved eye. The paralysis is generally unilateral and complete although the pupil may be of normal size or even small because of aberrant regeneration: the affected eye is exotropic and usually develops amblyopia. For most individuals evidence of aberrant regeneration is present in the form of lid retraction and/or papillary constriction on attempted adduction (Prats et al. 1993). Cyclic phenomena with spasm of adduction, papillary constriction and lid elevation alternating with adductor paresis, ptosis and papillary constriction may occur. Surgical management of the strabismus involves resection of the medial rectus but is of purely cosmetic value.

Congenital IVth Nerve Palsy

Congenital trochlear nerve paralysis is the most common of congenital ocular motor palsies. There is usually no associated neurological or developmental anomaly but occasionally trauma has been associated (Reynolds et al. 1984). Almost all patients are affected unilaterally (Vön Noorden et al. 1986) with the presenting complaint frequently a head tilt away from the paralysed side or even scoliosis. When the head is tilted to the paralytic side hypertropia becomes evident, with surgical therapy it is important to avoid torticollis and scoliosis.
Congenital IVth nerve palsy has been reported with occult cranium bifidum (Bale et al. 1988) and as familial occurrence (Astle and Rosenbaum 1985).

**Congenital VIth Nerve Palsy**

Abduccens nerve palsy, rarely seen in healthy neonates, is suspected to be a result of focal damage to the peripheral nerve: often when present it may go unrecognised. Congenital VIth nerve palsies can be unilateral or bilateral and when individuals are affected by the latter this is easily confused with non-paralytic strabismus. It may be a part of Moebius syndrome. The prognosis is typically good, with many children developing binocular vision.

**Congenital Cranial Dysinnervation Disorders**

Duane retraction syndrome is characterised by a palsy of the lateral rectus, limitation of adduction and narrowing of the palpebral fissure due to globe retraction on attempted adduction. It is the most common congenital dysinnervation disorder (Oystreck et al. 2011) and more often unilateral than bilateral while also attributed to absence or hypoplasia of the abduccens nerve with innervations of the ipsilateral lateral rectus muscle by the oculomotor nerve (Breinin 1957; Miller et al. 1982; Miller 1985; Parsa 1998). Interestingly, a majority of children with Duane syndrome are able to maintain binocular vision by turning their head toward the side of the lesion with abnormalities of the brainstem auditory evoked potentials also found (Jay and Hoyt 1980).

Duane syndrome is often associated with additional brainstem anomalies. More complex forms associated with Marcus Gunn phenomenon (Isenberg and Blechman 1983) (see below) or with the ‘crocodile tears’ phenomenon (Biedner et al. 1979) are on record, indicating that the tendency to abnormal synkinesis may be widespread. Crocodile tears are thought to be due to a discrete lesion in the vicinity of the abduccens nucleus with innervation of both the lateral rectus and salivary gland by ocular motor fibres. Several different phenotypes have been described, involving a number of different chromosome mutations. For some individuals this may be transmitted as an autosomal dominant condition.

**Fibrosis of Extraocular Muscles (Congenital Familial External Ophthalmoplegia)**

This disorder is characterised by the local (Prakash et al. 1985) or diffuse (Hiatt and Halle 1983) replacement of muscle fibres by fibrous connective tissue and for most individuals affected is dominantly inherited. The only manifestation is restricted ocular motility in the fields of affected muscles while ptosis is generally present. Diagnosis can be made through the biopsy of the fibrotic muscles with the classic type caused by a mutation in the region of chromosome 12q12 (Engle et al. 2007). Several phenotypes of congenital fibrosis have been described (Engle et al. 1994, 2002; Yazdani and Traboulsi 2004).

Brown syndrome differs from congenital fibrosis. The condition is often caused by shortening of the superior oblique muscle or tendon (Walsh and Hoyt 1969) while passive elevation of the globe in adduction is restricted as is voluntary elevation. For some individuals this may occur as a result of rheumatoid arthritis (Wang et al. 1984) or trauma. Surgical treatment can produce cosmetic benefit for patients with muscle fibrosis.

**CONGENITAL PTOSIS**

Congenital ptosis is a common condition caused by absence or fibrosis of the levator palpebrae. This may be congenital although the condition is usually sporadic (Walsh and Hoyt 1969). Seventy per cent of patients are affected unilaterally while ptosis is rarely associated with extraocular muscle involvement. Some patients demonstrate a synkinesis between the movements of the jaw and those of the upper lid such that lowering the jaw or moving it sideways produces elevation of the lid which is especially striking in infants when sucking, the so-called jaw-winking or Marcus Gunn phenomenon (Pratt et al. 1984). An inverted Marcus Gunn phenomenon in which there is drooping of the lid on opening of the mouth has been reported as a congenital (Lubkin 1978) or acquired (Rana and Wadia 1985) phenomenon. The mechanism of this phenomenon may be aberrant regeneration but a central mechanism is possible and has also been proposed for other synkineses (McLeod and Glaser 1974).

Congenital ptosis should be distinguished from acquired ptosis and especially from myasthenia gravis. Corrective surgery is indicated for cosmetic reasons or when vision is impaired by the drooping lid.

**GAZE PALSIES**

Gaze palsies are due to involvement of the supranuclear pathways that control the orientation of the head and eyes (Daroff and Troost 1978). Such control is integrated at several levels including the vestibular nuclei, other brainstem structures, the basal nuclei and cerebral cortex (Pierrot-Deseilligny et al. 1997). The diagnosis of supranuclear ocular palsies rests on the characteristics of abnormal head movements and on demonstration that the eyes can move normally in response to the doll’s head manoeuvre, caloric testing and Bell’s phenomenon. The main causes of gaze palsies are listed in Table 22.11 and only some of the manifestations and causes will be discussed here.

**Horizontal Gaze Palsies**

Horizontal gaze palsy may occur sporadically or as part of an hereditary condition. It can be due to a cortical lesion in the
Chapter 22  Disorders of Visual and Oculomotor Functions

Vertical Gaze Palsies

Paralysis of vertical gaze, especially upward gaze, may be difficult to distinguish from a simple difficulty in looking upwards, which is frequent in patients with mild disturbances of consciousness and even in fatigued patients. Transient disturbances in supranuclear vertical gaze occur in up to 2% of healthy neonates with downward deviation of gaze (Hoyt et al. 1980) which can be associated with upbeat nystagmus (Goldblum and Effron 1994). Yokochi (1991) reported episodes of downward gaze deviation in 13 neurologically impaired preterm or term infants with a history of perinatal asphyxia. These episodes lasted several seconds each during wakefulness with all patients having imaging evidence of periventricular leukomalacia involving predominantly the optic radiations, and half having intellectual disabilities or cerebral palsy at 5 years of age; however, similar episodes with a benign course have also been reported (Kleiman et al. 1994).

Ouvrier and Billsom (1988) reported a syndrome which they termed benign paroxysmal tonic upgaze of childhood, characterised by episodes of sustained tonic conjugate upward deviation of the eyes, lasting from 30 minutes to several hours, with compensatory forward bending of the head. On attempted downward gaze downbeating ocular saccades would occur with fluctuating symptoms increased by fatigue and intercurrent illnesses and relieved by sleep. The onset was between 6 and 24 months of age with affected children having no other difficulty except mild ataxia. All symptoms spontaneously disappeared in a few weeks or months, with similar instances reported by Deonna et al. (1990) and by Guerrini et al. (1998) who also mentioned the occurrence of occasional atomic falls. Very similar symptoms but with an earlier onset in the first month of life have also been described (Ahn et al. 1989). The syndrome has, in various instances, been reported as inherited from family and the episodes of downward gaze can be abolished by low-dose-L-dopa treatment, suggesting a possible link to dopa-sensitive dystonia (Campistol et al. 1993). Association with psychomotor retardation has been rarely reported (Sugie et al. 1995). However, recent work (Hertle et al. 1998) indicates a less favourable outcome with respect to both cognition and fine motor control.

Paralysis of vertical gaze that has been described in intoxication with anticonvulsants, antidepressants and other drugs may be explained in part by the disturbance of consciousness, but this does not apply to all patients and true ophthalmoplegia has been repeatedly observed.

The most important cause of vertical gaze palsy is represented by tumours in the pineal region. The sylvian aqueduct syndrome can also be seen in patients with hydrocephalus due to aqueductal stenosis. The syndrome features associated eyelid retraction, mydriasis with dilated pupils with better contraction to near objects than to lights (light-near dissociation), skew deviation of the eyes and sometimes convergent-retraction nystagmus (nystagmus retractorius) and disturbances in horizontal gaze. The pretectal syndrome has been reviewed in detail by Keane (1990). Disorders of the basal ganglia such as Huntington disease are frequently associated with vertical supranuclear gaze palsies while vertical downward gaze palsy is also a feature of Niemann-Pick and Gaucher diseases and is a key clinical feature of Niemann-Pick type C disease (Salsano et al. 2012). In the latter paralysis, horizontal gaze

DAF, downward gaze palsy, ataxia and foam cells.

contralateral frontal lobe (area 8), in the anterior occipital lobe or ipsilateral para-abducens pontine nucleus. The palsy is not uncommonly associated with other neurological anomalies including hemiplegia or with more complex disturbances such as hemineglect or hemianopia. In addition, some system features can also be found including musculoskeletal anomalies such as kyphoscoliosis (Steffen et al. 1998) and ear dysplasia.

Subcortical (pontine) lesions are a common manifestation of brainstem glioma, less commonly of vascular malformations or destructive lesions. They may be a sign of central pontine myelinolysis while pontine gaze palsy can be difficult to distinguish from Moebius syndrome or other causes of bilateral VIth nerve palsy. Familial congenital gaze palsy has been reported (Vetterli and Henn 1981; Jen et al. 2002).
is frequently associated (Grosse-Tsur et al. 1989) and may be isolated (Patterson et al. 1993).

Keane and Finstead (1982) have reported that isolated upward gaze palsy may be the initial manifestation of the Miller Fisher syndrome and Sandyk (1984) has described the same phenomenon in vitamin B12 deficiency.

Internuclear Ophthalmoplegia

Internuclear ophthalmoplegia is characteristic of the involvement of the medial longitudinal fasciculus which connects the abducens nucleus on one side and opposite ocular motor nucleus to permit conjugate lateral gaze (Pons). When these nuclei are disconnected attempted lateral movements produce abduction of the eye ipsilateral to the fasciculus lesion and absence of the normal adduction of the contralateral eye. The phenomenon may be uni- or bilateral and is mainly due to multiple sclerosis although in children brainstem tumours and head trauma may be a more frequent cause (Mueller et al. 1993). Other causes such as metabolic, immunological and inflammatory processes have been associated. When the disorder is mild contraction of the medial lateral rectus may be present but slower than that of the lateral rectus, while nystagmus of the abducting eye is usually present. The ‘one-and-a-half syndrome’ is a variant characterised by complete lateral gaze palsy to one side (‘one’) with contralateral paralysis of the adduction (‘and-a-half’). It is caused by a lesion involving the paramedian pontine reticular formation and the longitudinal fasciculus on the same side (Pierrot-Deseilligny et al. 1981; Wall and Wray 1983).

Convergence Palsy

Convergence palsy is an inability to adduct both eyes in the absence of medial rectus paralysis with the most common cause probably closed head injury (Krohel et al. 1986) and other factors including stress and fatigue (van Leeuwen 1999); convergence palsy may be encountered even following minor head trauma. Before making the diagnosis it is necessary to rule out the presence of a tumour of the quadrigeminal plate of neighbouring structures. In such instances patients may have a complete insufficiency to converge. Treatment of post-traumatic convergence palsy consists of convergence exercises and/or wearing prisms.

Oculogyric Crisis

Oculogyric crisis is an idiosyncratic reaction leading to restlessness, agitation, malaise or a fixed stare. Typically there is extreme and sustained upward deviation of the eyes which may converge, deviate upward and laterally or deviate downward. There are many drugs commonly used in paediatrics that can trigger an oculogyric crisis including neuroleptics, carbamzepine, diazoxide, metoclopramide and domperidone.

Anne O’Hare

Hearing impairment is defined as sensorineural when it arises from abnormalities of the inner ear and cochlear nerve, conductive when it is related to disease or deformity of the outer and middle ear, and mixed if both sets of structures are involved. Sensorineural hearing loss can also be of central origin if it results from abnormalities of the central nervous system (CNS) that subserve audition but lie rostral to the cochlear nerve.

The World Health Organization (WHO) defines a hearing impairment on the basis of the residual hearing in the better ear averaged over 0.5, 1, 2 and 4kHz (WHO 1991) as follows: slight 26–40dB hearing loss (HL), moderate 41–60dB HL, severe 61–80dB HL and profound ≥81dB HL.

Hearing impairment can be further classified on the basis of the age at detection and aetiology. Congenital impairment refers to a hearing impairment that has been recognised at birth or that is believed to have been present since birth. Progressive impairment is one that may become evident either at birth or postnatally, or that worsens over time. A hearing impairment may also have a late onset, but the term ‘acquired impairment’ is reserved for those patients in whom there is an identifiable exogenous cause.

Most countries deliver neonatal hearing screening, with universal screening detecting 69% of significant hearing loss by the age of 6 months compared with 12% in targeted screening (Wake 2005). However, not all hearing impairment will be present in the neonatal period and therefore a high index of suspicion must be exercised during paediatric neurological practice, even for children who have been receiving this screening. It is important to be familiar with your local methods and pathways (Watkin 2012). Fortnum et al. (2001) reported a UK prevalence of 0.91 per 1000 (95% confidence interval [CI] = 0.85–0.98) for 3 year olds, rising to 1.65 (95% CI = 1.62–1.68) for children aged 9–16 years. Around half of the overall prevalence is, therefore, contributed by these older children whose problem is detected after the age of 3 years; they must make up those with congenital impairment who had missed neonatal hearing screening or were false negatives, as well as children who have acquired impairment or developed their impairment postnatally. The latter include children affected by genetic impairments that have a late onset.

Many children seen in neurological practice have experienced an adverse perinatal course and such factors now account for 27% of the childhood population with significant hearing loss, a much higher prevalence rate than that described over 20 years ago. If one takes into account neonatal intensive care unit (ICU) experience, combined with a family history of hearing loss and craniofacial abnormalities that were noticeable at birth, around two-thirds of all types of hearing loss can be identified.

In addition, 30–40% of children with a confirmed hearing loss have developmental delays or other disabilities. Chromosomal abnormalities are associated with the sensorineural hearing loss in around 5% of hearing-impaired children. At the molecular level of aetiology it is salutary to reflect that 1% of the approximately 30 000 or more human genes are necessary for hearing. Many genetic conditions that are associated with hearing impairment are syndromic, although this may not be immediately evident clinically because the wider implications of the disorder are not initially recognised.

The genes implicated in sensorineural hearing loss cover a wide range of processes that are also involved in neurological development and function. These include structural genes, transcription factors, tumour suppressors, signal transduction processes such as ion homoeostasis and intracellular transport, and mitochondrial genes responsible for oxidative phosphorylation and energy production. Advances in this field are rapid and increase our understanding of the role of genes and their interaction with environmental factors, which should result in earlier accurate diagnosis and effective treatments for neurological disorders and hearing loss (Smith 2001; Raviv et al. 2010).
Children need to hear all the sounds of speech in order to acquire language. Figure 23.1 shows the frequency range of average conversational speech.

The major contribution to speech intelligibility is made by high-frequency speech phonemes, which contain the least acoustic power. A high-frequency hearing impairment interferes with the recognition of the speech sounds 's', 'th', 'sh', 'b', 'k' and 't' because they have primary acoustic energy >2000Hz. It impacts on the perception of fricative phonemes, which make up 50% of the consonant sounds in the English language, and also contribute as linguistic markers to indicate aspects such as grammatical tense, plurals, possession and gender. Even with high-frequency losses >4000Hz there will be a negative effect because children may not hear plural forms of words in the English language or hear them inconsistently, especially when they are listening to particular voices such as those of women and children. In addition, high-frequency hearing loss may reduce the audibility of low-frequency speech cues. For adolescents and adults, a high-frequency hearing loss does not typically affect speech recognition until the loss involves frequencies <3000−4000Hz. This protection arises because they have already achieved language competence and thus have at their disposal semantic and syntactic cues that help compensate for decreased audibility. In contrast, young children who are acquiring language do not have enough linguistic experience to employ these cues as effectively. It is important also to realise that young, typically developing children who have normal hearing have greater difficulty than adults when it comes to understanding speech in noisy and reverberant environments, and this is the result of developmental factors and inexperience with language exposure. Understanding speech in noise is therefore interfered with further by high-frequency hearing loss. In addition, a lot of a child's learning is incidental by over-hearing the conversations of others, and these opportunities are diminished when a child has a high-frequency hearing loss (Stelmachowicz et al. 2004). The loss of these opportunities for social communication can have far-reaching consequences and, even after aiding, children show delays in 'mentalising', which is the ability to impute and understand other people's thoughts and motives (Peterson 2004).

Hearing impairment has a very early effect on language acquisition. Infants have a capacity to learn a language simply by being exposed to it during the first 6 months of life, before that they are able to use words themselves. By 6 months of age, this exposure has led to language-specific organisation, such that infants have a stronger perception for a native language phonetic pattern, in contrast to the first few weeks of life when human infants show a similar pattern of phonetic perception, regardless of the language environment in which they are born. These findings clarify that fundamental, cognitive, building blocks are in place for language acquisition because of this perceptual process (Kuhl et al. 1992).

THE PERIPHERAL AUDITORY SYSTEM

The peripheral auditory system consists of the external ear of the pinna and external auditory canal, the middle ear and finally the inner ear or cochlea. Conductive hearing loss arises from interference in the passage of sound waves that pass through the pinna and the external auditory canal to make the tympanic membrane vibrate. This movement of the tympanic membrane is mechanically conducted through the middle ear by the three ossicles of the malleus, incus and stapes. The stapes is located within the oval window of the cochlea where its motion transmits sound waves to the fluid-filled inner ear. In the cochlea, this physical stimulus of sound is converted to an electrochemical stimulus, which in turn is transmitted by the auditory nerve to the higher levels of the auditory system. A sensorineural hearing loss can arise from a lesion of the cochlear, the auditory nerve, auditory brainstem, midbrain or cortex. Conventionally, lesions of the central auditory nervous system involve the relay systems of the superior lateral lemniscus, inferior colliculus and medial genulate body, with a contribution from the reticular formation, cortical and subcortical areas of the Heschl gyrus, planum temporale and sylvian fissure, with the insula and corpus callosum. The central auditory nervous system has extensive interconnections between its structures, which may make it comparatively resistant to expressing symptomatology after impairment (Moore 1991). The cochlea matures in early embryonic life and there is extensive myelination of the auditory pathways, including the inferior colliculus and the medial geniculate body, by the start of the third trimester (Guzetta et al. 2011).

The inner ear consists of the vestibular system and the cochlea and contains the three fluid-filled chambers of the scala vestibuli and scala tympani, which are filled with perilymph, and the scala media, which contains endolymph. The basolateral surfaces of outer hair cells and basilar membrane are bathed in perilymph, which has a composition similar to that of typical extracellular fluids or cerebrospinal fluid (CSF) in that it has a low potassium concentration of around 5mmol/L and a high sodium concentration of around 145mmol/L. The endolymph of the scala media contains an unusually high concentration of potassium (around 150mmol/L) and a low concentration of sodium (around 1.3mmol/L). The cochlea has a resting potential of +60mV to +150mV relative to the interior of a cochlear hair cell. Hearing function requires this electrochemical battery, which depends largely on the high concentration of potassium in the endolymph. Tight junctions in the paracellular spaces of epithelial cells maintain these gradients of sodium and potassium ions in the fluid compartments of the inner ear.

The normal human ear has exquisite sensitivity and can perceive sounds over a dynamic range of six orders of magnitude, and discriminate different frequencies with 0.2% precision.
in the range 50–20,000 cycles per second (Hz). Inside the cochlea, the hydromechanical stimulus of sound results in wave movements of the basilar membrane, which supports the organ of Corti with its two types of receptor cells, one row of inner hair cells and three rows of outer hair cells. Inner and outer hair cells transduce the mechanical energy of sound waves into the electrochemical energy of action potentials. The transduction of sound waves into a neural signal is initiated by the physical deflection of the cochlear hair cells, which mechanically opens channels in the hair cells and allows the passive inward flow of potassium ions from the high potassium environment of the surrounding endolymphatic fluid. This high potassium concentration is maintained by active transport through potassium channels which are located in the strial vascular areas at the outer periphery of the coiled cochlear duct.

The cochlea is tonotopically tuned. The base is most sensitive to high-frequency sound and the apex detects low-frequency sound. To achieve this tonotopic sensitivity, the inner ear tunes the basilar membrane at particular positions along its length and also has a narrow band of frequencies to which hair cells, both inner and outer, are tuned at a particular position on the basilar membrane. These frequency-placed properties of the cochlea are copied in a frequency-specific map of cochlear ganglion neurons (Dallos 1992). Some mutant alleles of deafness genes may initially cause pathology in just one area of the cochlea, and this results in a hearing deficit that is restricted to a particular frequency range of the hearing spectrum.

The primary auditory cortex organisation is shaped by exposure to salient acoustic inputs (Chang and Merzenich 2003). In congenitally deaf humans there is poor cochleotopic organisation, but the chronic auditory stimulation that follows the intervention of a cochlear implant produces many aspects of the auditory cortex picture seen after normal activation, and this supports the hypothesis that severe auditory

---

Figure 23.1 A quick reference to speech and the audiogram. The blue shaded area shows the range of average conversational speech. Approximately 50% of average conversation occurs at levels quieter than above the dotted blue line. (Provided by the Electronic Deaf Education Network, www.bradingrao.com.)
deprivation extends the window of the 'critical developmental period’. Mammalian studies also suggest that noise present in a child's environment has the potential to contribute to auditory- and language-related developmental delays. However, there is no clear evidence that noise-induced hearing loss occurs in infants receiving intensive care, probably because it is these infants who are the most sick and thus spend the longest period of time exposed to high levels of noise in the ICU, and who are also those who have the highest rates of hearing loss from a range of other factors (Wachman and Lahav 2011).

**CLINICAL ASSESSMENT OF HEARING IMPAIRMENT**

During the physical examination of a child with a sensorineural hearing loss, particular attention needs to be paid to height and weight, cranial nerves, shape of the skull and head circumference, and the appearance of the face and ocular region, particularly looking for abnormalities of the scleral colour, the inner and outer canthal and interpupillary distances, palpebral fissure shape and orientation (Bamiou et al. 2000a).

The ears need to be carefully examined for the presence of preauricular tags, fistulae, pits or abnormalities of size, and shape (Alasti and Van Camp 2009). In one study, brainstem-evoked response audiometry was abnormal in 17% of newborn infants with isolated preauricular tags or pits, and behaviour audiometry confirmed a higher incidence of both conductive and sensorineural hearing impairment (Kugelman et al. 1997). As a result of the association of some syndromes of deafness with dermatological conditions, one should look for pigmentation, keratinisation and onychodystrophy of the skin and nails, with any increase in the number and size of fingers and toes. Attention should also be paid to exploring for cleft lip or palate, micro- or retrognathia, the shape of the philtrum and inspection of the neck, looking for branchial remnants and thyroid enlargement.

Developmental examination is important because of the known association of developmental difficulties with hearing impairment.

**Visual and Ophthalmological Examination**

All children with severe or profound sensorineural deafness should have a visual examination soon after diagnosis. Children with multiple disabilities have a greater likelihood of visual impairment. A visual impairment defined as a visual acuity <6/9 (Snellen chart or equivalent), and/or abnormal binocular vision, was found to affect 34.9% of hearing-impaired children, and 10.9% had ophthalmological abnormalities that did not interfere with vision (Armitage et al. 1995). As the deaf child is more dependent on vision for communication and learning, it is important to consider this aspect of the examination. Refractive errors were the most commonly encountered abnormalities. Many abnormalities may be seen on ophthalmological investigation, including salt-and-pepper retinopathy, glaucoma and cataracts as sequelae of congenital rubella syndrome, and choroidoretinitis following congenital cytomegalovirus infection or toxoplasmosis. Dystopia canthorum, heterochromia iridis and hypoplastic iris stroma are clinical features of Waardenburg syndrome. In Alport syndrome, there may be an anterior lenticous or macular flecks. A range of metabolic disorders associated with hearing impairment includes eye disease, for example, retinitis pigmentosa in Alström syndrome and Refsum syndrome. Electroretinography (ERG) should be considered for any child with a congenital bilateral hearing loss, and there may be early changes of retinitis pigmentosa with abnormal ERG in Usher syndrome type I, with these features arising after puberty in Usher syndrome type II. Usher syndrome type I is associated with severe audiovestibular system deficits, so difficulties in balance can lead to early presentation (Tsilou et al. 2002).

**Investigations**

The investigation strategy for a child with a hearing impairment can be considered at two levels (Wilson et al. 2005). All children with a hearing impairment should have a close exploration for a family history of deafness that includes conducting audiograms of first-degree relatives. It is also important to enquire about metabolic disorders in first- and second-degree relatives, as well as renal, thyroid and cardiac disorders, craniofacial malformations, pigmentary disorders, vision deficits and developmental problems. One needs to enquire about consanguinity and common origin from an ethnically isolated population (Bamiou et al. 2000a, 2001).

Children with sensorineural hearing loss may require computed tomography (CT) of the temporal bones; in addition, a fine-section, high-resolution MRI is required for any cochlear implant candidate to ensure that the cochlear nerve is present. CT of petrous temporal bones involves radiation but will show the bony structures, including the middle-ear ossicles. MRI of inner ears and the internal auditory meati will show soft tissues of the brain, nerves VII and VIII, and the membranous labyrinth including the endolymphatic sac (Held et al. 1998; Tan and Teh 1998; Bamiou et al. 2000b). Children with profound or progressive hearing loss and craniofacial abnormalities are the ones most likely to have abnormal CT findings. This dual imaging must be timely because the cochlear can calcify within weeks of meningitis (Durtis et al. 2010; Caye-Thomasen et al. 2012), making subsequent cochlear implantation technically challenging and possibly unfeasible.

Children should also have electrocardiography (ECG), an ophthalmological examination, urinoscopy for haematuria and, in some cases, testing for a connexin-26 mutation. Clinically available genetic testing is offered for the three genes that cause non-syndromic deafness: GJB2, SLC26A4 and...
Audiological Assessment

A wide range of behavioural tests of hearing for typically developing infants aged >6 months is available, which can be adapted for delayed development, provided that the child has sufficient development to cope with the strictures of the testing situation. Behavioural tests of hearing when conducted with precision complement the role of electrophysiological techniques. Behavioural testing includes the distraction test, visual reinforcement audiometry, the performance test for which a child is conditioned to perform a simple action in response to a sound stimulus and pure-tone audiometry. In addition, there is a range of tests of auditory discrimination of speech (Hickson 2002). Although brainstem audiometry tests can be employed to examine speech acoustics, they are not yet in widespread clinical use (Bishop et al. 2011).

Objective physiological measures are more appropriate for detecting hearing impairment in newborn and very young infants, and for children who are unable to cooperate with behavioural testing. These techniques include otoacoustic emission (OAE) testing (either transient-evoked or distortion-product) and auditory brainstem responses (ABRs). These technologies comprise non-invasive recordings of physiological activity which underlie normal auditory function. The two measures are highly correlated with a degree of peripheral hearing sensitivity.

OAEs are sensitive to outer hair-cell dysfunction and testing can detect sensory hearing loss. The recordings are reliable in neonates in response to stimuli and a frequency range >1500Hz. As OAEs are also sensitive to outer-ear canal obstruction and middle-ear effusion, a positive test result can occur in the presence of normal cochlear function but temporary conductive dysfunction. As OAE responses are generated within the cochlea by the outer hair cells, the technique does not detect nerve VIII or auditory brainstem pathway dysfunction. OAE testing, therefore, may not detect infants with auditory neuropathy or neural conduction disorders without concomitant sensory outer hair-cell dysfunction.

In contrast, the ABR reflects activity of the cochlear, auditory nerve and auditory brainstem pathways. The click-evoked ABR is highly correlated with hearing sensitivity in the frequency range 1000–8000Hz. As the ABR is sensitive to auditory nerve and brainstem dysfunction, ABR screening can lead to a positive result in the absence of peripheral (i.e. middle-ear or cochlear) hearing loss, but in the presence of auditory neuropathy or neural conduction disorders in newborn infants.

An audiological test battery to assess the integrity of the auditory system should include OAEs, a measure of middle-ear function, acoustic reflex thresholds, observation of the infant’s behavioural response to sound, and parental reports of emerging communication and auditory behaviours. There should be appropriate measures of middle-ear function including reflectance tympanometry, using appropriate frequency probe stimuli, bone-conduction ABR or pneumatic otoscopy (Joint Committee on Infant Hearing 2000).

NEONATAL HEARING SCREENING

Many countries have adopted universal newborn infant screening programmes. Although there is consensus from a number of influential advisory bodies (Joint Committee on Infant Hearing 2000), the long-term effectiveness of these programmes is still being evaluated (Puig et al. 2005). However, studies of language ability, after early detection of permanent childhood hearing impairment through neonatal screening, has confirmed improved receptive language scores, reading and communication skills (Pimpton and Kennedy 2012). The advocates of neonatal hearing screening propose that all infants should have access to hearing screening using a physiological measure, and that infants with confirmed permanent hearing loss should receive appropriate services before the age of 6 months. The target for universal neonatal hearing screening programmes is a permanent bilateral or unilateral sensory or conductive hearing loss averaging ≥30–40dB in the frequency region important for speech recognition at 500–4000Hz. Infants who pass a newborn infant hearing screen, but who have risk indicators for other auditory disorders or speech and language delay, should receive ongoing audiological and medical surveillance. All programmes must be in a position to take forward the care of an infant who has
been identified as having a hearing loss through a screening programme of neonatal newborn infant hearing. The doctor involved must have an appropriate level of competence and would therefore usually be an audiological physician or a community doctor in audiology, or a paediatrician or otolaryngologist with an appropriate level of training.

AETIOLOGY OF SENSORINEURAL HEARING IMPAIRMENT

Genetic Causes

This is a rapidly advancing field, traditionally categorised into syndromic (30%) and non-syndromic (70%) causes (Friedman and Griffith 2003; Nance 2003; Raviv 2010). Although it is still helpful to make this distinction initially clinically, it is important to appreciate that some syndromic conditions may simply appear non-syndromic because the wider manifestations of the disorder have not been recognised, for example, prolonged Q–T intervals in Jervell–Lange-Neilsen syndrome, thyroid dysfunction in Pendred syndrome and retinitis pigmentosa in Usher syndrome. At a molecular level, the distinction can also be confusing. Although 50% of non-syndromic sensorineural hearing loss arises from mutations in connexin-26, other connexin genes can have associated abnormalities, for example, dermatological abnormalities with connexin-30 and connexin-31, palmoplantar hyperkeratosis with a dominant G59A allele, mutilating keratoderma associated with the D66H allele, and neurological abnormalities with connexin-32 seen in X-linked Charcot–Marie–Tooth disease. Around 33 recessive, 41 dominant and five X-linked loci have been mapped for non-syndromic genetic deafness. Despite the very large number of loci that have been identified, most instances of genetic deafness are caused by those mutations that involve a single gene from the connexins (Denoyelle et al. 1999).

The connexins are a family of genes that code for the subunits of gap-junction proteins. Gap junctions form when the hexameric hemi-connexins on the surface of two adjacent cells join to form a complete gap junction. The resulting channels permit the flow of ions and small molecules between the cells. The GJB2 gene at the locus 1q312-13 is one of the more commonly clinically available genetic tests for non-syndromic deafness, the others being for SLC26A4 and WFS1 (Smith 2004). These genes make a substantial contribution to the total genetic deafness mutation load and they are relatively easy to screen for. GJB2 at the DFNB1 locus results in autosomal recessive non-syndromic deafness. GJB2 encodes the transmembrane protein known as connexin-26, which oligomerises with five other connexins to form a connexion, which is the constituent component of gap junctions. The severity of hearing loss in connexin-26 gene mutations is extremely variable and cannot be predicted even within families, although it has been shown to be non-progressive in most cases on follow-up into young adult life (Denoyelle et al. 1999). The DFNB1 gene responsible for this recessive, non-syndromic sensorineural hearing loss causes approximately 15% of all infant hearing losses. It is important to consider testing for this common mutation because this will detect 95% of instances in white families who are not consanguineous. If the test is positive, then there is no further requirement for CT, perichondrial washout or investigations for retinitis pigmentosa (Joint Committee on Infant Hearing 2000).

DFNA36 mutation hearing loss is a condition of early onset and rapid progression of dominant non-syndromic deafness (Makishima et al. 2004).

Mutations of several genes that encode for a variety of different myocins, psychoskeletal motor proteins that create tension or facilitate the movement of cell components along actin filaments, are associated with hearing loss: MYO6, MYO7A, MYO15A, MYO1A and MYO3A (Ben-Yosef and Friedman 2003).

The A1555G mitochondrial mutation infers susceptibility to normal doses of aminoglycosides, an example of a situation in which genetic vulnerability combined with environmental risk factors results in sensorineural hearing loss (Bittner-Glindzicz et al. 2014).

GENETIC SYNDROMES

Again, progress in this area is very fast and there are an increasing number of conditions in which the following molecular analysis can confirm diagnosis: Waardenburg syndromes types I–IV, Treacher Collins syndrome, Alport syndrome, branchio-otorenal syndrome, Usher syndrome, Jervell–Lange-Neilsen syndrome, Pendred syndrome, Charcot–Marie–Tooth disease and craniosynostosis–deafness. The three syndromes of Jervell–Lange-Neilsen, Pendred and Usher may all initially appear to be non-syndromic until the involvement of other organs is recognised.

Prolonged Q–T Syndrome/ Jervell–Lange-Nielsen Syndrome

Mutations in the various potassium channel genes may result in the long Q–T syndrome and, when this is associated with congenital sensorineural deafness it is known as the Jervell–Lange-Nielsen syndrome (JLNS) (Neyroud et al. 1997). The prevalence is 0.21% in children with congenital deafness (Ocal et al. 1997). Prolongation of the Q–T interval is seen on ECG, and reflects a defective cardiac repolarisation that can lead to recurrent episodes of syncope, ventricular arrhythmia and sudden death. Syncope episodes can be precipitated by fright. The long Q–T syndrome is defined on the basis of a QTc (corrected QT) interval >470ms in asymptomatic individuals. The KVLQ71 gene that causes JLNS also causes Ward–Romano syndrome, in which there is no hearing loss. KVLQ71 maps to chromosome 11p15.5 (JLNS1 locus);
a recessive mutation involving another potassium channel gene, KCNE1, at the JLNNS2 locus on chromosome 21q22.1, may produce an identical phenotype which affects the active potassium transport system in the hair cells of the cochlea. Another potassium channel gene, KCNQ4, which is limited to the outer hair cells, has mutations that cause a relatively common dominant form of progressive hearing loss, which typically begins in the first two decades of life, first involving the high frequencies and then progressing within a decade to profound deafness.

All children with hearing impairment should have ECG, and if marginal or abnormal they should be referred to a cardiologist for further investigation because they may require further monitoring with ECG and exercise testing to establish whether there is a prolonged Q–T interval. This is associated with a high risk of syncope and sudden death during the first year of life or later, and there is also a vestibular areflexia.

**Pendred Syndrome**

Pendred syndrome, which arises from mutations in SLC26A4, is the most common cause of syndromic deafness, accounting for more than 5% of all individuals with autosomal recessive hearing loss. It is characterised by bilateral sensorineural hearing loss associated with goitre with or without hypothyroidism (Reardon et al. 1997). There appears to be a relationship between the severity of the hearing impairment and the degree of hypothyroidism. The deafness is congenital and associated with temporal bone abnormalities, which range from isolated enlargement of the vestibular aqueduct to Mondini dysplasia, which is a more complex malformation that also includes cochlear hypoplasia (Napiontek et al. 2004). The hearing loss is usually profound but can be variable in onset, rapidly progressing and unilateral. The goitre generally develops after the age of 10 years, and the thyroid dysfunction is variable. The sensorineural deafness is occasionally associated with disturbed vestibular function.

**Usher Syndrome**

Usher syndrome affects 2–4% of all patients with profound deafness and 50% of the deaf–blind population. Usher syndrome type I is characterised by vestibular dysfunction, profound congenital hearing loss and early onset of retinitis pigmentosa. The progressive degeneration of the retina results in loss of night vision and restriction of visual fields, leading to blindness. Type I is distinguished from type II by this early onset of retinitis pigmentosa. Type II also has a generally less severe hearing loss and normal vestibular function. Usher syndrome type III is characterised by a progressive postlingual hearing loss and varying severity of retinitis pigmentosa, without a vestibular component. Usher syndrome is phenotypically and genotypically complex with, for example, USH1 loci mapping to 10q21-22 and 11q13.5 (Ben-Yosef and Friedman 2003).

**Alport Syndrome**

In Alport syndrome, the hearing loss may not present until the age of 8–10 years, and 50% of those affected have progressive bilateral hearing loss involving high frequencies initially. There is a progressive nephritis. The incidence is one in 10 000 births, and X-linked, autosomal recessive and autosomal dominant varieties occur. Haematuria is seen in the first decade of life, and diagnosis is based on this plus a family history of haematuria or renal failure, characteristic renal biopsy findings, sensorineural hearing loss, and ophthalmic signs of anterior lenticonus or macular flecks. Ocular findings might also include congenital cataracts and spherophakia. The disease results from mutations involving one or other of three tissue-specific polypeptide subunits of collagen that are encoded by the COL4A3, COL4A4 and COL4A5 genes. The COL4A5 gene is located at Xq22, whereas the genes coding for collagens 3 and 4 are next to each other on 2q35. (See Chapter 26.)

**Alström Syndrome**

Alström syndrome is a recessively inherited genetic disorder caused by mutation of the ALMS1 gene (Hearn et al. 2002); it is characterised by congenital retinal dystrophy, which leads to blindness, sensorineural hearing impairment, childhood obesity, insulin-resistant type 2 diabetes mellitus, and hypertriglyceridaemia that can precipitate pancreatitis and pulmonary symptoms (Michaud et al. 1996). Among 182 patients studied by Marshall et al. (2005), 20% showed neurological symptoms, including clonic tic and absence seizures, whereas developmental motor or language delays were observed in almost 50%. There were fibrotic infiltrations of multiple organs including the kidney, heart, liver, lung, bladder, gonads and pancreas.

**Waardenburg Syndrome**

Waardenburg syndrome affects 1–2% of individuals with profound hearing loss, which can be bilateral or unilateral and is associated with defects in tissues and structures derived from neural crest cells (Liu et al. 1995). Pigmentary abnormalities include brilliant blue eyes, complete or segmental heterochromia, and patches of cutaneous hyper- or hypopigmentation. There is lateral displacement of the inner canthi of the eyes, a pinched appearance of the nose and synophrys. Gastrointestinal symptoms can occur, and there may be a history of Hirschsprung disease. There is an increased incidence of neural tube defects and limb defects. There are at least eight loci that contribute to the phenotype. Waardenburg syndrome type I can result from more than 50 different mutations involving the PAX3 gene on 2q35. Waardenburg type IIA results from mutations at the MITF locus on 3q12, and this condition has less frequent eyelid anomalies and a higher degree of deafness and heterochromia. Some Waardenburg type IIA patients have albinism, with or without freckling, and this is known as...
Tietz syndrome. A number of other loci have been described such as those in Waardenburg syndrome type III, a condition that features various limb defects. The mechanism here appears to be that the cochlear neural crest cells contributing to the intermediate layer of the stria vasularis are affected and likely to be the cause of the deafness because the stria cannot maintain the critical endocochlear potential that is required for the hair cells to function normally.

### Wolfram Syndrome

Wolfram syndrome is an autosomal recessive disease characterised by diabetes insipidus, diabetes mellitus, optic atrophy and deafness; it arises from mutations of WFS1. There is high-frequency hearing loss, and the condition can also involve peripheral neuropathy with urinary tract atony and psychiatric illness. A dominant low-frequency sensorineural hearing loss can also be caused by mutations in WFS1 (Lespérance 2003). As routine hearing screening of newborn infants will not typically identify hearing loss affecting frequencies <2000Hz, children at risk of deafness in Wolfram syndrome need to be specifically monitored. (See Chapter 26.)

### Congenital Fixation of the Stapes Footplate with Perilymphatic Gusher

This is an X-linked syndrome featuring mixed or sensorineural deafness, the conductive component of which involves congenital fixation of the stapes footplate. If attempts are made to mobilise this, there is a profuse flow of endolymphatic fluid. CT shows dilatation of the internal auditory meatus, with abnormal communication between the subarachnoid space and the cochlear endolymph. Carrier females may have a mild hearing loss and a less severe abnormality of the inner ear. The locus maps to Xq21.1; in many families the mutation has been shown to be a deletion, and it can sometimes involve nearby genes for intellectual disability and chooroideaemia.

### Syndromic Hearing Loss Associated with Dermatological Disorders

There are at least five dermatological disorders that are associated with syndromic hearing loss; these also involve a wide variety and severity of organ involvement. An example is the Bart–Pumphrey syndrome, which is an autosomal dominant disorder characterised by sensorineural hearing loss, palmoplantar keratoderma, knuckle pads and leukonychia (Richard et al. 2004).

### Dominant Optic Atrophy, Sensorineural Hearing Loss, Ptosis and Ophthalmoplegia

This syndrome is caused by a missense mutation in OPA1 (Payne et al. 2004). OPA1 is a nuclear gene but the gene product localises to mitochondria, suggesting that mitochondrial dysfunction might be the common pathway to many forms of syndromic and non-syndromic optic atrophy, hearing loss and external ophthalmoplegia.

### Craniofacial Abnormality Syndromes

A large number of syndromic conditions with craniofacial abnormalities are associated with deafness, some of which have delineation of the underlying molecular basis of the hearing impairment. An example is branchio-oto-renal syndrome, associated with mutations in EYA1 and EYA4 genes affecting transcription factors. This syndrome may have associated Mondini syndrome-type cochlear hypoplasia with hypoplastic and displaced ossicles. Renal ultrasonography may demonstrate agenesis or hypoplasia or dysplasia of the kidneys.

Children with profound or progressive hearing loss and craniofacial abnormalities are more likely to have abnormal CT findings. A dilated vestibular aqueduct correlates with the presence of progressive hearing impairment. CT of the petrous temporal bones has been found to be abnormal in 6.8–12.8% of patients with bilateral sensorineural hearing loss and in up to 30% of cochlear implant candidates. Mondini syndrome-type dysplasia is the presence of a cochlea with a normal basal turn and a distal sac. Semicircular canals are absent or dysplastic in the colobomas, heart defect, atresia of the choanae, retarded growth/development, genital hypoplasia and ear anomalies or deafness (CHARGE) association and in VATER–RAPADILINO syndrome (VATER is the association of vertebral defects, anal atresia/stenosis, tracheoesophageal fistula, radial defects and renal anomalies, whereas RAPADILINO includes radial defects, absent/hypoplastic patellae, high cleft palate, diarrhea and dislocated joints, little size, a long slender nose and normal intelligence, with hearing loss also a feature) (Bamiou et al. 2000a).

### Sensorineural Hearing Loss with Chromosomal Abnormalities

Chromosomal abnormalities occur in around 5% of children with sensorineural hearing loss. Hulcrazn (2003) reported that 61% of females with Turner syndrome experienced otitis media and sensorineural dip in hearing; in some patients this was observed as early as age 6 years and it progressed over time.

The 6q− syndrome can be accompanied by a bilateral severe sensory hearing loss. This rare disorder, due to a monosomy or trisomy of 6q, results in intellectual disability, microcephaly, asymmetrical face, broad nasal bridge, hypertelorism, epicanthus, strabismus, high arched palate, ventricular septum defect and seizures. Tetraplegia and diaphragmatic hernia have also been described (Schuster et al. 2003).

### Hearing Loss with Neurological Disease

An inherited disorder of white matter with ataxia, leukodystrophy and sensorineural hearing loss, progressing to complete...
Chapter 23 Disorders of Auditory and Vestibular Function

Charcot–Marie–Tooth syndrome. With sensorimotor neuropathy in Friedreich ataxia and neurodegenerative disorders, such as Hunter syndrome, and of anticonvulsants in the study by Pillion et al. (2003). Participants and those who had had seizures requiring the use of anticonvulsants in the study by Pillion et al. (2003).

Comfort with sound was common, affecting 18% of cases; serious otitis media occurred in 23.5%, with an associated conductive hearing loss in 18.3%.

Prevalence of sensorineural hearing loss of 17.3% has been described in Rett syndrome, and was increased in the older participants and those who had had seizures requiring the use of anticonvulsants in the study by Pillion et al. (2003).

Sensorineural hearing loss may be associated with neurodegenerative disorders, such as Hunter syndrome, and with sensorimotor neuropathy in Friedreich ataxia and Charcot–Marie–Tooth syndrome.

Refsum Disease

Refsum disease is characterised by retinitis pigmentosa, anosmia, chronic sensorimotor neuropathy and ataxia. Hearing loss is common, so those patients who report hearing difficulties should have a full audiometric investigation (Bamiou et al. 2003). There is a range of hearing loss types in the condition, varying from mild, predominantly high frequency, to moderate, as well as some evidence to suggest that there may be subtle auditory nerve involvement. Oysu et al. (2001) described the absence of ABRs but the presence of otoacoustic emissions in a patient with Refsum disease and hearing loss. This suggests that the hearing loss might be secondary to auditory neuropathy, with the hearing abnormality determined from the post-outer-hair-cell level. There may therefore be limited benefits and a risk of noise-induced damage to outer hair cells with the use of hearing aids, so the latter should be carefully considered and otoacoustic emission measurements undertaken in individuals with Refsum disease.

Brown–Vialetto–Van Laere Syndrome

Brown–Vialetto–Van Laere syndrome is a progressive motor neuron disease accompanied by a sensorineural deafness. Onset is in late childhood or early adulthood, usually signalled by a sensorineural hearing loss which is then followed by other lower cranial nerve involvement (VII–XII), along with lower and upper motor neuron signs in the limbs, and respiratory insufficiency. Usually death followed in 6–18 months but recent advances in the understanding of the condition has implicated the C2orf54 gene located in 20p13; recently there has been some benefit seen in patients after the successful administration of riboflavin (Bosch et al. 2011). Patients demonstrate both familial and sporadic syndromes. Some neurophysiological studies show evidence of nerve damage with subsequent improvement, which raises the possibility that the disorder is caused by primary nerve damage rather than motor neuron disorder (Degrandis 2005; Prabhu 2005).

Mitochondriopathies

Co-segregation of the mitochondrial DNA A1555G and G4309A mutations has been described, which results in deafness and mitochondrial myopathy. Symptoms include progressive external ophthalmoplegia, exercise intolerance and deafness after aminoglycoside exposure (Campos et al. 2002). Mitochondrial cytopathies can present with a variety of symptoms, but occasionally sensorineural hearing loss is the first manifestation and some patients have been described who responded well to cochlear implantation.

Sensorineural hearing loss is a common symptom in patients with myoclonic epilepsy associated with ragged-red fibres (MERRF). In this situation pure-tone threshold audiometry can show bilateral, sloping-type, sensorineural hearing loss and the primary lesion appears to be in the cochlea, although there may be some involvement with retrocochlear structures (Tsutsumi et al. 2001).

There is a high incidence (42%) of sensorineural hearing loss in children with mitochondrial encephalopathies including Kearns–Sayre syndrome, Friedreich ataxia and MELAS (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes). The hearing impairment is progressive but does not have a prognostic value for understanding the progression of the underlying disorder. Findings suggest that there may be cochlear and retrocochlear involvement (Zwirner and Wilichowski 2001). The histopathology in MELAS has shown that there is severe degeneration of the stria vascularis and degenerative change of spiral ganglion cells which causes the sensorineural hearing loss (Karkos et al. 2005).

Bioppterin Deficiency

Three-quarters of affected infants will develop a hearing loss that may be profound and persists even after treatment has been instigated (Wolf et al. 2002). Hearing loss can be completely prevented by presymptomatic diagnosis and the administration of supplemental biotin. (See also Chapter 9.)

CONGENITAL INFECTIONS

Rubella

Hearing impairment may be an isolated sequela of congenital infection with rubella, but rubella infection is currently very rare in the UK; the National Congenital Rubella Surveillance Programme reported that the incidence of congenital rubella births had fallen to an average of four per year over the period 1991–5 (Miller et al. 1997). Even after a resurgence of infection in the community, only 12 congenital rubella births were reported in 1996 (Tookey and Peckham 1999). However, it
is important to remember that the uptake of vaccine varies across countries, and this can result in cohorts of susceptible women (Crowcroft and Pebody 2004).

**Cytomegalovirus**

Cytomegalovirus (CMV) is the leading cause of sensorineural hearing loss (Boppanna et al. 2010). Of all instances of deafness in patients, 20–30% may be caused by CMV, and congenital CMV infection results in sensorineural hearing loss in around a fifth of affected children (Barbi et al. 2003). Half the symptomatic, antenatally infected infants will have neurological manifestations with poor outcomes, and a third will have a bilateral sensorineural hearing impairment (Townsend et al. 2011). Hearing loss may be progressive or fluctuating, and infants will need to be kept under review (Fowler et al. 1997). Therefore, the diagnosis of a sensorineural hearing loss in a child with neurological impairment should always trigger reflection as to whether CMV may be the aetiology for both conditions. Sensorineural hearing impairment is more likely to occur in the presence of a viraemia via cytopathic and immune-mediated processes acting on the organ of Corti (Amir et al. 2011). Sometimes the CMV viraemia can be identified retrospectively, through polymerase chain reaction (PCR) by examining the Guthrie blood spot (Walter et al. 2008), but, as not all children will have a viraemia at all stages of gestation, only the isolation of virus in saliva and urine in the first phase of life is fully confirmatory (Boppanna et al. 2010); however, Amir et al. (2011) have argued that the presence of lenticular striatal vasculopathy on neonatal ultrasoundography can be a marker of CMV infection that will progress to involve a sensorineural hearing impairment. In that study, children were treated with ganciclovir and valganciclovir with good effect; however, neutropenia with ganciclovir is common, affecting almost two-thirds of treated infants (Kimberlin et al. 2003). (See also Chapter 16.)

**Toxoplasmosis**

Congenital toxoplasmosis may cause hearing loss (see Chapter 16).

**Syphilis**

Syphilis can also cause hearing loss in the secondary or tertiary phase, and a positive fluorescent treponemal antibody absorption test assists in diagnosis.

**PERINATAL CAUSES OF SENSORINEURAL HEARING LOSS**

The prevalence of sensorineural hearing impairment in graduates of neonatal units is 4.9% (D’Amore et al. 2011) and risk factors encompass very low birthweight, assisted ventilation over 5 days, low Apgar scores and exposure to ototoxic medications. Hearing impairment, defined as a loss of >70dB in the better ear before amplification, affects 3% of children with cerebral palsy who were born moderately preterm and 2% of those who were moderately low birthweight (Andersen et al. 2011). The prevalence of sensorineural hearing impairment increases with increasing severity of cerebral palsy (Baird et al. 2011; Reid et al. 2011) and affects up to 6% of children with dyskinetic forms (Himmelman et al. 2009).

**Hyperbilirubinaemia**

The auditory pathways are especially vulnerable to bilirubin toxicity, which impairs mitochondrial function and viability of astrocytes, and promotes neuronal apoptosis. There may be preservation of cochlear microphonics with abnormalities of the ABRs because bilirubin does not appear to be as toxic to the inner and outer hair cells of the cochlea, although it affects the cell bodies of the auditory nerve in the spiral ganglia and the auditory brainstem nuclei, inferior colliculus and superior olivary complex (Shapiro 2005). There is no clear interrelationship of the level of clinical and biochemical jaundice and the underlying aetiology or the findings on the ABRs in the early stages after kernicterus, and the long-term prognosis (Yilmaz et al. 2001). Therefore, any child who has been exposed to toxic levels of bilirubin merits a comprehensive audiological assessment, with particular care to assess both cochlear and auditory nerve function.

**POSTNATAL ACQUIRED HEARING IMPAIRMENT**

**Meningitis and CNS Infection**

Meningitis is the most frequent cause of acquired sensorineural hearing loss in childhood (Watkin 2012). The risk of this sequela is increased with the development of hydrocephalus and/or if the child is aged <1 month or >5 years and the CSF glucose concentration is <2.2mmol/L. Additional risk factors that increase the likelihood of a hearing loss after non-haemophilus bacterial meningitis include duration of symptoms before admission of >2 days, absence of petechiae, CSF glucose level <0.6mmol/L, a *Streptococcus pneumoniae* infection and ataxia (Koomen et al. 2003). Most commonly there is either a completely flat audiogram or a predominantly high-frequency hearing loss. Brainstem auditory-evoked potentials (BAEPs) from 101 children with bacterial or aseptic meningitis showed a frequency of BAEP impairment of 35% among those with bacterial meningitis, with 31% experiencing hearing loss on discharge, compared with rates of 21% and 14%, respectively, for aseptic meningitis. Most of the BAEP impairment in the bacterial meningitis cases was associated with *Haemophilus influenzae* infection. Follow-up in this situation with BAEPs is necessary for those children with initially abnormal findings as a small number return to normal and some deteriorate further (Bao and Wong 1998).
Since the introduction of the *H. influenzae* type b (Hib) vaccine, *S. pneumoniae* has emerged as a dominant causative organism of bacterial meningitis in children, and 14% of 79 children with confirmed bacterial meningitis in one clinical series experienced permanent sensorineural hearing loss after confirmed bacterial meningitis (Wellman et al. 2003). Routine inpatient audiological screening of postmeningitic children has been advocated in order to avoid compliance problems with outpatient audiological assessment. High-frequency hearing loss has been described after Epstein–Barr virus infection, and sensorineural hearing loss is an important complication of mumps, with mumps meningoencephalitis increasing this risk (Kanra et al. 2002).

**Ototoxicity: Drug-Induced Hearing Loss**

A wide range of drugs is associated with ototoxicity, including antimalarial drugs such as quinine and chloroquine, non-steroidal anti-inflammatories including salicylate and indometacin, loop diuretics including furosemide, chelating agents such as desferrioxamine, and antibiotics including the aminoglycosides and other antimicrobial agents such as chloramphenicol, colistin, erythromycin, minocycline, polymyxin B and vancomycin; these are reviewed by Schacht and Hawkins (2006).

Aminoglycoside ototoxicity occurs sporadically but also within families in association with a mitochondrial DNA (mtDNA) 155A–G point mutation in the 12S ribosomal RNA gene. Transmission of the same predisposing mutation can render individuals susceptible to sensorineural hearing loss after treatment with streptomycin (Fischel-Ghodsian et al. 1997; Gardner et al. 1997). Aminoglycosides can affect the vestibular system or result in destruction of hair cells in the organ of Corti, depending on the type of aminoglycoside.

Ototoxicity to the cochlear or vestibular system can also follow the application of ototopic antibiotic eardrops (Matz et al. 2004).

**Hearing Impairment Associated with Haematological and Immunological Disorders**

The prevalence of sensorineural hearing loss is raised in sickle cell disease (Mgbor and Emodi 2004).

High-frequency hearing loss and middle-ear conductive loss have been described in leukaemia and thalassaemia. The thiamine-responsive megaloblastic anaemia, also known as Rogers syndrome, is an early onset, autosomal recessive disorder defined by the occurrence of megaloblastic anaemia, diabetes mellitus and sensorineural deafness (Neufeld et al. 1997).

There are reports of a possible autoimmune-related sensorineural hearing loss, and examination of the erythrocyte sedimentation rate and immunoglobulins with their subclasses, complement studies and autoantibodies may be informative (Bamiou et al. 2000a).

**Ototoxicity from Antineoplastic Chemotherapy and Radiotherapy**

Children treated for megaloblastoma, osteosarcoma and neuroblastoma have a greater incidence and severity of hearing loss as a sequela of treatment. Bilateral decreases in hearing were seen in 61% of 67 patients studied by Knight et al. (2005), and their median time to hearing loss was 135 days. The platinum compounds cisplatin and carboplatin are essential components in the chemotherapeutic treatment of a variety of paediatric malignancies. However, platinum agents have adverse effects including ototoxicity and associated permanent hearing loss. This is manifested as bilateral, high-frequency, sensorineural hearing loss and, with continued administration and cumulative dose, the hearing loss tends to increase in severity and progressively spreads to affect hearing at lower frequencies. Hearing loss can also progress after the completion of treatment and this has been reported in 15–20% of patients. Prior or concurrent craniospinal radiation enhances the ototoxicity of cisplatin. Young age at the time of treatment also increases a child’s risk for ototoxicity (Knight et al. 2005). In addition to these agents, aminoglycosides and irradiation can adversely affect high-frequency hearing. A progressive hearing loss can occur after stereotactic radiation treatment in the management of posterior fossa tumours (Jackson et al. 2000).

**Neurofibromatosis**

Neurofibromatosis type 2 can give rise to a vestibular schwannoma which commonly presents with deafness and is sometimes associated with tinnitus, a facial nerve paralysis or headache. Vestibular schwannomas may be bilateral, and a few selected patients may benefit from auditory brainstem implants. Hearing loss can also occur in neurofibromatosis type 1 (Samii et al. 1997; Cunningham et al. 2005).

**Post-traumatic Hearing Loss**

Falls and blows to the head that result in temporal bone fracture can result in hearing loss in >80% of patients. Post-traumatic hearing loss may be related to a post-traumatic perilymphatic fistula, whereas minor head trauma may be associated with a progressive sensorineural hearing loss in the presence of a dilated vestibular aqueduct (Fig. 23.2) (Gopen et al. 2011).

**CONDUCTIVE HEARING LOSS**

**Otitis Media with Effusion**

Otitis media with effusion (OME) affects 10–30% of 1–3-year-olds, and by the age of 4 years the cumulative incidence is 80%. By definition, OME involves a middle-ear effusion without signs or symptoms of an acute infection and it is a sequel to acute otitis media. It can result in a conductive hearing loss.
of around 25–30dB. Children with positive single tests need to begin a period of observation, because it seems that only long-term OME requires treatment (Burler and MacMillan 2001). Therapies offered for OME include decongestants, mucolytics, steroids, antihistamines and antibiotics, and myringotomy as the surgical treatment. A Cochrane Review of treatment efficacy for children who were otherwise typically developing showed that the benefits of grommets was small (Lous et al. 2005). There is also a risk of tympanosclerosis from surgical procedures. A large trial (Paradise et al. 2005) followed children prospectively from the age of 2 months, and then assigned those who had persistent middle-ear effusion before age 3 years on a random basis to the insertion of tympanostomy tubes. There was no significant difference at the age of 6 years in the outcome measures of intelligence, language skills, central auditory processing, behaviour and emotion. Measures of intellectual and language ability at the age of 6 are strongly predictive of later academic performance, so the authors concluded that it was unlikely that these children would develop later developmental difficulties. Lous et al. (2005), however, stressed that clinicians need to make decisions about treatment for children who have speech and language delays, behavioural and learning problems, or defined clinical syndromes on an individual basis because such children have been excluded from the primary studies looking at the effectiveness of treatment of OME.

Conductive Hearing Loss Associated with Skeletal Dysplasias

Many different forms of skeletal dysplasia have a conductive hearing loss component (Hilhorst-Hofstee et al. 1997; van den Ende et al. 1998; Brown et al. 2003; De Leenheer et al. 2003; Imani et al. 2003; Vanhoenacker et al. 2003; Visosky et al. 2003; Daneshi et al. 2005; Weekamp et al. 2005). Associated features are variable. The reader is referred to references in Table 23.1 for details.

Although these conditions are rare, it is important to appreciate that the diagnosis may be missed in females who have very mild craniofacial anomalies and whose deafness may be mistakenly attributed to an isolated ossicular deformity (Robertson et al. 1997).

Fanconi Anaemia

Many morphological anomalies affecting the structures of the ear, head and neck are reported in Fanconi anaemia, although they are present in only a minority of patients.
Conductive hearing loss, external auditory canal stenosis and auricular malformation have been described (Santos et al. 2002).

Auditory Neuropathy

The term ‘auditory neuropathy’ describes functional disturbance or pathological change in the peripheral nervous system, although in this situation the exact site of a lesion is not known. Auditory neuropathy is a sensorineural disorder characterised by absent or abnormal auditory evoked potentials and normal cochlear outer-hair-cell function. In auditory neuropathy children show repeatable cochlear microphonic potentials in the absence of click-evoked ABRs. Although the audiometric findings for some children with auditory neuropathy vary significantly, thresholds on behavioural testing range from normal to profound levels. Speech discrimination skills are also very variable, and in one series (Rance et al. 1999) half of the participants showed little understanding or even awareness of speech inputs in both unaided and aided conditions. However, some children who score at significantly impaired levels on a speech discrimination task may benefit from the provision of amplification (Dowley et al. 2009; Breneman et al. 2012). Auditory neuropathy can follow a compromised neonatal course (Madden et al. 2002), particularly in the presence of neonatal hyperbilirubinaemia, and it can also be seen in children who have a family history of childhood hearing loss (Joint Committee on Infant Hearing 2000). Auditory neuropathy can be associated with a loss of myelin. The pathophysiological changes in neural conduction properties associated with demyelination are likely to have a profound effect on auditory evoked responses because they depend on the relatively precise synchronous response of a population of auditory nerve fibres to a transient acoustic stimulus. Auditory neuropathy has been described in Charcot–Marie–Tooth disease type 1 and in adrenoleukodystrophy.

MANAGEMENT OF SENSORINEURAL HEARING IMPAIRMENT

Permanent childhood hearing impairment can have a devastating impact on communication skills, educational attainments and quality of life, with a resultant high cost to society. Outcomes are improved for children with congenital impairments if they are diagnosed and intervention starts by age 6 months (Fortnum et al. 2001; Kennedy et al. 2006; Pimper ton and Kennedy 2012). Families should expect choice and confidentiality, and communication in their native language, which should include the following: information about childhood hearing loss, the prevalence and effects of early hearing loss, the potential benefits and risks of screening and evaluation procedures, and prognosis and intervention. Hearing aid fitting may be indicated to give the child access to amplified speech. Cochlear implantation for profoundly deaf children continues to be offered at an earlier age of identification. Optimal benefit is seen from early implantation and children are implanted at earlier and earlier ages, dependent on the security of the diagnosis of permanent deafness and technical, surgical and anaesthetic considerations (Sampaio et al. 2011). Children’s additional disabilities are no longer seen as a contraindication to implantation; rather it is their ability to be ‘mapped’ with the implant, that is, their ability to be conditioned to signal a response with the hearing stimuli, that is important. Health, social services and education agencies all need to be associated with early intervention for the child.

The views and interests of individuals who are affected with deafness must be considered when developing policies with regard to the appropriate use of genetic testing and counselling for families who carry the genes associated with hearing loss. The Joint Committee on Infant Hearing (2000) suggested benchmarks and quality indicators of service with comprehensive coordinated services of the infant’s home, family, related professionals with expertise in hearing loss, and state and global agencies responsible for provision.
of services to children with hearing loss. Infants referred from universal neonatal hearing screening should have audiological and medical evaluations before the age of 3 months. Infants who are at risk of progressive or delayed-onset sensorineural hearing loss or conductive hearing loss should have audiological monitoring every 6 months until the age of 3 years. Early intervention services need to be designed to meet the individualised needs of the infant and the family, and to address the child’s acquisition of communication with competent social skills, emotional well-being and positive self-esteem. Communication support planning needs to consider both a visual language and other sign systems, as well as auditory oral communication.

HEARING AIDS

The successful rehabilitation of the deaf child using hearing aids depends on careful assessment of hearing in all frequencies, individualised hearing aid prescription, and attentive follow-up and educational support. The primary aim is to make speech accessible for the child and, if insufficient care is taken in matching the aid to the child’s needs, the aid will be rejected. Hearing aid technology advances rapidly but it cannot as yet completely compensate for the damaged human ear. This is because the mammalian cochlear outer-hair-cell system is a biologically active process that amplifies in a highly frequency-selective manner and with almost instantaneous response (Dallos 1992). The following are two reasons why an impaired ear cannot have its narrow tuning restored by a hearing aid: (1) because the outer-hair-cell system responsible for the tuning is compromised, and (2) because hearing aids must amplify gain to input signals, and therefore stimulate the cochlea at moderate and high levels where tuning is no longer narrow, even in a normal ear. This means that even the narrower span compression system will still produce broader than normal excitation in an impaired ear.

Digital hearing aids have superseded analogue aids because they are able to take a signal from a microphone and convert it into numerical data, which can then be manipulated by a computer within the hearing aid to give a tailored match of the aid to the hearing loss of the child. They can be worn behind the ear or within the ear canal or on the body. There are also bone-conduction hearing aids for people with conductive hearing loss or who cannot wear a conventional hearing aid, where the sound is delivered through the skull by vibration (Trine and Van Tasell 2002).

INDUCTION LOOP AND INFRARED SYSTEMS

The loop system helps deaf people who use a hearing aid or loop listener to hear sound more clearly, by reducing or cutting out background noise. Anyone sitting in an area of loop can pick up the sound if they switch their hearing aid or loop listening aid to the T setting. Electrical equipment and wiring can cause interference. As an alternative, an infrared system can be fitted; infrared receivers are not usually prone to interference, unless they are in direct sunlight.

RADIO-MICROPHONE SYSTEMS

These systems are designed for use in classrooms or similar settings and they can help deaf learners hear the teacher or lecturer from a distance. Learners will need to be wearing hearing aids to benefit from them, and some systems also work with cochlear implants. The lecturer wears a clip-on microphone and the deaf learner wears the receiver. There is no evidence to support the use of radio-microphone systems for children with central auditory processing disorders.

SOUNDFIELD SYSTEMS

A soundfield system amplifies the teacher’s voice at a low level and distributes it around the room from speakers mounted above head height. Deaf learners seated anywhere in the room will be able to hear equally well.

COCHLEAR IMPLANTATION

In cochlear implantation the sensory organ of the ear is replaced by an implantable electronic prosthesis. This cochlear implant stimulates the auditory nerve by electrical pulses and thus generates the sensation of hearing along the auditory pathway. In cochlear implants, the electrical signal provided by the device bypasses the portion of the auditory pathway linked to internal hair cells and the synapse to the auditory nerve fibre, and stimulates the spiral ganglion cells directly. Cochlear implants in prelingually deaf children permit improved development of speech reception, language acquisition and reading comprehension (Rubinstein 2002; Francis and Niparko 2003; Ramsden 2004).

Cochlear implantation is an effective intervention for the acquisition of speech perception and verbal language for children with severe-to-profound hearing impairment (Francis and Niparko 2003; Ramsden 2004). Early identification of the hearing loss, early hearing aid use, and language intervention and cochlear implantation by 2 years of age are positive predictors for language acquisition, which can even approach the levels of normal hearing children. Although implantation of children under age 2 years is potentially associated with higher surgical and anaesthetic risk, many results have been very positive (Rubinstein 2002). A late age of implantation does not preclude beneficial development of vocabulary (El-Hakim et al. 2001). Variations in the temporal bone anatomy in some patients such as those with the CHARGE association can give increased technical challenges and an increased risk to the facial nerve during cochlear implantation. Cochlear implantation in children with inner ear malformations...
can give rise to complications such as CSF leak, but can be a successful method of rehabilitation (Woolley et al. 1998). Children who have their hearing loss identified by the age of 6 months have been demonstrated to have significantly better language scores than children identified after this period (Yoshinaga-Itano et al. 1998; Kennedy et al. 2006; McCann et al. 2009).

**PROGNOSIS OF HEARING IMPAIRMENT**

Studies from animal models and patterns of infant language acquisition suggest that early intervention with aiding is important in hearing impairment. However, the literature also suggests that there are other important factors that influence prognosis. A report from a geographical cohort of intellectually normal children, who had undergone neonatal screening for high-risk infants, revealed outcomes were related to the severity of the hearing impairment and the non-verbal IQ rather than the age of diagnosis (Wake et al. 2005).

It is important to consider that up to 40% of children with a confirmed hearing loss have developmental delays or other disabilities. These need to be taken into account in the evaluation of a child who is failing to show the development of speech production that might be otherwise expected after successful aiding. Speech perception abilities of both cochlear implant and hearing aid users suggest that the performance of an average implant user is similar to that of a hearing aid user with a hearing loss of 70–90dB. Cochlear implantation in infants between the ages of 6 and 18 months can give a good outcome, with prelexical babbling correlating significantly with the age of implantation (Schauwers et al. 2004). Speech and language proficiency is greater for children who had exhibited normal hearing for even a short period after birth and who received their cochlear implant shortly after losing their hearing (Geers 2004). Improvements in speech can continue over many years; 6 years after cochlear implantation, a child’s speech acquisition process is incomplete and there is no evidence of a plateau in performance, with the mean number of intelligible words per utterance increasing from 0.15 to 4.2. In children exposed to aural/oral communication rehabilitation, the age at implantation is an important variable affecting the level of speech production achieved by prelinguistically deaf cochlear implant users. The percentage of intelligible syllables shows a dramatic improvement in intelligibility in the first 3 years after implantation (Blamey et al. 2001). As children with additional disabilities are increasingly admitted to cochlear implantation programmes, there is an increasing challenge to truly capture outcome in the sense of a meaningful improvement in their quality of life because some children may not develop oral communication with speech as a result of their additional impairments (Rafferty et al. 2011). The International Classification of Functioning, Disability and Health (ICF) framework should include understanding outcome in terms of activities and participation in components such as listening and conversing within groups of people (Danermark et al. 2010).

**CENTRAL AUDITORY PROCESSING DISORDERS**

Central auditory processing disorder (CAPD) is an inability or impaired ability to attend to, discriminate, recognise, remember or comprehend information presented through the auditory channels, even though the person has normal intelligence and hearing sensitivity (Keith and Pensak 1991). Functionally, a child with CAPD shows a range of difficulties with the following: the localisation of sound; binaural synthesis, in that stimuli presented simultaneously or alternately to opposite ears are incompletely perceived; and figure ground difficulties in which a primary signal or message is difficult for the child to perceive in the presence of competing sounds. In addition there are problems with binaural separation, memory for auditory stimuli, forming words out of separately articulated phonemes, discriminating two acoustic stimuli, perceiving whole words or messages when parts are omitted, showing listening attention over a reasonable period of time, associating correspondence between a non-linguistic sound and its source, and establishing a correspondence between the linguistic sound and the meaning.

Children with CAPDs show behavioural symptoms with the following: inconsistent responses to auditory stimuli; requests that information be repeated; poor auditory attention; difficulty listening if there is background noise; easy distractibility; problems with phonics and discrimination of speech sounds; poor auditory memory; and poor development of spoken and written language skills (Gordon and Ward 1995).

CAPDs would arise from situations in which information from the cochlear nucleus in the brainstem is affected when relaying to the auditory cortex or subsequently when handled by the cortical and subcortical auditory areas so that audition can be fully appreciated and interpreted. Two main areas of controversy in the concept of CAPDs relate to how best to assess the symptomatology and avoid misinterpretation when, for instance, the primary reason for the child’s presentation lies with an intellectual or attentional deficit (Howard et al. 2010; Moore et al. 2010), and how best to objectively measure the degree of processing dysfunction. This is exemplified by work comparing measures of listening and cognition between children with dyslexia and those diagnosed with an auditory processing disorder through audiology departments, in which there were insufficient differences to assign the children to these diagnostic groupings, and features from either group suggested that some children had social communication and interactional difficulties implying that they should be assessed for autistic spectrum disorders (Dawes and Bishop 2009). Also, children may have a common aetiology, such as hypoxic damage, that has resulted in impairment to the auditory nuclei, brainstem and cerebral
Vestibular Testing

Vestibular function testing can be a useful adjunct to audiometric evaluation, even in infants and young children, provided that the testing environment is rendered appropriate (Phillips and Backous 2002). Study of optokinetic and caloric nystagmus can be informative in children presenting with acute vertigo, and significant vestibular hyperreflexia can be demonstrated some time after disease onset (D’Agostino et al. 1999). Young children with idiopathic spontaneous recurrent episodes of vertigo should have an audiogram in addition to vestibular testing (Brantberg et al. 2012).

Electro- and video-nystagmography reveal spontaneous vestibular nystagmus and benign paroxysmal positional nystagmus in children with episodic vertigo. The former is considered to be a sign of a vestibulopathy and the latter is associated with benign paroxysmal positional vertigo. In a series of 34 children aged 4–18 years with episodic vertigo four had bilateral sensorineural hearing loss in low frequencies; in addition, unilateral caloric responses were diminished in eight children (Uneri and Turkdogan 2003). Benign paroxysmal positional vertigo (BPPV) is a labyrinthopathy that results in postural imbalance and brief episodes of vertigo precipitated by specific movements. The symptoms can be secondary to shifting of otoloids in the semicircular canal and, although it is rare in children, it should be recognised because it may be demonstrated only by a particular diagnostic test such as the Dix–Hallpike manoeuvre, which is a diagnostic test for posterior semicircular canal BPPV. Liberating manoeuvres may lead to the mass being removable through the non-ampullary hemicanal (Marcelli et al. 2006).

Patients who have experienced vestibular symptoms associated with migraine headache in so-called vestibular migraine frequently have abnormal caloric test responses, especially with a directional preponderance, and often have spontaneous nystagmus. The hypothesis is that the patients are considered to have have hypersensitivity of the labyrinth, presenting with nausea and vomiting, and in the headache-free period the electronystagmography is almost normal (Szirmai 1997). The function of the inferior vestibular nerve and oto-lithic function can be assessed by measuring the vestibular evoked myogenic potentials in the healthy newborn infant (Young et al. 2009), but the measure is technically challenging (Shinjo et al. 2007) and there is limited experience in the preterm or unwell infant.

Peripheral Vestibular Dysfunction

Peripheral vestibular problems in childhood present with a wide spectrum of symptoms, varying from a short episode of dizziness to a typical vestibular attack with vertigo and its sensation of rotation, accompanied by nausea and vomiting (Choung et al. 2003). Symptoms may be precipitated or increased by a changing position of the head or rapid movement. The presentation may require very careful delineation because it can be difficult for young children to describe the subjective phenomena of tinnitus that they might experience in Ménière disease (Miyahara et al. 2009; Brantberg et al. 2012), and sometimes there are particularly unusual symptoms such as vertigo and disequilibrium induced by sound. The latter can occur in dehiscences of the superior semicircular canal, confirmed with CT of the temporal bones, and surgical resolution can be beneficial (Minor et al. 1998). Weisleder and Fife (2001) reported the outcome for a series of children referred for vestibular testing after a presentation with a combination of dizziness and headache, with other symptoms including episodes of loss of consciousness, poor balance and
blurred vision. The most common abnormal test outcome was a unilateral vestibular dysfunction, followed by bilateral peripheral vestibular dysfunction. Central vestibular dysfunction was seen in only one of the 31 children. Final diagnoses included vestibular migraine, benign paroxysmal vertigo of childhood, anxiety attacks, Menière disease in two children, and one patient with idiopathic sudden-onset sensorineural hearing loss and one with familial vertigo–ataxia syndrome; in a small number of patients no definitive diagnosis was established. Unilateral vestibular hyporeflexia is not exceptional in the child referred for vestibular testing. A considerable number of these vestibular problems might be related to migraine syndromes (Uneri and Türköğlu 2003). Also, children who complain of vertigo or dizziness, but have normal clinical neurological and vestibular examination, should have a complete ophthalmological examination (Anoh-Tanon et al. 2000). Vertigo can be caused by a perilymphatic fistula, with a good outcome after surgery (Weber et al. 2003).

As the cochlear and vestibular organs are closely related anatomically and developmentally, vestibular function may be impaired in sensorineural hearing impairment, particularly that after bacterial meningitis, and can be temporarily disturbed in around 20% of individuals after cochlear implantation (Vibert et al. 2001).

Toxic Causes
Many drugs that have the potential to affect auditory function, such as the aminoglycosides, can also have an adverse effect on vestibular function. Antibiotics can produce disturbance in the labyrinth, and the vestibule is particularly vulnerable to toxicity from streptomycin. Vestibular dysfunction can also follow the use of anticonvulsant medication such as phenytoin.

ACUTE LABYRINTHITIS
The differential diagnosis of vertigo in children is extensive, and otitis media and middle-ear effusion may be the most common cause with the development of an acute serous labyrinthitis (Tarlow 1998; Goldstein et al. 2000).

Acute labyrinthitis is also an important sequela of acute bacterial meningitis. Infection spreads from the meninges via the cochlear to the inner ear and can result in serous labyrinthitis or suppurative labyrinthitis. Sensorineural hearing loss may result from damage to the cochlea but in some patients spiral ganglion cells in the retrocochlear region are severely degenerated (Merchant and Gopen 1990).

Acute labyrinthitis can also be virally mediated, and particularly in preschool children can result in episodes in which they are rendered suddenly atactic in the context of a self-limiting illness that lasts no more than a few days.

Labyrinthitis can occur in association with acoustic schwannoma (Held 1998; Tan and Teh 1998).

MIGRANE EQUIVALENTS
Paroxysmal vertigo is discussed in Chapter 21. Vertigo and headache occur in vestibular migraine and benign paroxysmal vertigo (Weisleder and Fife 2001).

EPILEPSY AND VERTIGO
Rotational vestibular epilepsy has been described arising from a focus in the temporoparieto-occipital junction (Altay et al. 2005). A more detailed description of related seizure semiology can be found in Chapter 16.

VESTIBULAR NEURONITIS
Infection with Borrelia sp. in Lyme disease is a very rare cause of sudden-onset sensorineural hearing loss and vestibular neuronitis (Walthier et al. 2003; Ergul et al. 2006). Vestibular neuronitis results in acute episodes of severe vertigo with complete loss of unilateral caloric response. There may be complete recovery of the function of the affected vestibular nerve, or a partial recovery, or indeed no recovery of the affected vestibular nerve but CNS compensation for the vestibular imbalance.

MÉNIÈRE DISEASE
Ménière disease is a disease of the inner ear, characterised by a triad of presentations with vestibular symptoms, auditory symptoms and pressure. The pathophysiology of the symptoms is disputed but an endolymphatic hydrops is described and may involve a deficiency in the absorption of endolymph. Typically it is a disease of adults (Da Costa et al. 2002), although it has been described in children (Rodgers and Telischi 1997; Choung et al. 2003). Ménière disease was the aetiology of vertigo in 2.9% of children, and they may describe tinnitus (Akagi et al. 2001).

POST-TRAUMATIC VERTIGO
Acute vertigo may follow trauma to the labyrinth and may go on to take a chronic or fluctuating course. Vestibular symptoms with disequilibrium have been described in 50% of patients who sustained otological injuries after inflation of airbags used to mitigate against injury severity in road traffic accidents (McFeely et al. 1999). Hearing loss can also fluctuate and be progressive, or even suddenly deteriorate after a head injury, but its relationship to the common finding of enlargement of the vestibular aqueduct and endolymphatic sac (reported in 5–15% of children with permanent childhood hearing impairment) remains unclear (Gopen et al. 2011).

BASILAR ARTERY DISEASE
The sacculococullic reflex is a descending pathway that traverses the territory of the basilar artery and can, therefore, be
implicated in basilar artery migraine and basilar artery cerebrovascular disease. Vestibular evoked myogenic potentials indicate reversible ischaemia in the territory of the basilar artery, and patients may show abnormal eye tracking tests on electroneystagmography, with abnormal optokinetic nystagmus testing and abnormalities of caloric testing (Liao and Young 2004).

Diseases of the Motor Neuron

Mariacristina Scoto and Francesco Muntoni

Motor neuron diseases are neurological disorders characterised primarily by the degeneration of spinal motor neurons, skeletal muscle atrophy and weakness, as well as debilitating course with often fatal motor dysfunction. Motor neuron diseases can occur at different ages from infancy to adulthood, are genetically heterogeneous and follow very diverse disease courses from a fatal course in infancy to conditions compatible with normal survival into adulthood. The spinal muscular atrophies (SMAs), originally described in the early 1890s by Werdnig and Hoffman, comprise a group of autosomal-recessive disorders characterised by progressive degeneration of the lower motor neurons. Since their first description several SMA types have been described based on age at onset and predominant clinical features with the most common types acute infantile (SMA type 1, or Werdnig-Hoffman disease), chronic infantile (SMA type 2), chronic juvenile (SMA type 3 or Kugelberg-Welander disease), and the less prevalent adult onset (SMA type 4) forms. The genetic defect associated with these SMA variants is localised on chromosome 5q and due to homozygous deletions or mutations involving the survival motor neuron SMN1 gene. Neighbouring SMN2 gene(s) can in part compensate for the absence of SMN1 genes and there is a correlation between the SMN2 copy number and the severity of the disease, as will be discussed below. Optimal standards of care have been proposed and have improved significantly the outcome of types 2 and 3 SMA and are also shifting survival in SMA type 1.

There are other inherited motor neuron disorders not caused by mutation of the SMN1 gene and these, often referred to as non-5q SMA, can also present with early denervation weakness but different clinical symptoms from classic chromosome 5q-linked SMA. In this chapter we will review the most common forms of SMA focusing on their diagnosis, treatment and management issues, the effect of optimal standards of care on survival and the most recent experimental therapeutic approaches.

CHROMOSOME 5-PROXIMAL SPINAL MUSCULAR ATROPHY

The term spinal muscular atrophy refers to a group of genetic conditions characterised by degeneration of the anterior horn motor cells and resulting in muscle atrophy and weakness.

The most common SMA is caused by mutations of the Survival Motor Neuron 1 gene (SMN1) on chromosome 5 (5q11.2-13.3) (Brzustowicz et al. 1990; Melki et al. 1990; Lefebvre et al. 1995) This type of SMA was originally described in 1891 in two infant brothers with onset of weakness at around 10 months by Guido Werdnig (Werdnig 1891), followed by seven more individuals described by Johan Hoffman between 1893 and 1900 (Hoffmann 1893, 1897, 1900) while a milder form of the disease in which patients could achieve the ability to walk was described in 1956 by Kugelberg and Welander (Kugelberg and Welander 1956). All these descriptions had a common pathology characterised by anterior horn cell degeneration leading to specific clinical features characterised by symmetrical muscle weakness (proximal more than distal) of the limbs (lower limbs more than upper limbs) together with axial, bulbar and intercostal weakness. The multiple phenotypes were eventually formalised into a classification scheme at an International Consortium on Spinal Muscular Atrophy sponsored by the Muscular Dystrophy Association in 1991. This classification highlighted three SMA types based on the highest level of motor function (i.e. sitting or standing) and age at onset. Subsequent modifications divided the type 3 category by age at onset, adding a type 4 for adult-onset cases and including a type 0 for patients with prenatal onset and death within weeks (Table 24.1) (Munsat and Davies 1992).

SMA TYPE 1 (SEVERE, INFANTILE OR WERDNIG-HOFFMAN DISEASE)

Patients with SMA type 1 present between birth and 6 months of age with progressive muscular weakness affecting the lower limbs more than the upper limbs, poor head control and hypotonia as showed by the typical ‘frog-leg’ posture assumed when lying supine, as well as the ‘slip through’ on vertical suspension. There is also weakness in the intercostal muscles with relative sparing of the diaphragm clinically evident.
in the ‘bell-shaped’ chest and paradoxical breathing pattern. Patients also have tongue fasciculations and eventually show bulbar weakness with difficulty swallowing, risk of aspiration and failure to thrive. There is no involvement of other cranial nerves, however facial weakness can develop during the late stage of the disease, while tendon reflexes are invariably absent. Cognition is typically normal and infants often have a bright and alert expression that contrasts with the general weakness. Within SMA type 1 at least three clinical subgroups can be defined according to the severity of clinical signs:

1a Severe weakness since birth/neonatal period, head control never achieved;
1b Onset of weakness after the neonatal period but generally within 2 months with head control never achieved;
1c Onset of weakness after the neonatal period but head control achieved. A small proportion of children with SMA1c may be able to sit with support indicating a blurred boundary between type 1 and type 2 SMA, which was also highlighted in previous articles in which a decimal classification was proposed (Dubowitz 1995a; Bertini et al. 2005).

SMA type 1 is a very severe condition in which the affected infants are at risk of severe chest infections with acute respiratory failure and usually die before the second year of age (Dubowitz 1995b; Darras 1997) although there has been increase in survival with using assisted ventilation and feeding support (Zerres and Thomas and Dubowitz 1994; Davies 1999; Oskoui et al. 2007). Noninvasive ventilation can be used at a very young age, as early as the neonatal period, because interfaces are now available for small infants (Simonds 2007). Bilevel positive airway pressure ventilation can be provided at home with a face mask enabling the introduction of noninvasive ventilation while the infant is still in relatively good health. As weakness progresses the requirement for ventilation typically increases and the decision to proceed to tracheostomy with long-term invasive ventilation becomes an individual choice for the family of the child (van der Pol et al. 2013). Ideally the palliative care team should meet the family soon after diagnosis to help them understand the difference between prolonging life and improving quality of life in accordance with the severity of the condition of the child and family choice for intervention at every step of the management. Decreased feeding followed by failure to thrive is often the first manifestation of progressive weakness and in a vicious circle poorly nourished children become fatigued and more susceptible to respiratory infections: early gastrostomy is often recommended to improve the quality of life.

It has been reported in the literature that some patients with SMA type 1 can have heart defects, mostly atrial and ventricular septal defects as well as possible involvement of the autonomic system which might cause arrhythmia and sudden death (Rudnik-Schoneborn et al. 2008; Shababi et al. 2010).

A large retrospective study of long-term ventilated SMA type 1 patients demonstrated that 15 of 63 patients experienced severe, symptomatic bradycardia (Bach et al. 2007) while a series of autonomic tests on SMA type 1 patients revealed a sympathetic-vagal imbalance, fluctuation of blood pressure and irregular skin responses to temperature changes (Hachiya et al. 2005). Additionally, vascular abnormalities such as distal digit necrosis have been occasionally reported in SMA type 1 patients, also associated with atrial septal defect and asymmetrical left ventricular hypertrophy (Araujo et al. 2009; Rudnik-Schoneborn et al. 2010) while other studies have also highlighted brain involvement, with thalamic lesions (Ito et al. 2004) and sensory nerve involvement (Rudnik-Schoneborn et al. 2003).

While the muscle weakness that dominates the clinical presentation of SMA type 1 clearly plays the largest role in determining the condition morbidity, the full contribution of other organs to the disease manifestation and progression is still a matter of debate both in the human and in animal models.

Recently decreased vascular density was reported in skeletal muscle of both the SMA mouse model and in children with SMA type 1 (Somers et al. 2016).

**SMA TYPE 2 (INTERMEDIATE, sometimes referred to as DUBOWITZ DISEASE)**

Patients with SMA type 2 usually present between the age of 7 and 18 months as they acquire the ability to sit unsupported but are unable to walk. Some of these children may benefit from support of assistive devices for standing and even walking.

These patients have marked proximal weakness affecting the lower limbs more than the upper limbs, muscle hypotonia and areflexia. An almost invariable complication due to the axial muscle weakness is progressive scoliosis with increasing pelvic obliquity and seating instability that in combination with intercostal weakness leads to reduced lung function (Fujak et al. 2005, 2007, 2010a, 2010b, 2011). These children also develop contractures in the lower and upper extremities while very often a subtle hand tremor and increase in palm sweating are present, which can aid in diagnosing the condition.

Cognitive function is well preserved and the overall experience in clinical practice is that infants with SMA type 2 have an early speech development in comparison to their normally developing peers (von Gontard et al. 2002).

The progress can vary greatly and life expectancy is somewhat reduced as a result of the risk of respiratory compromise (Zerres and Rudnik-Schoneborn 1995; Crawford 2003) but most SMA type 2 patients live well into adulthood and a study published in 1997 on 240 Type 2 patients reported a survival rate of 95% at 5 years and 68.5% at 25 years (Zerres et al. 1997).

Respiratory complications in type 2 patients are less severe than in type 1. For the respiratory assessment physical examination and assessment of cough effectiveness with respiratory muscle function tests should be routinely undertaken as indicated in the standard of care guidelines (Somers et al. 2016). Forced vital capacity should be measured in children older than 5 years while in younger patients regular sleep studies can be offered. Overnight oximetry should be regularly undertaken, especially in patients with severely reduced vital capacity (<65% predicted) or with clinical signs of nocturnal hypoventilation that should be treated with non-invasive ventilation (Markstrom et al. 2010).

**SMA TYPE 3 (MILD OR KUGELBERG-WELANDER DISEASE)**

Patients with SMA type 3 are able to stand alone and walk at some point of their motor development. Symptoms of muscle weakness usually appear after 18 months of age but this is very variable and sometimes symptoms may not appear until late childhood. From a clinical standpoint these children have progressive symmetrical and proximal weakness affecting the legs more than the arms and can present with hand tremor.

SMA type 3 is subdivided into SMA type 3a with disease onset before three years of age and the milder form SMA type 3b with an onset after the age of 3 years. Patients with SMA type 3 have a normal life expectancy (Munsat and Davies 1992; Zerres and Rudnik-Schoneborn 1995).

While by definition all these patients acquire independent ambulation, there is often progression of difficulties and patients with SMA type 3a often lose the ability to walk, typically during major growth spurts such as puberty: it has been reported that about half of patients with SMA type 3 will lose independent ambulation by age 14 years (Russman et al. 1996; Rudnik-Schoneborn et al. 2001). These patients then need wheelchairs and may develop scoliosis, obesity and other complications related to lack of mobility (D’Amico et al. 2011; Kaufmann et al. 2012).

**SMA TYPE 4 (ADULT-ONSET)**

SMA type 4 is a less common form that begins in adulthood (>18 years) with symptoms that are usually mild to moderate and include proximal muscle weakness, difficulty walking, muscle tremor and twitching: life expectancy is not affected (Zerres and Rudnik-Schoneborn 1995). This group includes patients able to walk in adulthood and without respiratory and nutritional problems.

**GENETICS OF 5-PROXIMAL SMAs**

SMA is one of the most common genetic disorders with an incidence of one in 6000–11000 live births and a carrier frequency of about one out of 50 (estimated at from 1:38 to 1:70 depending on ethnic group) (Pearn 1978; Ogino et al. 2002, 2004; Sugarman et al. 2012). SMA is inherited as an autosomal recessive condition and in particular by the homozygous mutations of the SMN1 gene. The diagnostic test demonstrates the homozygous deletion of the SMN1 gene in most patients and has 95% sensitivity and nearly 100% specificity (Somers et al. 2016). If copy number analysis suggests the patient carries one intact copy of SMN1 the coding region of the undeleted allele should be sequenced to assess the presence of a second causative mutation, usually subtle sequence variations such as point mutations, small insertions or deletions, or splice site mutations. Sequence analysis of SMN1 is recommended for patients with two copies of SMN1 who have typical symptoms and who are born to consanguineous parents or originate from genetic isolates as homozygosity for minor point mutations in SMN1 have been rarely reported (Cusco et al. 2003).

A large inverted duplication region located at chromosome 5q have caused two forms of the SMN gene exist on each allele.
in humans: a telomeric form (SMN1) and a centromeric form (SMN2). The coding sequence of SMN2 differs from that of SMN1 by a single nucleotide (840C > T) which does not alter the amino acid sequence but results in alternative splicing of exon 7. The alternative splicing of exon 7 causes SMN2 genes to produce a smaller amount of full length transcripts (SMN-4) and protein while most of the transcript lacks exon 7 which give rise to a truncated and unstable protein (Vitte et al. 2007). The small proportion of full length transcript derived from SMN2 provides a sufficient amount of SMN protein to prevent lethality yet not enough to fully compensate for the loss of SMN1, resulting in motor neuron disease. Importantly, the intrinsic instability of the 5q chromosomal duplication can cause multiple copies of SMN2 to be present in different individuals and a higher SMN2 copy number correlates inversely with disease severity (McAndrew et al. 1997; Wirth et al. 2006): all patients retain at least one copy of SMN2, generally two to four. Less than 10% of patients with SMA type 1 retain only one copy of the SMN2 gene and generally have a congenital onset as well as very severe and early lethal course (also sometimes denoted as SMA type 0) (Mercurio et al. 2012) (Table 24.1).

The majority (80%) of patients with SMA type 1 have two copies of SMN2 (Gavrilov et al. 1998) while three SMN2 copies present in more than 80% SMA type 2, with three to four copies identified in 95% of SMA type 3: patients with the adult form typically carry four or more copies of SMN2 (Table 24.1) (Feldkotter et al. 2002; Rudnik-Schoneborn et al. 2009). SMN2 genes encode for a protein ubiquitously expressed and localised in the cytoplasm and in the nucleus, particularly abundant in motor neurons of the spinal cord (Rudnik-Schoneborn et al. 2009). Within the nucleus SMN protein is concentrated in dot-like structures associated with coiled (Cajal) bodies, named ‘gems’ (gemin of coiled bodies). Although the exact cellular function of SMN protein responsible for the pathogenesis of SMA remains unknown, cells from patients with SMA contain fewer gems compared with controls and carriers (Liu and Dreyfuss 1996).

Several animal models have been obtained in yeast, nematode, fly, zebrafish and mouse by disruption of SMN expression. These SMA models have been fundamental for increasing knowledge about the molecular and cellular pathways of SMN but also allowed investigators to better understand the mechanism(s) of disease and provide a platform from which high-throughput genetic and drug screenings have been performed (Schmid and DiDonato 2007). To explain the pathogenesis of SMA two main hypotheses have been postulated (D’Amico et al. 2011): (1) SMN is involved in the biogenesis of small nuclear ribonucleoproteins (snRNPs) and in mRNA splicing; thus SMN reduction may affect snRNPs assembly (to which motor neurons may be more sensitive) and/or SMN complex is involved in the splicing of one or few transcripts with a key function in motor neurons. (2) SMN also appears to have a motor neuron specific function such as mRNA transport along the axon so that transcription can occur close to the nerve terminal endings. Although SMN protein is expressed in all somatic cells it is unclear why motor neurons of the spinal cord are specifically vulnerable in SMA. In support of hypothesis 1 some studies suggest SMN protein might play a key role in cellular functions unique to motor neurons (Carvalho et al. 1999; Fan and Simard 2002; Gabanella et al. 2007). In support of the second hypothesis, other studies suggest SMN protein might sustain the survival of motor neurons by allowing normal axonal transport and maintaining the integrity of neuromuscular junctions.

In addition to the above hypothesis it has been recently demonstrated that SMN is required for 3-end formation of histone mRNAs. Defective 3’-end processing can lead to a reduction in the mRNA and protein levels of replication-dependent histones meaning that the consequences of SMN deficiency are largely related to the disruption of fundamental RNA processing, relevant both for neurons and other cell types outside the nervous system (Hamilton and Gillingwater 2013).

There is a better correlation between the level of SMN protein and severity of disease compared to the simple assessment of the SMN2 copy number, suggesting that not all SMN2 genes are transcribed with the same efficiency (Sumner et al. 2006). Usually, SMA-affected siblings are very similar in terms of their age at onset and the progression of disease (Rudnik-Schoneborn et al. 1994) but there can be discordance of phenotype severity in siblings carrying identical numbers of SMN2 genes, suggesting the influence of modifier genes (Cobben et al. 1995; Hahnen et al. 1995; Wang et al. 1996; Prior et al. 2004). In the last decade SMA-discordant families with asymptomatic females who had inherited the same SMN1 and SMN2 alleles as their affected siblings were reported (Hahnen et al. 1995; Oprea et al. 2008) and it was suggested that unaffected SMN1-deleted females have significantly higher expression of plastin 3 (PLS3) than their SMA-affected counterparts. PLS3, a protein important for axonogenesis, has been suggested to be an SMA disease modifier (Oprea et al. 2008); however, this role remains uncertain as no changes in the PLS3 gene have been reported so far.

### Key Diagnostic Features and Differential Diagnosis

Clinical features are highly suggestive for the diagnosis of SMA particularly in the severe variant of a floppy infant or weak child. The facial expression and attentiveness are typically good with the weakness usually symmetrical and more proximal than distal, affecting the legs more than the arms.

The clinical differential diagnosis with SMA type 1 should include the congenital myopathies or central nervous system (CNS) pathologies leading to profound hypotonia. However, the typical pattern of preserved diaphragmatic breathing together with preserved facial expression and the lack of tendon reflexes would guide the diagnosis. Similarly, in SMA...

type 2 the differential diagnosis is with some congenital myopathies and congenital muscular dystrophies but the distribution of weakness together with the wasting of intercostal muscles, hand tremor and intact facial expression will help distinguish these disorders. The differential diagnosis in SMA type 3 patients can be more difficult as the clinical features and possibility of elevated creatine kinase level overlap with other rare myopathies and muscular dystrophies (Table 24.2).

Trembling of the baseline trace on a standard ECG can already give the first clue of denervation due to intercostal muscles denervation. The first-level diagnostic test for a patient suspected to have SMA should be the search of the SMN1 gene for homozygous deletions. The absence of SMN1 exon 7 (with or without deletion of exon 8) confirms the diagnosis of SMA (Somers et al. 2016) while if first-level assay tests are negative further laboratory examinations including creatine kinase levels, which can be mildly elevated especially in type 3 patients (Rudnik-Schoneborn et al. 1998), and electrophysiological tests such as electromyography (EMG) and nerve conduction study should be performed. If EMG suggests a motor neuron disorder (Hausmanowa-Petrusewicz and Karwanska 1986; Shababi et al. 2010). A reduced interference pattern is seen with maximal effort with polyphasic waves, positive sharp waves and fibrillations present in all individuals with SMA, while motor and sensory nerve conduction velocities (NCVs) are normal. This test remains a useful tool in the diagnosis of SMA.

The tests below have been used in the past to establish the diagnosis of SMA but currently have little or no role in the diagnosis of most affected individuals. They are used primarily if molecular genetic testing of SMN1 does not identify mutations.

Muscle histology Muscle biopsy reveals group atrophy of type 1 and type 2 muscle fibres as opposed to the normal checkerboard pattern. Rare angulated and large type 1 fibres are scattered throughout. Muscle biopsy findings can sometimes help to establish the diagnosis but they do not help predict the severity of disease among infants with this condition (Buchthal and Olsen 1970; Zalneraitis et al. 1991). With the advent of rapid genetic screening the role of a muscle biopsy in the diagnosis of SMA has been greatly reduced and this test is now not recommended.

Nerve histology This is not a recommended diagnostic test for SMA. Hypomyelination of the peripheral nerve can nevertheless be observed in the severe type 0 form otherwise the sensory nerves (conventionally biopsied) usually show normal histology, meaning that this technique should not be used for the diagnosis of SMA (Korinthenberg et al. 1997; MacLeod et al. 1999; Hergersberg et al. 2000).

Electromyography Electromyography (EMG) reveals denervation and diminished motor action potential amplitude. The EMG regular spontaneous motor unit activity, a unique feature in SMA, is seen most commonly in SMA type 1 and occasionally type 2, but not in type 3 (Hausmanowa-Petrusewicz and Karwanska 1986; Shababi et al. 2010). A reduced interference pattern is seen with maximal effort with polyphasic waves, positive sharp waves and fibrillations present in all individuals with SMA, while motor and sensory nerve conduction velocities (NCVs) are normal. This test remains a useful tool in the diagnosis of SMA.

STANDARD OF CARE IN SMA

There have been recent meetings and consensus guidelines for aspects of diagnosis, assessment and monitoring of SMA published in 2007 (Somers et al. 2016). Clearly there have been remarkable improvements in the outcome of patients with SMA in the last decade. However, complete agreement on systematic management in several areas is still lacking, although it is clear that patients with SMA and their families should be supported by a multidisciplinary team (Roper and Quinlivan 2010). In this chapter we will concentrate the discussion on the following aspects: respiratory, feeding/nutrition and orthopaedic issues.

Respiratory

Patients with SMA type 1 are the most fragile group and respiratory muscle weakness is an inevitable feature, with early intercostal weakness being particularly prominent. Infants should be examined regularly to review cough effectiveness, work of breathing and presence of paradoxical (diaphragmatic) breathing and evolution of chest deformity. Assessment of efficacy and safety of swallow should be undertaken by a speech and language therapist to reduce the risk of aspiration. In order to prevent infections infants should receive all standard immunisations. Clinical experience suggesting that physiotherapy helps with secretion clearance in infants with severe SMA type 1. Intermittent chest percussion, appropriate positioning and nasopharyngeal suctioning may provide symptom relief and parents can be taught these techniques by a paediatric physiotherapist experienced in respiratory management. The use of a mechanical insufflator/exsufflator via a face mask (cough assist machine) increases peak cough flow and aids airway clearance, with such devices having been demonstrated as effective in reducing infection in older children with neuromuscular conditions. As some degree of patient cooperation is essential for success, their use in very young infants is challenging. However, those experienced in their use find that cough assist devices may be used in infants from 6 months of age (Chatwin et al. 2003; Miske et al. 2004; Vianello et al. 2005; Fauroux et al. 2008).

An early discussion should include the option of noninvasive ventilation and secretion management because of the rapid progression of the disease while anticipatory guidance and education for chronic care, illness management and perioperative care should also be provided (Somers et al. 2016). The natural history of SMA1 has changed substantially in the past decade because of the availability of new technology and implementation of an aggressive approach to improve survival and quality of life (Schroth 2009). Noninvasive ventilation (NIV) can be used at a very young age— as early as the neonatal period— because interfaces are now available for small infants (Simonds 2007) while bilevel positive airway pressure ventilation can be provided at home with a face mask, with evidence suggesting NIV may reduce the frequency of hospital admissions (Rudnik-Schoneborn et al. 2008). The use of NIV can also have a beneficial impact on chest shape, reducing the development of the typical chest deformities that characterises SMA type 1 (Bach and Bianchi 2003).

As weakness progresses the requirement for ventilation might increase to 24 hours per day. With full-time ventilation the upper airway can become damaged, resulting in oedema and increased secretions and such complications in the airway or intercurrent infections can necessitate intubation.

Whether to proceed to tracheostomy for long-term invasive ventilation is an individual choice for the family of the child and the involvement of the palliative care team to offer support and advice to families who have to make difficult decisions is recommended. Children with SMA type 1 who undergo tracheostomy and long-term ventilation remain dependent on ventilators for the rest of their lives: speech develops in infants treated with NIV but development is more challenging in those ventilated by tracheostomy (Bach et al. 2007), with some patients at high risk of recurrent hypoxia, which results in ischaemic brain injury. The goal of intervention should always be to improve quality of life of the child, not to prolong life (Roper and Quinlivan 2010).

Patients with SMA type 2 also have weak intercostal muscles and invariable scoliosis contributes to progressive restrictive lung disease (Iannaccone 2007; Schroth 2009) that can result in onset of sleep disordered breathing: regular sleep studies are recommended. Initiation of NIV in children with abnormal respiratory studies typically leads to improvement in their symptoms (fatigue, headaches, disturbed sleep and lack of appetite in the morning) (Mellies et al. 2004).

Feeding and Nutrition

In infants with SMA type 1 the suck is invariably weak, feeding inefficient and growth possibly compromised. With progressive bulbar and respiratory involvement there is an increased risk of aspiration of liquids, solid food and saliva as the poor head control exacerbates swallowing difficulties leading to silent aspiration and eventually respiratory tract infections. Infants’ feeding and swallowing should be assessed by a speech and language therapist who can offer advice on safe swallow: a videofluoroscopy can objectively assess the swallow and demonstrate silent aspiration in case of doubt. These infants are also at risk of developing gastro-oesophageal reflux so should be assessed for symptoms to be managed appropriately. As oral feeds alone are usually not sufficient to sustain growth supplementation using nasogastric feeding or a gastrostomy should be considered early in the course of the disease before significant failure to thrive occurs. The volume of feed depends on the energy of the infant and their protein requirements: there are various equations available to calculate energy expenditure but none has been validated for infants with type 1 SMA (Roper and Quinlivan 2010).

Feeding and swallowing difficulties are not uncommon in SMA type 2 but rare in type 3, while gastro-oesophageal reflux can be present also in this population. Growth failure can occur for various reasons, from reduced intake because of tecticatory muscle fatigue or prolonged meal times to recurrent...
respiratory infections. Development of dysphagia due to progressive weakness of bulbar and oesophageal muscles can occur in adolescents with SMA type 2 (Chen et al. 2012) while restriction of movements of the temporomandibular joint is also present in some individuals. At the other extreme reduced activity and low energy expenditure increases the risk of obesity but little evidence exists about how best to monitor these patients (Sproule et al. 2009, 2010a, b).

**Orthopaedic**

Children with SMA type 1 are almost invariably too severely affected to be eligible for orthopaedic surgical interventions but supported seating and passive stretching may be useful. Scoliosis occurs in almost all nonambulant patients which can be controlled by spinal braces, other sitting adjustments or trunk orthoses (Granata et al. 1989; Tangsrud et al. 2001). Growing rods (Akbarnia et al. 2005) or vertical expandable prosthetic titanium ribs (Emans et al. 2005; Hell et al. 2005) can also be used to prevent progression of scoliosis in very young children if bracing is unsuccessful; such techniques have been effective in controlling progressive early-onset scoliosis before definitive spinal fusion (Thompson et al. 2007; Chandran et al. 2011; McElroy et al. 2011).

**Newborn Screening for SMA**

In the past decade development and implementation of standard of care protocols and proactive approach have improved survival in children with SMA types 1 and 2. At the same time exciting novel therapies are at various stages of development with some having recently successfully completed randomised clinical trials. For therapy to be as effective as possible it is necessary for it to be administered as close as possible to the onset of clinical symptoms and ideally ahead of the development of such as the loss of motor neurons, which is likely to be an irreversible phenomenon.

As an example, in SMA type 1 the pathological process typically begins in the perinatal period with loss of more than 90% of motor units within 6 months of age. Swoboda et al. performed a prospective study in prenatally diagnosed infants with SMA type 1, showing that in association with the initial onset of symptoms or decline in function there was electrophysiological evidence of abrupt denervation (Swoboda et al. 2005). With this fast rate of neuronal loss, the extent of therapeutic response in infants with SMA type 1 is likely to be influenced by the timing of the intervention and this has been very clearly demonstrated in the preclinical models of the disease. The benefit of novel therapeutics should therefore ideally be assessed as close as possible to the birth and presymptomatic diagnosis. The purpose of newborn screening would be, therefore, not only to provide genetic counselling to families as early as possible in order to avoid the birth of more affected children in a family but, with the advent of experimental therapies in which early data appears to be extremely encouraging, also to identify affected infants prior to the presentation of clinical symptoms. Studies have been conducted to examine the legal, ethical and social issues with population-based pilot studies for SMA (Rothwell et al. 2013; Wood et al. 2014).

In 2008 SMA was submitted for formal consideration to the US Health and Human Services Secretary’s Advisory Committee on Heritable Diseases in Newborns and Children by a collaborative group of physicians, researchers, the SMA community and the families of SMA. The consensus of the internal Nomination and Prioritization Workgroup of the committee was that the addition of SMA to the uniform screening panel was premature at that time (for more information visit http://www.hrsa.gov/advisorycommittees/mchbadvisory/heritabledisorders/). Since then clinical trials have made considerable progress and the validation of screening methods in public health by newborn blood spot screening laboratories is now underway (Pyatt and Prior 2006; Pyatt et al. 2007; Prior 2010; Prior et al. 2010; Dobrowolski et al. 2012; Taylor et al. 2015). An initial pilot has been completed by the Wadsworth Center of the New York State Department of Health with further validation planned and a population-based pilot study in Taiwan that began in November 2014 had detected two children affected within 4 months (Han 2015).

**Approved and Experimental Therapies Aiming at Increasing SMN Protein Levels**

With Greater understanding of the molecular basis of SMA in the past two decades a major focus of therapeutic developments has been on increasing the full-length SMN protein by enhancing SMN2 gene expression, increasing the inclusion of exon 7 in SMN2 transcripts, stabilising the SMN protein or replacing the SMN1 gene (for more information visit: SMA Drug Pipeline <http://www.curesma.org/research/latest-advances/>). Within few months, the treatment scenario for SMA has dramatically changed as an oligonucleotide drug, called Spinraza, has received FDA approval for the treatment of SMA in the US in December 2016 and more recently EMA approval in Europe (April 2017).

Ongoing clinical trials include (1) antisense oligonucleotides, (2) small-molecule drugs, and (3) gene therapy.

1. **Antisense oligonucleotides (ASO)** Splice switching ASO are synthetic RNA molecules that interfere with physiological splicing of exons. As all patients with SMA carry at least one copy of SMN2, in which a single nucleotide change determines an exclusion of exon 7 in 90% of the transcript, an attractive approach is to manipulate SMN2 splicing so that exon 7 is retained in the mature transcript, so as to create a mRNA and eventually a protein identical to the one produced by SMN1. These ASOs are highly effective at promoting inclusion of exon 7 in SMN2 transcripts and increasing SMN...
(2) Small molecules

A number of low-molecular-weight drugs can modestly increase levels of full-length SMN protein by activating the SMN2 promoter, increasing expression, or altering the splicing pattern of SMN2 transcripts so as to favour the inclusion of exon 7 (Tsai et al. 2008; Hastings et al. 2009).

Histone deacetylase inhibitor and quinazoline compounds increase SMN2 mRNA levels and improve the disease phenotype in mouse models of SMA (Avila et al. 2007; Narver et al. 2008; Garbes et al. 2009; Riessland et al. 2010).

Other small-molecule drugs such as aminoglycosides promote reading of the stop codon of SMNΔ7 transcripts, enabling the translation of a protein variant with, however, increased stability when compared to the SMN2 product (Mattis et al. 2009). These molecules had shown promising results in mouse models and cell lines derived from patients with SMA but when tested in clinical trials showed little or no benefit (Mercuri et al. 2007; Oskoui and Kaufmann 2008; Swoboda et al. 2009).

Another small-molecules member – quinazoline – increases full-length mRNA by inclusion of exon 7 in SMN2 gene transcript, resulting in an increase in SMN protein levels. The primary function is in the inhibition of human scavenger decapping enzyme (DcpS). The role of DcpS is best understood in the degradation of the 50 cap during the 30–50mRNA decay and may have additional functions in nuclear–cytoplasm transportation as well as first intron pre-mRNA splicing (Shen et al. 2008). Quinazoline is anticipated to progress to phase I clinical trials.

RG7800 is a small molecule SMN2 splicing modifier being developed by Roche for the treatment of SMA. A phase I multicentre randomised, double blind, placebo-controlled study was initiated in 2015. The purpose of the study is to administer multiple doses to investigate the safety, tolerability, pharmacokinetics and pharmacodynamics of RG7800 following 12 weeks of treatment in adult and paediatric patients with SMA. After recruiting the first cohort of patients the study has suspended participant recruitment due to unexpected eye findings observed in an animal study evaluating the long term safety of RG7800 (study on holding and suspended participant recruitment in April 2015; for more information visit www.clinicaltrials.gov). More recently Roche has initiated another phase I study for SMA 1 and 2/3 with a related compound: Novartis is also pursuing a similar strategy with a small molecule also capable of increasing exon 7 retention in SMN2 gene, in SMA1 (https://clinicaltrials.gov/ct2/show/NCT02268552).

(3) Gene therapy

As a monogenic disease SMA is a good target for vector-based gene replacement therapy to restore a normal form of the SMN1 gene in patients. Viral-mediated SMN gene delivery has been remarkably successful in preclinical studies. Both systemic and intra-cerebro-ventricular injection of self-complementary adeno-associated viral vectors (scAAV) expressing SMN showed efficient transduction of motor neurons in both mice and nonhuman primates as well as nearly complete correction of the SMA phenotype in mice (Fouste et al. 2010; Passini et al. 2010; Valori et al. 2010).

In selecting a potential vector to deliver the SMN1 gene adeno-associated virus vectors (AAV) 8 and 9 appeared to be excellent contenders as a result of their ability to cross the blood–brain barrier through the vascular system in mouse models (Valori et al. 2010; Dayton et al. 2012; Seo et al. 2013).

At the time of writing, AveXis is conducting the first gene therapy phase I clinical trial to assess the safety of multidose intravenous delivery of scAAV9-SMN in infants with SMA type 1 at Columbus University in the United States (for more information visit www.clinicaltrials.gov).

OTHER THERAPEUTIC APPROACHES

Neuroprotective compounds

Olesoxime is another small molecule that has showed neuroprotective properties in a number of in-vitro and in-vivo studies promoting neurite outgrowth and communication with the mitochondrial permeability transition pore (Bordet et al. 2007).

This compound has been tested in a phase II randomised, multicentre, double blind, placebo-controlled trial completed in 2013. A total of 165 nonambulant patients with SMA types 2 and 3, aged 3–25 years, were recruited in 23 sites in different European countries (France, Germany, Italy, United Kingdom, Poland, Netherlands, Belgium) and followed in the study for approximately 2 years. The randomisation ratio was 2:1, therefore 108 in the olesoxime group (10mg/kg) and 57 in the placebo group with preliminary results suggesting olesoxime maintains motor function and improves overall health status over the 2-year treatment period.

An open-label study to evaluate long term safety, tolerability and effectiveness of olesoxime in patients with
SMA has recently started recruiting patients who participated in the phase II study (for more information visit www.clinicaltrials.gov).

**ALBUTEROL**

Albuterol is a beta-adrenergic agonist recognised to have a positive anabolic effect in healthy individuals, evaluated in a pilot study on patients with SMA types 2 and 3 that showed a significant improvement of myometry, forced vital capacity and DXA scores at 6 months evaluation (Kinali et al. 2002). A following open label pilot study using salbutamol, a form of albuterol, showed an improvement of the functional scores at the Hammersmith Functional Motor Scale (HFMS) after 6 and 12 months of treatment (Pane et al. 2008). In-vitro studies have also shown that salbutamol can increase the full length SMN mRNA, SMN protein and gem numbers by promoting the exon 7 inclusion with this effect found to be directly proportional to the SMN2 gene copy number (Angelozzi et al. 2008; Tiziano et al. 2010).

**STEM CELLS**

One of the goals of transplanted stem cells is to support endogenous motor neurons through the delivery of neuroprotective agents and ideally also partially restore neuronal and non-neuronal cells (Hedlund et al. 2007; Koliatsos et al. 2008; Suzuki and Swensden 2008). Neural stem cells obtained from the spinal cord administered intrathecally to SMA mice showed appropriate migration into the parenchyma and capability to generate a small proportion of motor neurons: these treated mice exhibited improved motor unit and neuromuscular function and showed a 38% increase in life expectancy (Corti et al. 2008).

Despite the positive results of neural stem cell transplantation in mice translational value in human is unclear and therefore alternative protocols, which include the use of embryonic stem cells or induced pluripotent stem cells for transplantation, have been tried in animal models. These cells have the ability to differentiate in vitro and in vivo into neural stem cells and motor neurons (Wichertel et al. 2002; Li et al. 2005; Dimos et al. 2008).

The findings of improved SMA phenotype in mice following the intrathecal transplantation of embryonic stem cell derived neural stem cells included proper migration to target tissue in the spinal cord, neuroprotective function and a 58% increase in lifespan (Corti et al. 2010).

A protocol to test neuronal stem cells in patients with SMA is currently on hold by the FDA. However, there are no imminent clinical trials expected in humans (Taylor et al. 2015).

Similarly, a controversial approach of allogenic mesenchymal cell transplantation, administered intravenously and intrathecally, initiated by a private enterprise in Italy, was interrupted in 2014 by a panel of experts appointed by the Italian Ministry of Health. Concerns cited included a lack of proven efficacy and serious concerns on the quality of the proposed drug as the mesenchymal cells given to patients were not grown under the approved EU strict set of quality control standards.

---

**NON-5Q SPINAL MUSCULAR ATROPHIES**

There are other inherited motor neuron disorders not caused by mutation of the SMN gene (non-5q spinal muscular atrophy) that present with early denervation weakness but different clinical symptoms from those of the common 5q variant (Zerres and Rudnik-Schoneborn 2003). These disorders can be classified on the basis of the clinical distribution of weakness and the pattern of inheritance (Table 24.3).

**CONGENITAL DISTAL VARIANTS OF SMAS, MOST OFTEN AFFECTING THE LOWER LIMBS (SMA-LED)**

Autosomal dominant congenital SMA-LED, also known as congenital spinal muscular atrophy affecting predominantly the lower limbs, or ‘distal SMA’, has been clinically described for decades and is characterised by congenital or early childhood onset, motor neuron degeneration confirmed on electromyography and lower limb–predominant weakness (Fleury and Hageman 1985; Frijns et al. 1994; van der Vleuten et al. 1998; Mercuri et al. 2004).

These SMA-LED variants share core phenotypic features including congenital/early childhood onset, very slow progression or more frequently static course and lower limb–predominant weakness; however, there are also some distinctive features.

Dominant mutations in TRPV4 have been described in both peripheral nervous system and skeletal diseases. The peripheral nervous system diseases include hereditary motor and sensory neuropathy type 2C or Charcot–Marie–Tooth disease type 2C (HMSN2C or CMT2C), congenital spinal muscular atrophy and arthrogryposis (CSMAA) as well as scapuloperoneal spinal muscular atrophy (SPSMA). Vocal cord paralysis and sensorineural hearing deficit are frequently associated findings in patients with neuropathies. Muscle MRI of the thighs and calf muscles from some patients with SMA associated with TRPV4 mutations demonstrate a selective...

involvement of the vastus medialis, long heads of biceps and semimembranosus as well as of the gastrocnemius (Astrea et al. 2012). A recent study has however described more diffuse fat atrophy at both the thigh and calf level (Evangelista et al. 2015).

Dominant or sporadic missense mutations in the tail domain of the cytoplasmic dynein heavy chain gene 1 (DYNCHI1) were first described by Harms (Harms et al. 2012) as causative of an SMA-LED phenotype although since this first description several individuals have been reported with mutations located in other portions of the gene and also in association with malformations of cortical development (Vissers et al. 2010; Tsurusaki et al. 2012; Fiorillo et al. 2014).

DYNCH11 is a large gene encoding the heavy chain of the cytoplasmic dynein protein complex, a ubiquitously expressed multisubunit molecular motor involved in retrograde axonal transport (Schnapp and Reese 1989), cell migration, nucleokinesis, Golgi localisation and autophagy (Corthesy-Theulaz et al. 1992; Ravikumar et al. 2005; Schiavo et al. 2013).

A compelling candidate mechanism for the pathogenicity of DYNCHI1 mutations would be interference with dynein-dependent mitochondrial trafficking leading to mitochondrial dysfunction and subsequent neurodegeneration (Anesti and Scorrano 2006). It has been recently confirmed that mutations in dynein relevant for SMA–LED compromise mitochondrial morphology and function (Eschbach et al. 2013).

We recently reported a large cohort of children and adults affected by SMA-LED due to DYNCHI1 mutations which is likely to be the most common subgroup of SMA-LED, expanding the clinical spectrum to include individuals with severe generalised arthrogryposis and instances with onset in adulthood (Fig. 24.1) (Scoto et al. 2015). In this study it was confirmed that in a significant proportion of patients the onset of clinical signs is at birth or in the first few years of life although in approximately one quarter of individuals there were no concerns until adulthood. Almost all individuals acquired the ability to walk irrespective of age at onset and all remained ambulant, confirming the stable course of the disease, with this group of patients showing a more pronounced involvement of the lower limbs in comparison to the upper limbs, with well-preserved muscle function in the arms and only minimal distal (hand) weakness in a few individuals. Despite the clinical appearance of distal muscle wasting and foot deformities the proximal muscles, especially the hip extensors, are the weakest lower limb muscles, in contrast to the more prominent distal weakness reported in dominant SMA families with mutations in TRPV4, suggesting this could be a key clinical aspect in the differential diagnosis. In the majority of individuals contractures are a presenting feature while the muscle MRI of the lower limbs shows a striking pattern, appearing to be highly suggestive of this condition especially at the thigh level with a selective sparing and relative hypertrophy of the adductors compartment and of the semitendinosus muscles (Mercuri et al. 2004; Scoto et al. 2015). It is of interest that this imaging pattern is different from that described in the form of lower-limbs SMA due to mutations in TRPV4 especially at the calf level. (Astrea et al. 2012)

Another feature observed in many individuals is a brain malformation resembling polymicrogyria, characterised by cortical nodularity or gyral overconvolutions, best seen in the frontal and peri-Sylvian cortex with posterior extension of the Sylvian fissures. It has been observed that CNS malformations are often associated with a degree of cognitive impairment and behavioural difficulties resembling attention-deficit-hyperactivity disorder (Scoto et al. 2015).

More recently, mutations in the dynein adaptor protein BICD2 have been identified in a series of patients also characterised by SMA with predominant lower extremity involvement (Neveling et al. 2013; Oates et al., 2013; Peeters et al. 2013; Synofzik et al. 2014). These patients also had lower limbs disproportionately affected with the degree of wasting often out of proportion to the degree of weakness. Mutations in BICD2 typically cause early onset non-length dependent lower limb predominant weakness, wasting and contractures with a relatively static clinical course. The marked degree of lower limb muscle involvement is also evident on muscle MRI which shows a characteristic pattern of muscle fat replacement and selective hypertrophy similar to that seen in patients with DYNCHI1 mutations. Despite the lower extremity predominance mild upper limb involvement such as scapular winging can be present in a subset of patients. While the motor phenotype associated with BICD2 mutations is similar to that seen in individuals with DYNCHI1 mutations malformations of cortical development have not been reported so far in patients with BICD2 mutations. While the phenotype of early-onset, lower extremity predominant wasting and weakness is common to most patients with mutations in BICD2 there is considerable heterogeneity in terms of the severity of the phenotype, with the reason for phenotypic heterogeneity unknown but having important implications for genetic counselling: in a proportion of patients with BICD2 there is involvement of upper motor neurons as well. The clinical similarity between BICD2- and DYNCHI1-spinal muscular atrophy, lower extremity predominant, has highlighted dynein-dynactin trafficking as a key cellular pathway in motor neuron patterning, primary development and survival (Rossor et al. 2015).

BROWN-VIALETTA-VAN LAERE SYNDROME AND FAZIO-LONDE DISEASE

Brown-Vialetto-Van Laere syndrome (BVVLS) (OMIM 211530) is a rare neurological disorder first described by Brown in 1894 and later by Vialetto and Van Laere. It is characterised by progressive ponto-bulbar palsy associated with bilateral sensorineural hearing loss, mainly affecting cranial nerves VII–XII, often with progression to involve the anterior horn cells of the spinal cord over time. The same clinical presentation without deafness is traditionally known as Fazio-Londe Disease (FLD) although the two are now regarded as part of a spectrum of neuronopathic disorders.
Figure 24.1  Clinical phenotype, muscle imaging and brain imaging in different forms of spinal muscular atrophy with lower extremity predominance (SMA-LED)

Images (a)–(d) show SMA-LED caused by mutations in \textit{DYNC1H1}. (a) Standing with support at 8 years of age and distal wasting in lower limbs and foot deformity. (b) Achilles tendon tightness and foot deformity. (c) Muscle MRI scan of the lower limbs shows diffuse involvement of the quadriceps muscles and relative sparing of the adductor compartments with relative hypertrophy of the adductor longus (white arrow) and semitendinosus muscle (black arrow) at the thigh level: at the calf level there is diffuse involvement with sparing of the anterior-medial muscles. (d) Brain MRI scan shows polymicrogyric pattern of frontal lobe cortex, sylvian fissure extending to the parietal lobe and thin corpus callosum.

Images (e)–(g) show SMA-LED caused by mutations in the \textit{BICD2} gene. (e, f) show wasting of both upper and lower leg typically seen in more severely affected individuals and the pes planus and pes cavus foot deformities commonly seen in this disorder (g). Muscle MRI scan of the lower limbs shows a common pattern of muscle involvement in individuals with mutations in \textit{BICD2} and \textit{DYNC1H1} lightface with variable fat replacement of muscles of the anterolateral thigh but relative sparing with or without relative hypertrophy of the semitendinosus muscle. At calf level there is diffuse involvement with sparing of the anterior-medial muscles.
The first gene associated with BVVLS/FLD was SLC52A3 and it encodes the human intestinal riboflavin transporter-2 (hRFT2). A second gene SLC52A2, encoding human riboflavin transporter-3 (hRFT3), a brain riboflavin transporter, has also been demonstrated to cause BVVLS as well as the SLC52A1 (GPR172B) gene, coding for human riboflavin transporter hRFT1.

The recognition of abnormal acylcarnitine profiles mimicking multiple acyl-CoA dehydrogenase deficiency in patients with BVVLS (Bosch et al. 2011) has elucidated a link between the putative function of SLC52A3 and SLC52A2 as riboflavin transporters and this neurodegenerative condition.

A recent study in a large cohort of patients carrying mutations in SLC52A2 has further defined the clinical presentation and the course in those carrying mutations in this gene (Foley et al. 2014). The most common presenting symptom is an ataxic gait, secondary to a progressive sensory neuropathy with parents reporting symptoms as early as age 7 months (nystagmus) and as late as age 8 years (ataxic gait): optic atrophy is frequently encountered in up to 93% of patients following formal ophthalmological evaluations. All patients have hearing loss with audiometry documenting bilateral sensorineural hearing loss while tongue fasciculations are also commonly found with evidence of a correlation between severity of fasciculations and length of time following the onset of first symptoms. Rapidly progressive upper limb weakness occurs after evidence of a sensory ataxic gait, with an initial pattern of weakness of neck extension and the distal upper limbs progressing to involve the proximal upper limbs. This pattern of weakness leads to a striking phenotype (sometimes referred to as ‘the child in a barrel syndrome’) characterised by maintenance of the ability to walk (with head and trunk support) despite subgravity upper limb and neck strength, resulting from the comparatively milder lower limb weakness in contrast to the severe involvement of axial and upper limb muscles (Fig. 24.2).

Respiratory muscle weakness leading to respiratory insufficiency can develop in the majority of individuals. Other clinical features observed include the absence of deep tendon reflexes and presence of a flexor plantar response. In a subset of patients the acute onset of weakness in the first few months of life can be preceded by respiratory failure, increased limb tone and increased tendon reflexes with clonus with neurogenic findings on EMG able to assist in suspecting this condition in these infants. Cognition is preserved despite significant visual and hearing impairments while inheritance is autosomal recessive which helps to differentiate this disorder from other optico-acoustic neuropathies including autosomal dominantly inherited OPA1 or MFN2 mutations, X-linked PRPS1 mutations and mitochondrial inherited neuropathy.

Normal nerve conduction velocities have been reported in patients diagnosed with BVVLS although patients with mutations in SLC52A2 who presented with sensory ataxia had axonal sensorimotor neuropathy revealed by nerve conduction studies. The sural nerve biopsies from these patients show a preferential loss of large diameter myelinated axons which correlate with the clinical findings of absent deep tendon reflexes and the prevalent sensory ataxia.

Supplementation of riboflavin has demonstrated remarkable efficacy in a number of young patients both in patients with and without a plasma flavin deficiency, especially those treated early (Green et al. 2010; Bosch et al. 2011; Anand et al. 2012; Ciccolella et al. 2012; Koy et al. 2012). When untreated, BVVL is a severe disorder with a variable but mostly rapid downhill progression, especially in the younger age groups and with a possible fatal outcome.

**SPINAL MUSCULAR ATROPHIES WITH RESPIRATORY DISTRESS**

Spinal muscular atrophy with respiratory distress type 1 (SMARD1) is a form of SMA with respiratory distress due to diaphragmatic involvement (Grohmann et al. 1999, 2001). It has been recently renamed distal spinal muscular atrophy type 1 (DSM1A MIM#604320) and is also known as hereditary motor neuropathy type 6 (HMN6) (Kaindl et al. 2008).

The exact prevalence of SMARD1 is unclear but studies have shown diaphragmatic palsy affects approximately 1% of patients diagnosed with early onset SMA (Giannini et al. 2006; Eckart et al. 2012) with currently more than 60 described. SMARD1 is caused by homozygous or compound heterozygous mutations in the immunoglobulin l-binding protein 2 (IGHMBP2) gene located on chromosome 11q13.2-q13.4 where frameshift deletion, in-frame deletion, non-sense, splice donor-site and recessive missense mutations have been described (Grohmann et al. 2001). The location and type of mutations do not appear to correlate with the severity of clinical features (Grohmann et al. 2003; Joseph et al. 2009).

As a result of mutations in the IGHMBP2 gene there is a degeneration of motor neurons in the anterior horns which explains the main phenotypical features of SMARD1, irreversible diaphragmatic palsy and progressive distal symmetrical muscular weakness (mainly of the lower limbs). Life expectancy is very low, with most patients dying within 13 months and only few surviving longer (Appleton et al. 2004; Pierson 2011).

Patients with a clinical picture similar to SMARD1 but without abnormalities in the IGHMBP2 gene have been described, suggesting the clinical phenotype can be caused by mutations in other genes currently unknown.

Extremely severe and rapidly progressive respiratory distress caused by diaphragmatic palsy is the main symptom of SMARD1 (Kaindl et al. 2008). The onset, usually within the first months of life, is often sudden and dramatic, needing prompt and irreversible invasive ventilation: the diaphragmatic palsy can be seen on a chest X-ray as an abnormal elevation of the dome of diaphragm. The eventration starts more often on the right side of the chest, probably because of pressure on the diaphragm by the liver (Grohmann...
Part X  Neuromuscular Diseases

et al. 1999, 2001, 2003). Early signs of the disease include weak cry, inspiratory stridor, difficulty eating and recurrent bronchopneumonia. Intrauterine growth delay, preterm and reduced fetal movements can often be seen as part of SMARD1 (Grohmann et al. 2003).

Unlike patients with proximal SMA, muscular weakness in patients with SMARD1 involves the distal muscles at first, often accompanied by congenital foot deformations which can lead to secondary finger contractures and fatty pads due to deposits of adipose tissue in the proximal phalanges, only later affecting the proximal muscles (Grohmann et al. 2003; Rudnik-Schoneborn et al. 2004). SMARD1 patients typically present a complete paralysis of the four limbs and later develop a progressive kyphoscoliosis while the deep tendon reflexes cannot be elicited in most affected individuals. Advanced SMARD1 often presents a significant autonomic involvement and symptoms can vary from cardiac arrhythmia to urinary retention needing catheterisation, bladder incontinence, excessive sweating and constipation (Grohmann et al. 2003; Pierson 2011).

Tongue fasciculations and facial weakness can also be present while the oculomotor neurons seem to be spared (Blaschek et al. 2014). In 2003 Pitt et al. proposed diagnostic criteria for SMARD1 based on clinical, histopathological and electrophysiological criteria with clinical criteria including low birthweight, onset of symptoms at birth with talipes and finger contractures or, by the age of 3 months, unilateral or bilateral diaphragmatic weakness, ventilator dependence within 1 month of onset and absence of dysmorphology or other conditions. The histopathological criteria included reduced myelinated fibre density and size without evidence of regeneration or demyelination on sural nerve biopsy, while electrophysiological criteria included evidence of distal denervation and severe slowing of conduction.

Figure 24.2  Phenotypic characteristics of Brown-Vialette-Van Laere syndrome caused by mutations in SLC52A2.
Severe weakness of neck extension and upper limbs with comparatively less weakness of lower limbs seen in patients at different ages: (a) 1.8 years (b) 5.8 years and (c) 8.6 years. (d) Symmetrical atrophy of intrinsic hand muscles of left and (e) right hands at 10.5 years of age.
in one or more nerves (motor or sensory) (Pitt et al. 2003; Ruiz et al. 2005; Jedrzejowska et al. 2014).

There is no effective treatment available for SMARD1 with patients generally requiring mechanical ventilation. Antibiotic therapy and prophylaxis for recurrent airway infections and optimal nutrition are also very important (Jedrzejowska et al. 2014) while physical and occupational therapy are also essential aspects of the treatment.

Preclinical animal model studies have demonstrated a modest role for monoclonal antibodies with an agonist effect on the tyrosine kinase receptor C which is involved in the regulation of neuron plasticity and synaptic strength (Huang and Reichardt 2003; Ruiz et al. 2005). Neurotrophic factors such as insulin-like factor 1 (IGF1) have been considered as a possible candidate for future treatment trials as they seem to play an important role in the pathogenesis of SMARD1 (Krieger et al. 2014).

As for SMA, gene therapy mostly focuses on replacing the defective gene using self-complementary adeno-associated virus vectors (Foust et al. 2010; Passini et al. 2010; Valori et al. 2010; Dominguez et al. 2011). Apart from classic neonatal/infantile presentations there have been only a few reports of patients with an unusual display of symptoms (Guenther et al. 2004; Guenther et al. 2009; Joseph et al. 2009).

**JUVENILE AMYOTROPHIC LATERAL SCLEROSIS**

Juvenile amyotrophic lateral sclerosis (JALS) is a form of chronic motor neuron disease with gradual weakness of voluntary muscles resulting from the destruction of neural cells, characterised by a combination of upper and lower motor neuron signs. The term JALS has been used for patients with onset of disease before 25 years of age who usually have a prolonged survival. It may be sporadic or familial (Ben Hamida et al. 1990) while the prevalence and incidence are not known: a relatively small number of patients have been reported to date but the disorder has been described in various ethnic groups. Onset is during childhood with a mean age of 6.5 years and reported range of 3–20 years. Patients then develop motor neuron degeneration leading to facial muscle spasticity, spastic dystarthis and spastic gait. Some patients are reported to have uncontrolled laughter and weeping (pseudobulbar syndrome) while mild atrophy of the legs and hands have also been observed in some individuals affected, with bladder dysfunction and sensory disturbances also found. The disease is usually slowly progressive and some patients have been reported to have become bedridden by 12–50 years of age. Mutations in the following genes have been found in patients presenting with JALS: ALS2 (2q33-q35), rarely SIGMARI (9p13.3), SPG11 (15q13-q15) and FUS (16p11.2). Mutations in the latter gene are sporadic and appear to be associated with a severe and aggressive course.

**X-LINKED INFANTILE SPINAL MUSCULAR ATROPHY (XL-SMA OR SMAX2)**

SMA with X-linked inheritance is much rarer and more heterogeneous with an adult-onset form (SMAX1 or Kennedy disease, OMIM 313200) due to a triplet repeat expansion in the AR gene on Xq12 encoding the androgen receptor (La Spada et al. 1991) and an infantile-onset form (SMAX2, OMIM 301830) due to hemizygous missense mutations in the UBA1 gene on Xp11.23 encoding ubiquitin-activating enzyme 1 (Ramser et al. 2008).

X-linked infantile SMA (XL-SMA) is a lethal disease characterised by severe hypotonia and areflexia with neurophysiological evidence of denervation and neuropathological findings of anterior horn cell loss in the spinal cord and brainstem. The clinical course is similar to the most severe forms of classic autosomal recessive SMA caused by mutations in the SMN1 gene, SMA type 0 and SMA type 1. The weakness in XL-SMA often has a prenatal onset manifesting with polyhydramnios and poor movements in utero, resulting in congenital contractures, especially digital contractures and possible fractures due to bone fragility. The course of the disease is progressive with no cognitive involvement reported so far, with other features variably presenting including micrognathia, kyphosis, scoliosis and cryptorchidism. Similarly to SMA1, the greatest difficulties in this disease are related to the respiratory complications in proportion to the weakness of the child, complicated by aspiration and frequent infections and children usually die by the age of 2 years as a result of respiratory failure (Iannaccone 2007). UBA1 is the only gene currently known in association with XL-SMA wherein the protein encoded by UBA1 catalyses the first step in ubiquitin conjugation to mark cellular proteins for degradation through the ubiquitin–proteasome system (UPS) (Tanaka 2004). The UPS pathway also plays an important physiological role in the degradation of the SMN protein implicated in autosomal–recessive SMA (Burnett et al. 2009).

Post mortem studies have demonstrated widespread involvement of the sensory system as well as developmental and degenerative cerebellar abnormalities, in addition to severe ventral motor neuron pathology while in contrast to typical SMN1-associated SMA the thalamus was unaffected. These findings indicate that SMAX2 would be more accurately classified as a motor sensory neuronopathy rather than a pure anterior horn cell disorder and that ubiquitin-proteasome pathway defects may not only cause neurodegeneration but also affect normal neuronal development (Dlamini et al. 2013).

Although UBA1 is the only gene currently known in association with XL-SMA there is evidence for locus heterogeneity as a linkage to the X chromosome region Xp11.3-q11.1 has been demonstrated in families with XL-SMA without mutations observed in UBA1 (Kobayashi et al. 1995).

**ARTHROGRYPOSIS MULTIPLE CONGENITAL**

The term arthrogryposis multiple congenital (AMC) refers to the presence of joint contractures in at least two areas of
the body at birth with associated muscle wasting and fusion.

**Neurogenic arthrogyrosis** due to dysgenesis of anterior horn cells of the spinal cord or motor nuclei in the brainstem is a rare variant with diverse clinical presentations (Clarren and Hall 1983).

AMC can overlap with other disorders including lethal and non-lethal Escobar variant, multiple pterygium syndromes, lethal congenital contracture syndromes and SMA type 1. At the milder end of the spectrum are the distal arthrogyroses in which contractures occur across the distal joints exclusively. Isolated AMC phenotypes arise as a result of mutations in genes encoding components required for (1) motor neuron structure, function and myelination (ADCY6, CNTNAP1, ECEL1, ERBB3, GLE1, PIP5K1C, SMN1 and TRPV4), (2) the neuro-muscular junction (CHAT, CHRNA1, CHRNB1, CHRNA4, CHRNG, CNTN1, DOK7, RAFFSN and ZBTB42) or (3) skeletal muscle (ACTA1, DMPK, KLHL40, KLHL41, MYBPC1, MYH2, MYH3, MYH8, NEB, PIEZO2, RYR1, SYNE1, TNNI2, TNNT3, TPM2 and TTN) (Gupta et al. 2013; Laquerriere et al. 2014; McMillin et al. 2014; Patel et al. 2014).

Despite the large number of known disease-associated genes many patients with AMC remain without a genetic diagnosis. Although contractures may lead to worsening of function ability most children improve with physiotherapy, well-fitted orthoses and corrective surgery if indicated (van Bosse et al. 2007). A recent study conducted on 27 children suggests neurogenic arthrogyrosis is usually a non-progressive disorder especially in the absence of concomitant brain abnormalities (Ambegaonkar et al. 2011).

The term **monomelic spinal muscular atrophy** or **Hirayama disease** refers to a peculiar spinal muscular atrophy characterised by young age at onset (second or third decade), sporadic occurrence, male preponderance, weakness and atrophy affecting intrinsic muscles of hand and forearm usually confined to a single limb. Infrequently symptoms of cold paresis and hyperhidrosis are described with an abnormal sympathetic skin response (Gourie-Devi et al. 1984; Gourie-Devi and Nalini 2001; Gourie-Devi and Nalini 2003).

Hirayama disease of a unilateral upper extremity was first described in 1959, more commonly reported from Asian countries like Japan and India and thought to be rare in western countries despite patients being reported from Europe and America (Ghosh et al. 2011).

The characteristic appearance of oblique amyotrophy is a forearm amyotrophy sparing the brachioradialis muscle and relatively benign non-progressive course which differentiates it from motor neuron disease. In Hirayama disease weakness and wasting are noted in the small muscles of the hand along with preservation of the brachioradialis muscle with the weakness usually involving both extensors and flexors of fingers. Tremulousness of the hand on extension of the fingers (polymymimyoclonus) is often seen with most patients also reporting aggravation of weakness in cold weather (cold paresis). The pathogenesis is still unclear but according to various imaging and pathological studies the disease could be caused by dynamic compression of the lower cervical cord due to repeated or sustained neck flexion (Pradhan and Gupta 1997; Hirayama 2000; Hassan et al. 2012). The application of a hard cervical collar during the early phase of illness can halt the progression of illness (Verma et al. 2012).

**SMA WITH PROGRESSIVE MYOClonic EPILEPSY**

Spinal muscular atrophy with progressive myoclonic epilepsy (SMA-PME) is a recently delineated, autosomal recessive lysosomal storage disorder caused by rare homozygous or compound heterozygous mutations in the N-acylphosphosine amidohydrolase 1 (acid ceramidase) ASAH1 gene. It is characterised by motor neuron disease followed by progressive myoclonic seizures and generalised seizures with progressive neurological deterioration, mild to moderate cognitive impairment and eventual death due to respiratory insufficiency. The main clinical feature of this condition is the onset of motor deficits during childhood or at a juvenile age after normal developmental milestones. Progressive muscle weakness is caused by the involvement of lower motor neurons confirmed by EMG and/or muscle biopsy while myoclonic epilepsy is observed later and generally resistant to conventional therapy when the onset is in childhood. The disease course is progressive and leads to respiratory muscle involvement as well as severe disability or death occurring before 20 years of age (Zhou et al. 2012; Dyment et al. 2014).

Individuals with juvenile/adult onset show a slower and more benign evolution without cognitive impairment, with epilepsy and myoclonus responding to antiepileptic drugs. Other clinical features may include sensorineural deafness and tremor.

**ACQUIRED VARIANTS OF MOTOR NEURON DISEASE**

The acquired motor neuron disorders are a heterogeneous group of conditions in which motor neuron degeneration or dysfunction produces the predominant manifestation of weakness while the sensory system is clinically spared. Such acquired motor neuron disorders may complicate metabolic, toxic or systemic disorders with the pathogenesis of such poorly understood and treatment mainly supportive. Paraneoplastic acquired motor neuron disorders may result from autoimmunity directed against antigens shared by the affected neurons and associated cancer cells. Lower motor neuron syndrome (MNS) has been described in association with breast cancer and in a few patients following radiation therapy in the course of cancer (Sadowsky et al. 1976; Ferracci et al. 1999).
SMA-LIKE DISORDER DUE TO SCO2 MUTATIONS

A possible pathogenic role of mitochondria in SMA has been proposed (Berger et al. 2003). Infants with deficiency of cytochrome c oxidase (COX) due to SCO2 mutations have been reported with a mild SMA-like phenotype associated with atypical neurological symptoms, as well as increase of lactate in plasma, cerebrospinal fluid or urine. In a recent study a homozygous mutation in the SCO2 gene was reported causing a SMA-like presentation with stridor and respiratory insufficiency (Pronicki et al. 2010).

Spinal muscular atrophies are inherited neuromuscular diseases characterised by degeneration of spinal cord motor neurons resulting in progressive muscular atrophy and weakness. The most common forms, those likely to be encountered by any paediatric neurologist, are linked to mutations in SMN1 (5q-SMA) with a wide clinical spectrum ranging from early infant death to normal adult life with only mild weakness. The care for spinal muscular atrophies requires a multidisciplinary approach and consensus reached on several aspects of care: this has enabled a more proactive role of anticipatory care, targeting disease-specific complications and resulting in a substantial effect on the disease prognosis, even for more severe forms. The recent progress in the understanding of molecular pathogenesis of SMA and advances in medical technology are inducing the development of a number of novel and exciting therapeutic approaches. At the time of writing several novel strategies are being tested in clinical trials.

Non-5q associated spinal muscular atrophies, the most common condition represented by the genetically heterogeneous group of SMA with lower-limb-predominant weakness, share recognisable clinical features and a slowly or non-progressive course. A less common but treatable condition is the BVVL syndrome which should be suspected in the presence of early onset weakness with respiratory failure associated with sensory ataxia, bilateral sensorineural hearing loss and later progressive pontobulbar palsy and/or predominant upper limb weakness. Treatment with riboflavin should be considered even while genetic confirmation is in progress.

Following the recent genetic advances it is likely the spectrum of these rare disorders will be further widened. However, the clinical presentation, with particular emphasis on the distribution of weakness and the pattern of inheritance, can help in differentiating the less common motor neuron diseases and guide the clinician toward a possible genetic confirmation.

Disorders of the Peripheral Nerves

Manoj Menezes and Robert Ouvrier

This chapter considers only those disorders in which the primary pathological process affects the axons of motor or sensory cells or both, or their myelin sheaths and associated Schwann cells. Diseases in which axonal damage results from primary lesions of the neuronal cell body have been described in Chapter 24. Hereditary neuropathies most often involve both sensory and motor fibres, though they may be purely motor or sensory in nature, or may predominantly affect one fibre type. Nerve fibre function can be disturbed in several manners (Fig. 25.1). Wallerian degeneration occurs when an axon is separated from the cell body or when the cell dies.

Axonal neuropathies are characterised primarily by involvement of the axon and may be the result of genetic disease, toxins, vascular disease and so on. In many cases, axonal neuropathies begin and remain more severe distally than proximally, perhaps because the enormous length of axons makes the metabolic needs of their most distal parts difficult to meet. This may also be due to disturbances in the axonal transport systems. In axonal neuropathies, nerve conduction velocities are normal or only slightly slowed despite evidence of denervation. Characteristically, the amplitude of sensory and compound muscle action potentials is reduced.

Diseases of the Schwann cell and the myelin sheath are also due to multiple (genetic or acquired) causes, especially inflammatory diseases. The lesions are diffuse or segmental, that is, limited to lengths of nerve depending on one Schwann cell (internode). Such a process may produce a conduction block or a slowing of nerve conduction velocities, either focal or generalised. Slowing may be diffuse and uniform as in some metabolic and hereditary neuropathies (Miller et al. 1985). Conduction block and temporal dispersion are indicative of multifocal segmental demyelination. Conduction block is defined at the cellular level as failure of an action potential to propagate throughout the length of an axon. When many individual axons are blocked, especially at a localised site, both the amplitude and the area under the curve of the evoked muscle action potential are reduced when proximal stimulation is compared to distal stimulation (beyond the region of conduction block) of the motor nerve. With pure temporal dispersion, increased duration of the evoked muscle action potential occurs, together with reduced amplitude but the area under the curve is preserved. Demyelination and axonal disease are not independent processes, but the exact nature of their relationship remains unclear. Inherited neuropathies may involve the peripheral nervous system exclusively or predominantly affect the peripheral nervous system (Charcot–Marie–Tooth disease) or may occur as part of a syndrome complex that involves the central nervous system (CNS) as well as other non-neurological organs.

**Charcot–Marie–Tooth Disease (Hereditary Motor and Sensory Neuropathy)**

Charcot–Marie–Tooth disease (CMT) is a group of genetically heterogeneous disorders that affect peripheral nerve function; CMT is named after Jean-Martin Charcot, Pierre Marie and Henry Tooth who originally described the disorder in 1886. CMT is the most common inherited neuromuscular disorder, affecting approximately one in 2500 individuals (Skre 1974) and accounting for approximately 40% of childhood chronic neuropathies (Ouvrier 1992). Degeneration of the axon, its myelin sheath, or both, results in progressive symmetrical distal weakness, sensory loss and areflexia. CMT is caused by disorders of genes with functions that vary from compaction and maintenance of myelin, to cytoskeletal formation, axonal transport and mitochondrial metabolism (Pareyson and Marchesi 2009). Inheritance may be autosomal dominant, autosomal recessive, X-linked or mitochondrial.

**Clinical Features of CMT**

While genetically heterogeneous, the classic CMT phenotype is broadly similar and characterised by gait difficulties, foot deformity, sensory loss and wasting of the distal muscles in the hands and feet (Ouvrier et al. 1999; Pareyson and Marchesi 2009). Age at onset may vary from soon after birth to the sixth and seventh decades of life, though most commonly is in the first two decades of life, and severity of disease may vary greatly. Irrespective of whether the genetic cause affects myelin
or axon function, axonal degeneration results and correlates with severity of weakness. This axonal degeneration affects the longest fibres first, and hence symptoms usually begin distally, and in the lower limbs before the upper limbs (Pareyson and Marchesi 2009).

Children usually present with gait disturbance or foot deformity. Pes cavus is typical and is often associated with hammer toes. Pes cavus has been attributed to imbalance between the long flexors and invertors of the ankle but involvement of the intrinsic muscles of the feet may be more important (Gallardo et al. 2006). Some children present with pes planus and marked valgus deviation of the feet. Gait disturbances include high-stepping gait, difficulties running, frequent falls or unsteadiness. Symptoms progress slowly and it may take a number of years before children are brought to medical attention. Examination reveals symmetrical atrophy of the peroneal muscles (hence the term peroneal amyotrophy classically applied to CMT), later involving the calves and eventually the lower third of the thigh (Fig. 25.2). In the upper extremity, atrophy of the small muscles of the hand may occur (claw hand – main en griffe) and weakness of the intrinsic muscles of the hands is more often demonstrable. Tendon reflexes are decreased or absent (Ouvrier et al. 1999). Sensory loss is characterised by abnormalities of touch, proprioception and vibration and by sensory ataxia. Dysesthesiae or shooting pains are not a feature, although pain due to foot deformities or calluses may be severe in some patients. Muscle cramps are not uncommon. Vasomotor disturbances are common, with frequent cyanosis and marbling of the skin.

Classification of CMT Types

CMT affects both sensory and motor peripheral nerves and is hence also called hereditary motor and sensory neuropathy (HMSN). In addition, types that affect predominantly sensory fibres (hereditary sensory neuropathy [HSN]) or predominantly motor fibres (hereditary motor neuropathy [HMN]) have been identified. CMT is classified based on these neurophysiological and histopathological characteristics and mode of inheritance, and this classification, together with phenotypic clues, is used to direct genetic testing. The availability of next-generation sequencing technologies, including whole-exome, whole-genome and disease-specific gene panels

Figure 25.1  (1) Wallerian degeneration. Following interruption of an axon, there is chromatolysis of the cell body. In the distal axon, myelin initially disintegrates (upper panel). Later, Schwann cells divide and line up inside the basement membrane to regenerate an axon (middle and lower panel). Axonal sprouting is also observed. Nerve conduction is normal in proximal axon and absent distally. Muscle atrophy is present.

(2) Segmental demyelination. Patchy damage to Schwann cells with secondary paranodal axonal degeneration. Secondary remyelination generates short internodes with thin myelin sheaths. Repeated episodes of demyelination and remyelination may produce ‘onion bulb’ formations. Conduction block or slowing of conduction may be seen in demyelinated segments.

(3) ‘Dying back’ neuropathy. Degeneration begins in terminal axon. Secondary demyelination often occurs. Conduction is normal proximally and absent distally in affected fibres. Preferential involvement of large fibres explains the mild/moderate reduction in nerve conduction velocity, as the measured velocity is that of the remaining small fibres.

Figure 25.2  Charcot-Marie-Tooth disease type 1 in an 8-year-old girl. Note wasting of lower limbs below the lower third of thigh and deformed feet.
promises to revolutionise genetic testing for CMT and its classification system. As the number of gene disorders causing CMT grows, it is increasingly recognised that there exists significant phenotypic and genotypic crossover between various CMT types.

Based on upper limb motor conduction velocities (MCV), CMT is divided into a demyelinating form, CMT1 (MCV < 38m/s) and axonal form, CMT2 (MCV > 38m/s in adults) (Harding and Thomas 1980a). Demyelinating CMT with an autosomal recessive inheritance is classified as CMT4. An intermediate form with motor conduction velocities between CMT1 and CMT2, in the range of 25–45m/s has also been identified. CMT3 (Déjerine–Sottas neuropathy) refers to severe, early-onset neuropathy with delayed motor milestones and hypomyelination on nerve biopsy and has now been shown to be caused mainly by point mutations of genes causing CMT1. Further classification is based on the identified gene or locus; for example, autosomal dominant demyelinating CMT due to duplication of the PMP22 gene is classified as CMT1A.

The nomenclature and classification systems for CMT have become chaotic but a new approach has been proposed by which each form of CMT is classified as of demyelinating (de), axonal (ax) or intermediate (int) conduction velocity with the pattern of inheritance and the causative gene, where known, being incorporated in the subtype designation (Mathis et al. 2015) (Table 25.1). In this Chapter, the traditional nomenclature will be utilised, as the proposed new nomenclature has not yet been officially adopted.

**CMT1/HMSN1**

CMT1 is the most common demyelinating disorder, representing 70% of all demyelinating CMT in adults (Nelis et al. 1996). The prevalence of CMT1 is 3.8 per 100 000 population, accounting for about 50% of paediatric cases of hereditary neuropathies (Hagberg and Westerberg 1983). Onset of CMT1 is usually within the first decade, although cases of later onset are known. CMT1 is genetically heterogeneous but more than 80% of childhood cases are linked to chromosome 17 (CMT1A). The defect in such cases is usually a submicroscopic duplication, approximately 1.5 megabases in length, within band 17p11.2 (Raeymaekers et al. 1991). The duplication includes the PMP22 gene encoding peripheral myelin protein 22 (Patel et al. 1992) so that the gene is present in three copies. The duplication is thought to result from unequal crossing-over during meiosis. Deletions of the same region result in hereditary neuropathy with liability to pressure palsies (HNPP). Cases of CMT1A due to trisomy 17 have also been recorded. The mechanism by which overexpression of PMP22 (whether produced by having three copies of the PMP22 gene or by a gain of function mutation) produces the clinical manifestations is not understood.

A very early onset during the neonatal period or the first year is not as rare as once thought in CMT1 and specifically in CMT1A (Ouvrier et al. 1987; Baets et al. 2011). Asymmetrical and even unilateral involvement has been rarely reported. Cases of CMT1 are not uncommonly associated with tremor of the upper limbs and sometimes with some degree of clumsiness. Hypertrophy of the calves occurs in some families (Uncini et al. 1994). Deep tendon reflexes, especially the ankle reflexes, are often lost early, and this may be a useful sign for the clinical diagnosis of the condition in young children with affected relatives or in parents of children with the disease (Garcia et al. 1998). Scoliosis, lordosis, hip dysplasia, metatarsal stress fractures and recurrent patellar dislocation may occur (Harding and Thomas 1980a; Thomas et al. 1997). Palpable nerve enlargement is not rare in children but is difficult to assess objectively. Ultrasound neurography is useful for detection (Yiu et al. 2016) The CSF protein level is elevated in over half the cases, but lumbar puncture is not indicated.

Progression of CMT1A is slow, and long periods of stability are common. Most patients remain ambulant but some severe cases exist. In an occasional patient, intercurrent infections or rapid growth may be associated with acceleration of the disease process. Pregnancy may cause significant deterioration (Gastaut et al. 2000), and exposure to vincristine can cause a severe regression (Igarashi et al. 1995). Rare cases of proven CMT1 with rapid deterioration and response to steroid treatment are on record (Dyck et al. 1993).

**Diagnosis of CMT1**

The diagnosis of CMT1 is easy in typical forms. The presence of sensory deficit is important to distinguish the condition from distal forms of myopathy or spinal amyotrophy. Slowing of motor and sensory nerve conduction velocities to less than 60% of the lower limit of normal values and increased distal latencies separate CMT1 from CMT2. There is no correlation between slowing of conduction velocities and clinical severity. Nerve conduction abnormalities appear early and are present in most children with CMT1A by 3 years of age (Ouvrier 1992) or even earlier (Berciano et al. 1989), although they are sometimes inconclusive (Ryan and Jones 2004). Prolongation of distal latencies may precede slowing of nerve conduction (Garcia et al. 1998). When inherited from a parent, conduction velocities are usually abnormal in the carrier parent, whether or not clinically affected. Neurogenic electromyography (EMG) changes are usually mild to moderate. Approximately 20% of affected individuals have a significant disability and a similar proportion remain asymptomatic.

Testing of DNA for the presence of the chromosome 17p11.2 duplication achieves a genetic diagnosis in most cases. When negative, sequencing of MPZ and PMP22 should be pursued. Diagnostic testing for other genes causing CMT1 (Table 25.1) is often available only on a research basis, but the recent development of neuropathy-specific gene panels has altered this approach of sequencing genes based on the population frequency and phenotypic clues.

Continued
Nerve biopsy is not specific and is not necessary for diagnosis, especially when there is a clear family history of the disease. The main indication for biopsy would be differentiation from chronic inflammatory neuropathy. In such cases, nerve biopsy and/or a trial of steroid treatment may be warranted.

Although the penetrance of the disease is high (83%), there is significant variability in clinical and pathological expression.
In some cases, the clinical and even nerve biopsy findings can be minimal, particularly in young children. Nevertheless, children affected by CMT1A almost always show some manifestations by the age of 3 years. Mild and even asymptomatic cases occur (Thomas et al. 1997) and systematic examination of parents and relatives, therefore, improves the diagnostic yield.

In children without the duplication, point mutations of the PMP22 (also classified as CMT1A) and MPZ (myelin protein zero) (CMT1B) genes have been found (Roa et al. 1993; Warner et al. 1996). Mutations of both the PMP22 and MPZ genes cause a variety of clinical pictures, ranging from congenital hypomyelination and Déjerine–Sottas phenotype to a CMT1A-like phenotype. MPZ may also cause late-onset axonal (CMT2I and J) and rarely, intermediate forms of CMT (CMTDID). Deafness (PMP22 and MPZ) and pupillary abnormalities (MPZ) may be associated (De Jonghe et al. 1999; Wilmshurst and Ouvrier 2011). Mouse and rat models that overexpress PMP22 develop phenotypic features consistent with CMT1A, and the severity of demyelination is proportional to the level of PMP22 expression. PMP22 comprises only 2–5% of peripheral nervous system myelin. Impaired cellular trafficking appears to be a possible mechanism in PMP22-related neuropathies (Lupski and Chance 2005). MPZ constitutes about 50% of myelin protein and is important for the process of myelin adhesion (Shy 2005).

Less frequently, mutations in LITAF/SIMPLE (CMT1C), a gene that may be involved in aberrant protein degradation, and zinc finger transcription regulator EGR2 (CMT1D), encoding Krox20/EGR2, a transcription factor regulating expression of a number of myelin-related genes, may also cause CMT1 (Warner et al. 1999; Street et al. 2003). Homozygous EGR2 mutations also cause a more severe autosomal recessive hypo- and demyelinating neuropathy CMT4E.

Pathology of CMT1

The pathology of CMT1 has been studied mainly by muscle and nerve biopsy. CMT1 is characterised pathologically by extensive segmental demyelination and remyelination with the development of ‘onion bulbs’ around nerve fibres (Gabreëls-Festen et al. 1992). Only a few postmortem examinations have been reported: these cases showed degeneration of the posterior columns, some loss of anterior horn cells, and degeneration of the anterior and posterior spinal roots (De Recondo 1975). There is a reduction in the numbers of myelinated fibres, with the greatest loss among those of large calibre. The distribution of fibre diameters is thus unimodal. Unmyelinated fibres are not affected. Proliferation of the sheath of Schwann produces the classic ‘onion bulb’ formations (Fig. 25.3) that can be shown by electron microscopy to contain only Schwann cells and their processes. Nerve fibre teasing shows numerous images of segmental and paranodal demyelination and remyelination, predominating in the distal part of nerves. Pathological lesions, in particular onion bulbs, are nonspecific and indicate only the succession of demyelinating and remyelinating episodes that can also be observed in many other neuropathies. When marked, the process leads to hypertrophy of nerve roots and plexuses. Degenerative changes in muscle are secondary to neural damage. The histopathological findings of CMT1B, due to MPZ mutations, are similar to those of CMT1A but uncompacted myelin may be seen in a significant number of fibres, and focal folding of myelin (tomacula) can also be prominent.

X-LINKED CMT

There are currently six known loci associated with X-linked CMT (CMTX) (Kennerson et al. 2013; Timmerman et al. 2014), which makes up approximately 10% of adult cohorts with CMT (Murphy et al. 2012). The most frequent X-linked form is CMTX1 caused by mutations in the GJB1/Cx32.
(gap junction beta 1/connexin 32) gene (Bergoffen et al. 1993), encoding a membrane-spanning gap junction protein localised adjacent to the nodes of Ranvier and the Schmidt–Lantermann incisures. Pedigrees show the expected absence of male-to-male transmission. Males are usually much more obviously affected than females but generally clinical involvement is less severe in the first decade than in those with CMT1A. On the other hand, the eventual degree of disability is greater in mature males with CMTX than in CMT1A. Occasional affected children may present with isolated deafness (Stojkovic et al. 1999) and some have had transient CNS symptomatology associated with white matter lesions (Hanemann et al. 2003). The neurophysiological features of the X-linked type in males may resemble those of CMT1A, but average motor conduction velocity (MCV) is about 10m/s faster in CMTX males (mean peroneal MCV 31m/s) than in CMT1A males (mean peroneal MCV 22m/s) (Nicholson and Nash 1993) whereas in females they may be in the axonal range. Most ‘intermediate’ types of CMT with mildly slowed conduction velocities are X-linked.

There are other rare forms of inherited neuropathy linked to the X chromosome. Of these, CMTX2 (linked to Xp22.2), CMTX4 (Cowchock syndrome, due to mutations in AIFM1) and CMTX5 (due to mutations in PRPS1) are syndromic inherited neuropathies, often associated with intellectual disability, and it has been argued that they should not be classified as CMT (Cowchock et al. 1985; Ionesescu et al. 1992; de Brouwer et al. 2010). CMTX3 has been linked to Xp26.3–27.1 and has recently been shown, using whole genome sequencing, to be due to a 78kb insertion from 8q24.3 while CMTX6 is caused by mutations in the PDK3 gene (Kennerson et al. 2013; Brewer et al. 2016).

In CMTX, the pathological lesions vary from predominant chronic de- and re-myelination to, more commonly, a mixture of demyelination and axonal degeneration with moderate loss of myelinated fibres (Sander et al. 1998).

### AUTOSOMAL RECESSIVE DEMYELINATING TYPES OF CHARCOT–MARIE–TOOTH (CMT4; AUTOSOMAL RECESSIVE HMSN TYPE I)

CMT4 includes the group of autosomal recessive demyelinating neuropathies (Table 25.1). All are rather severe, early-onset disorders with moderately slow motor conduction velocities (usually around 20m/s with a range 3–37m/s). As expected with recessive inheritance, affected children may have similarly affected siblings and clinically unaffected parents who may be related. Recent reports have shed light on clinical and molecular findings in a number of these conditions and have provided some insight into their relative frequency. North African and Middle-Eastern populations appear to show a higher prevalence of recessive CMT.

CMT4A is caused by mutations in the GDAP1 (ganglioside-induced differentiation-associated protein-1) gene, which is involved in mitochondrial fission (Niemann et al. 2005). Most patients show an early-onset severe phenotype with prominent foot deformities (Nelis et al. 2002). There is rapidly progressive weakness and sensory loss that involves the lower and then upper limbs, resulting in loss of ambulation in the second and third decades of life. The clinical spectrum of this disorder has been expanded by the recognition that patients with GDAP1 mutations may develop laryngeal and diaphragmatic paralysis in later life (Birouk et al. 2003; Stojkovic et al. 2004; Clarumunt et al. 2005). GDAP1 mutations may cause demyelinating or axonal degenerative changes in nerve biopsies in different kindreds (Di Maria et al. 2004; Stojkovic et al. 2004). GDAP1 mutations may also cause recessive axonal and intermediate CMT, or rarely, autosomal dominant CMT (Tazir et al. 2013).

CMT4B1 and CMT4B2 are characterised by the presence, on biopsy, of striking in- and out-foldings of myelin, although this finding is not invariable (Quattroone et al. 1996; Parman et al. 2004). Both disorders are associated with mutations of members of the myotubulin family. CMT4B1 is caused by mutations in the MTMR2 (myotubulin-related protein-2) gene which is involved in membrane trafficking (Previtali et al. 2007). Affected individuals have an early onset of mainly distal weakness followed by proximal weakness and wasting (Tazir et al. 2013). Deep tendon reflexes are usually absent even in the early stages. Sensory changes are difficult to detect in infancy but are usually evident later in childhood. Most cases have pes cavus. Ptosis, and internal and external ophthalmoplegia are reported. Facial nerve weakness may give rise to pouting lips. Dysphagia, vocal cord paresis, dysarthria, ataxia and nocturnal hypoventilation may occur later. The clinical course is usually more severe than in CMT1A. Scoliosis is frequent. Many adults are wheelchair-dependent and several have died in the fourth and fifth decades.

Apart from the myelin disturbance, CMT4B2, due to mutations in the SBF2/MTMR13 (set-binding factor/myotubulin-related protein-13) gene, is usually associated with congenital or juvenile glaucoma (Azeddine et al. 2003; Senderek et al. 2003b), although some kindreds lacked this feature (Hirano et al. 2004). Excessive myelin outfolding may also be seen with MPZ, PRX and FGDC mutations (Tazir et al. 2013). CMT4C, due to mutations in the SH3TC2 (SH3 domain and tetratricopeptide repeat domain 2) gene, important for regulation of endosomal recycling, is characterised by early-onset scoliosis that may predate the neuropathy by many years (Yger et al. 2012). Onset is usually in the first decade and while some patients progress slowly, allowing ambulation up to the fifth decade, others become wheelchair-dependent during their adolescent years (Senderek et al. 2003a). Nerve conduction velocities range from 4m/s to 37m/s. A remarkable difference in conduction slowing between nerves of the same limb, conduction block and dispersion of CMAPs may be seen (Yger et al. 2012). Histopathologically, nerve biopsies characteristically reveal basal lamina onion.
bulbs and extended Schwann cell cytoplasmic processes around unmyelinated fibres. Giant axons may also be seen (Vallat et al. 2005).

CMT4D (HMSN-Lom) is the commonest of three recessively inherited polyneuropathies that are largely confined to inbred Roma (Gypsy) populations. HMSN-Lom was originally identified in ‘travellers’ living in the city of Lom, Bulgaria. It is due to mutations of the NDRG1 (n-myc downstream-regulated gene 1) gene, which plays an important role in Schwann cell trafficking and endosomal transport (King et al. 2011). The clinical picture is similar to other autosomal recessive demyelinating neuropathies but deafness commonly supervenes after the first decade (Kalaydjieva et al. 2000).

CMT4E is a rare neuropathy attributed to homozygous mutations of the EGR2 (early growth response 2) gene that can produce a Déjerine–Sottas or congenital hypomyelinating neuropathy phenotype (Warner et al. 1999). Nerve conduction velocities are very low, often less than 5 m/s.

CMT4F is caused by mutations of the PRX (periaxin) gene which is considered important for the formation and maintenance of peripheral nerve myelin. Patients usually have an early-onset Déjerine–Sottas phenotype but progression can be slow (Boerkoel et al. 2001; Guilbot et al. 2001). Sensory involvement with dysaesthesiae and ataxia may be prominent. Nerve conduction velocities tend to be very slow (2–3 m/s). Nerve biopsies have shown a severe loss of myelinated fibres with many onion bulbs and some fibres with myelin outfoldings. Mice lacking periaxin show similar histopathological findings.

CMT4G (HMSN-Russe) is another of the neuropathies seen in the European Roma population. It is similar to CMT4D except for later occurrence of deafness and slower progression (Navarro and Teijera 2003). It has been mapped to 10q22 and the gene has been identified to be HK1 (hexokinase 1) (Hantke et al. 2009). The nerve biopsy shows loss of large myelinated fibres and prominent clusters of regenerated axons (Thomas et al. 2001).

CMT4H is caused by mutations of FGD4 (FGD1-related f-actin-binding protein), which encodes the Rho GTPase guanine nucleotide exchange factor, frabin, and has an important role in myelin development and maintenance (Stendel et al. 2007). Affected individuals have an early-onset sensorimotor neuropathy with slow progression, remaining ambulant into middle age.

CMT4J is caused by mutations in Fig4, which encodes a phosphatidylinositol 3,5-bisphosphate involved in cycling of intracellular organelles (Chow et al. 2007). Onset may vary from early childhood or as late as the sixth decade, and may show slow gradual deterioration or rapid progression. Proximal weakness is seen early and may result in wheelchair dependence as early as the third decade of life (Nicholson et al. 2011; Menezes et al. 2014). Asymmetric involvement of the extremities and rapidly progressive involvement of a single limb resembling chronic inflammatory demyelinating neuropathy have also been described (Cottenie et al. 2013). Nerve conduction studies show combined axonal and demyelinating features, often with MCV less than 20 m/s.

It has been suggested that CMT4A may constitute up to 25% of cases of autosomal recessive CMT, but only one GDAPI mutation was detected in a study of 20 Turkish patients with probable autosomal recessive early-onset demyelinating neuropathy who were carefully studied with screening for nine possible causative genes. The other five proven mutations included two cases of MTMR2, and one each of SH3TC2, NDRG1 and PRX mutations. Thus, no mutation was detected in 14 of the 20 patients (Parman et al. 2004). In a similar study in Japan, three of 66 patients with CMT4 were found to have PRX mutations (Kijima et al. 2004).

CMT2/HMSN II

CMT2 also produces a clinical picture consistent with the phenotypic description of CMT disease. Its frequency in children is classically much lower than that of CMT1 (Ouvrier 1992; Ouvrier et al. 1999; Ouvrier and Wilmshurst 2003). Data from our clinic show that CMT2 makes up 20% of all childhood CMT. Autosomal dominant and recessive forms of CMT2 have been described.

Clinical Features of CMT2

The clinical manifestations are similar to those of CMT1 but often have a later onset, during the second or third decade. Atrophy of posterior tibial and calf muscles is commonly as marked as in the anterolateral compartment. Absent reflexes and foot deformity are less frequent than in CMT1, but foot ulcers may occur making certain subtypes, such as CMT2B, difficult to distinguish from hereditary sensory and autonomic neuropathy (HSAN) type I (see HSAN1 [Sensory Radicular Neuropathy] section) (Elliott et al. 1997). There is no nerve hypertrophy and raised CSF protein is rare. Upper limb tremor is uncommon (Salisachs et al. 1979; Harding and Thomas 1980a; Westerberg et al. 1983). Differentiation from CMT1 is by electrophysiological investigation. Motor and sensory conduction velocities are normal or only mildly decreased. In CMT patients over 2 years of age, a motor conduction velocity more than 38 m/s in the median nerve is compatible with the diagnosis of CMT 2, whereas values less than 38 m/s are more in favour of CMT1 (Harding and Thomas 1980a; Quattrone et al. 1996).

Heterogeneity of CMT2

CMT2 has been linked to at least 22 loci and 20 genes (Table 25.1). While CMT2A was initially linked to a missense mutation in the KIF1B (kinesin family member 1B) gene in one pedigree, no such mutations have been identified in other affected kindreds. Mutations in the gene encoding a mitochondrial fusion protein, MFN2 (mitofusin 2) are...
responsible for around 20% of CMT (Zuchner et al. 2004; Kijima et al. 2005). There is wide phenotypic heterogeneity, with some patients having an early onset and rapid progression resulting in loss of ambulation in early adulthood, while others have a late-onset, slow progression and preserved ambulation (Feely et al. 2011; Bombelli et al. 2014). Optic atrophy and vocal cord paresis may be associated, and presentation may be as a pure motor neuropathy. Sural nerve biopsy shows axonal degeneration with small rounded abnormally aggregated mitochondria, with irregular inner and outer mitochondrial membranes and disrupted cristae (Funalot et al. 2009). Some families may have an early-onset severe neuropathy due to the presence of compound heterozygous MFN2 mutations (Nicholson et al. 2008). Mitochondria undergo continued cycles of fission and fusion of their inner and outer membranes. MFN2 is a large mitochondrial GTPase. It may function to tether mitochondria before fusion. The neuropathy may thus be due to a defect in mitochondrial fusion/fission that interferes with energy production and slows axonal transport.

CMT2B is caused by missense mutations in the small GTPase late endosomal protein RAB7, which may have a role in axonal transport (Houlden et al. 2004). It may be difficult to differentiate clinically from HSAN1, due to mutations in SPTLC1, because of the presence of moderate sensory loss with complicating ulcers in up to 50% of cases (Verhoeven et al. 2003).

CMT2C, a condition clinically characterised by diaphragm, intercostal and vocal cord paralysis, has been shown to be caused by mutations in the cation channel gene TRPV4 (transient receptor potential cation channel subfamily V member 4), a member of the large family of cation selective channels involved in sensory stimulus transduction (Klein et al. 2011b). The phenotypes associated with TRPV4 mutations may vary from CMT2C to congenital spinal muscular atrophy and scapuloperoneal spinal muscular atrophy (Deng et al. 2010).

CMT2D, which causes prominent weakness of the hands usually commencing in adolescence has been localised to chromosome 7p15 and is due to mutations of the GARS (glycyl aminoacyl tRNA synthetase) gene, which may also cause a predominant distal upper limb weakness with later and less severe involvement of the lower limbs (Rohkamm et al. 2007). Mutations in the genes encoding a number of amino-acyl tRNA synthetases have been reported to cause CMT. These include AARS (CMT2N), YARS (DICMTC), KARS (CMTRIB), MARS and HARS (Jordanova et al. 2006; Latour et al. 2010; McLaughlin et al. 2010; Gonzalez et al. 2013; Vester et al. 2013).

CMT2E is due to mutations of the NEFL (neurofilament light) gene. Nerve conduction velocities may span the demyelinating and axonal degenerative range. Cases with slow nerve conduction velocities have been classified as having CMT1F, while those with velocities in the axonal range have been grouped as CMT2E. Onset in those with slow nerve conduction is often before the age of 13 years and the nerve biopsy in one individual showed a mixed axonal/demyelinating picture (Jordanova et al. 2003).

CMT2L and CMT2F are caused by mutations in the genes encoding the heat-shock proteins HSPB1 and HSPB8 (also called HSP27 and HSP22). The heat-shock proteins are stress proteins induced in response to a variety of physiological and environmental factors (Evgrafov et al. 2004; Tang et al. 2004; Tang et al. 2005). Affected individuals present with the adult onset of distal weakness, mild sensory loss and foot deformity. CMT2I and CMT2J refer to axonal neuropathies caused by certain mutations of the MPZ gene (De Jonghe et al. 1999; Auer-Grumbach et al. 2003). CMT2K is caused by dominant GDAP1 (ganglioside-induced differentiation-associated protein-1) and is allelic to CMT4A. Dominant GDAP1 mutations are rare and cause a later-onset mild axonal neuropathy (Zimon et al. 2011).

Autosomal Recessive Forms of CMT2

Although autosomal recessive CMT of axonal degenerative types are known, few have been fully elucidated. LMNA mutations have been shown to cause CMT2B1, in addition to a variety of other syndromes including muscular dystrophy, lipodystrophy and premature ageing (Benedetti et al. 2007). The LMNA gene encodes the lamin A and C proteins, intermediate filaments that are components of the inner nuclear membrane. This recessive neuropathy has been described in Algerian and Moroccan families from North Western Africa, with a strong founder effect for the R298C mutation (De Sandre-Giovannoli et al. 2002). Onset is from childhood to early adulthood, and the phenotype may vary from classic to severe CMT, with varying rates of progression (Bouhouche et al. 2007). Rarely, other mutations have been described beyond this ethnic group, often in association with a myopathy (Goizet et al. 2004; Benedetti et al. 2005). Mutations in HINT1 (histidine triad nucleotide-binding protein 1) cause recessive axonal neuropathy with neuromyotonia (NMAN). Affected patients have a motor-predominant neuropathy with disease onset in childhood, action myotonia and neuromyotonia on EMG.

The series of axonal neuropathies described by Ouvrier et al. (1981) and Gabréels-Festen et al. (1991) included a number of autosomal recessive cases with a distinctive clinical phenotype at a time when recessive cases were not included in the Dyck classification of the hereditary neuropathies. The onset was in the first 5 years of life and there was rather rapid progression so that most patients were almost completely paralysed below the knees and elbows by adolescence. Motor conduction velocities were unmeasurable in five patients because of absent motor responses, but were over 35m/s in all other patients. Five of ten patients tested from the Sydney series have now been shown to have mitofusin
two (MFN2) gene mutations. Two were compound heterozygotes, that is, recessively inherited; three had dominant (heterozygous) mutations. Another Sydney patient with a less severe phenotype was homozygous for a phe216ser mutation on exon 7 of the MFN2 gene.

In addition to the axonal degenerative forms of CMT listed in Table 25.1, there are several other autosomal recessive axonal polyneuropathies that, for historical or other reasons, have not traditionally been included in CMT classifications. These include severe infantile axonal neuropathy with respiratory failure (now known as SMARD1, see below), giant axonal neuropathy (see the Complex Neuropathies Associated with Central Nervous System Involvement and Metabolic Neuropathies section), and Andermann syndrome, a neuropathy described initially in French Canadians that is associated with agenesis of the corpus callosum and which has been shown to be due to mutations of the gene SLC12A6, encoding the potassium-chloride cotransporter protein KCC3A (Casaubon et al. 1996; Howard et al. 2002).

Pathology of CMT2

The pathology is characterised by the presence of signs of axonal degeneration with secondary involvement of the myelin sheath or Schwann cell. Myelinated fibres, especially those of large calibre, are reduced in number, and regenerative clusters may be seen. Onion bulbs are infrequent. The internodes are shortened and of irregular length on teasing. Acute axonal lesions are rare and the pathological abnormalities may be inconspicuous.

Severe Infantile Axonal Neuropathy with Respiratory Failure

This autosomal recessive axonal neuropathy, that overlaps with spinal muscular atrophy, has been labelled severe infantile axonal neuropathy with respiratory failure (SIANR) (Wilmshurst et al. 2001) or spinal muscular atrophy with respiratory disease (SMARD) (Grothmann et al. 2001) depending on the degree of abnormality in the sensory peripheral nerves.

CMT3/HMSN III OR DEJERINE-SOTTAS DISEASE

The terms CMT3, HMSN type III and Déjerine–Sottas disease are applied to a heterogeneous group of inherited or sporadic neuropathies (Ouvrier et al. 1987) with various ages of onset and severity. The age at onset was widely different in the two patients originally reported by Déjerine and Sottas.

There is no universal agreement as to the limits of this group, and affected patients have been shown to have mutations of genes causing other forms of CMT, but it remains a useful clinical concept. There is considerable genetic heterogeneity, with dominant and/or recessive mutations in PMP22, MPZ, EGR2, GJB1, CNTNAP1 and PRX described. Pathologically, nerve alterations are reminiscent of those in type I but they are more intense. There is a marked decrease of myelinated fibres, especially the larger ones. Onion bulbs are well formed but often consist of double basement membrane lamellae, and the ratio of the axon diameter to the total fibre diameter is higher than normal, indicating hypomyelination. In some cases, there is massive interstitial collagen hypertrophy.

Classic Phenotype

The most typical form (Ouvrier et al. 1987) has an early onset, with slow motor development and hypotonia commonly present during the first year of life. Ambulation is delayed in 30–50% of patients. Weakness is more profound and more diffuse than in type I cases and frequently involves the proximal muscles. Ataxia is consistently present and the weakness may be asymmetrical. Prominent eyes with thickening and eversion of the lips are a not uncommon feature, particularly with PMP22 mutations. Pupillary abnormalities and even an Argyll Robertson pupil are occasionally observed. In older patients, tendon reflexes are abolished and nerve hypertrophy is frequent. The course tends to be more severe than in CMT1 and CMT2, but not greatly so, although a few patients are incapable of independent walking by adolescence. Nerve conduction velocities are severely diminished to below 10m/s or cannot be recorded.

Congenital Hypomyelinating Neuropathy

The congenital hypomyelinating neuropathies are usually considered a form of CMT3. Guzzetta et al. (1982) distinguished two groups of congenital cases. A severe form that may resemble Werdnig–Hoffmann disease with congenital hypotonia and paralysis, wasting, respiratory impairment and swallowing difficulties, and may be lethal in a few months or years. A raised cerebrospinal fluid (CSF) protein level is constant, and nerve conduction velocities are unmeasurable or extremely low. Less severe cases exist that permit survival for many years but with severe motor impairment. Some sensory impairment may be observed in the course of such cases.

The pathological picture in most cases is that of marked thinning or complete absence of myelin (amylodysic form or amylinating neuropathy) with formation of onion bulbs containing mainly rings of Schwann cell cytoplasm with little or no myelin. The molecular biological basis of the amylinating cases is poorly defined. The pathological findings have been interpreted as indicating that the process is one of deficient myelin deposition rather than demyelination–remyelination. In some cases, there is proliferation of microfilaments in Schwann cells, along with demyelination (Ulrich et al. 1981). In others, unstable myelin with infolding of myelin lamellae has been described (Peudenier et al. 1993).

Cases with congenital arthrogryposis and hypomyelinating neuropathy (Balestrini et al. 1991; Boylan et al. 1992) fall within this group and include Hirschsprung disease.
caused by SOX10 mutations (Inoue et al. 2002), and the autosomal recessive form of Pelizaeus–Merzbacher-like disease caused by GJA12 mutations (Uhlenberg et al. 2004). Recessive mutations in CNTNAP1, which encodes CASPR, have been described in non-syndromic arthrogryposis multiplex congenita (AMC). Arthrogryposis is not always present and mutations may result in a Déjerine-Sottas phenotype without AMC. Patients showed a marked reduction in motor nerve conduction velocity (<10m/s) and electron microscopy of sciatic nerve shows severe abnormalities of both nodes of Ranvier width and myelinated axons (Laquerriere et al. 2014).

Baets et al. (2011) have recently delineated the genetic basis of early-onset HMSN by testing patients on a panel of 11 common genes. Dominant mutations in PMP22, EGR2, NEFL, MPZ, MFN2, the CMT1A duplication, and recessive mutations in FGD4, MTMR2, MTMR13, PRX and SH3TC2 were shown to cause a spectrum of disease extending from neonatal hypotonia and breathing and feeding difficulties, to motor delay in the first 12 months of life.

HEREDITARY NEUROPATHY WITH LIABILITY TO PRESSURE PALSIES

Hereditary neuropathy with liability to pressure palsies (HNPP) is a dominantly inherited disease, rare in childhood, and characterised by an abnormal susceptibility to pressure palsies (Behse et al. 1972) usually with evidence of an underlying generalised neuropathy with moderate slowing of nerve conduction velocities and prolonged distal motor and sensory latencies. In most cases the disease is due to a deletion of the region of chromosome 17 that is duplicated in cases of CMT1A, probably as a result of unequal crossing-over during meiosis (Mariani et al. 1994; Verhalle et al. 1994). Some PMP22 mutations may cause a similar phenotype. Tyson et al. (1996) reported that the same genetic abnormalities may occasionally be found in cases of multifocal paralysis without pressure sensitivity, thus widening the spectrum of the disease. Affected children may develop symptoms during the first decade, although a later onset is more usual. The paralyses usually involve a single nerve trunk, especially the common peroneal nerve, following prolonged maintenance of postures such as squatting or sitting cross-legged, or the cubital nerve following pressure on the elbow. The brachial plexus, the radial nerve in the spiral groove, and the median nerve at the wrist may also be involved (Li et al. 2002). Paralysis also occurs following a brief, unusual effort such as intense physical activity, especially sport. Many patients develop a carpal tunnel syndrome of early onset, which may be clinically manifested but is present on electrophysiological examination in most cases. A few cases have had evidence of CNS involvement with lesions resembling those of multiple sclerosis on magnetic resonance imaging (MRI) (Sanahuja et al. 2005). Recovery from palsies is usually complete over a period of days to weeks, but in some cases permanent generalised motor and sensory neuropathy eventually develops.

The diagnosis is suggested by the disproportion between the minor degree of trauma and the occurrence of paralysis. The frequent presence of a similar history in relatives is virtually diagnostic. Electrophysiological examination confirms the suspicion of an underlying neuropathy by showing slowed conduction velocities outside the affected territory. Examination of family members may demonstrate a neuropathy even in the absence of attacks. Nerve biopsy, which is not necessary in most cases, can show segmental thickenings of myelin sheaths known as tomacula (Sanahuja et al. 2005). No treatment is known, but avoidance of repeated episodes that may leave sequelae may require changes in lifestyle.

DOMINANT INTERMEDIATE CMT

Davis et al. (1978) coined the term ‘dominant intermediate’ CMT (CMTDI) for families with median motor conduction velocities in the 25–45m/s range and dominant inheritance. The term has since expanded to include families that have some affected individuals with motor conduction velocities in the CMT1 range and other affected members in the CMT2 range. CMTX1, due to mutations in GJB1, also falls within this range, but is classified under X-linked CMT.

CMTDIB is caused by mutations in DNM2, the gene encoding the GTPase Dynamin 2. Onset age may vary from early childhood to the fifth decade, and some affected individuals may have rapid progression leading to wheelchair dependence. Some families have pro sis, ophthalmoplegia and cataracts (Claeys et al. 2009).

The increased incidence of glomerulosclerosis in patients with CMT has long been identified, and recently, mutations in IFN2 (inverted formin 2) have been shown to cause CMT with focal segmental glomerulosclerosis leading to end-stage renal failure (Boyer et al. 2011).

UNCOMMON NEUROPATHIES WITH MOTOR AND SENSORY INVOLVEMENT

HEREDITARY NEURALGIC AMYOTROPHY (BRACHIAL PLEXOPATHY)

This is also a dominantly inherited condition, genetically distinct from hereditary neuropathy with liability to pressure palsies. The onset is usually in the second decade, but earlier onset can occur and brachial plexus paralysis at birth may be the first manifestation. Attacks closely resemble those observed in the non-hereditary type of plexopathy. Pain may be intense and precedes weakness usually by a few days.
Weakness persists for variable periods. It is mainly proximal. Recovery takes place over a few weeks to months and is usually complete (van Alfen et al. 2000; Kuhlenbäumer et al. 2005). Occasional patients may experience phrenic nerve involvement or episodes of lumbar plexopathy (Awerbuch et al. 1989; Thomson 1993). In some cases, involvement may be limited to a single branch of the brachial plexus; for example, the long thoracic nerve with isolated palsy of the serratus anterior (Dawkins et al. 2001). The frequency of recurrences is extremely variable (Klein et al. 2002). Around 50% of families with hereditary neuralgic amyotrophy have mutations in the SEPT9 (Septin 9) gene (Kuhlenbäumer et al. 2005). In several families a particular kind of mild dysmorphism with short stature, partial syndactyly of the fingers or toes, characteristic craniofacial features with relatively closely spaced eyes, short palpebral fissures, and epicantus, and cleft uvula or palate are recognised (Jeannet et al. 2001). The dysmorphism is often related to a specific SEPT9 Arg88Trp mutation. Biopsies of involved nerves may show inflammatory infiltrates and/or acute axonal degeneration (Klein et al. 2002). Treatment is generally symptomatic but prednisolone may result in earlier improvement, especially in pain control (van Alfen et al. 2009).

THERMOSENSITIVE NEUROPATHY

Magy et al. (1997) reported on a remarkable family with intermittent episodes of extensive paralysis precipitated by body temperature elevations above 38.5°C with onset in childhood or adolescence, and not allelic to CMT1 or hereditary pressure-sensitive neuropathy. Another patient with HNPP, who developed bilateral peroneal nerve palsies associated with fever, with gradual improvement has recently been described (Pisciotta et al. 2011). It is hypothesised that the raised temperature causes conduction failure by altering the properties of ion channels in the paranode and internode.

HEREDITARY SENSORY AND AUTONOMIC NEUROPATHIES

The hereditary sensory and autonomic neuropathies (HSAN), also called the hereditary sensory neuropathies, are characterised by sensory (and autonomic) nerve involvement with relative sparing of the motor axons. The loss of pain sensation results in mutilating distal ulcers, delayed wound healing, Charcot joints, osteomyelitis and amputations. The unexplained injuries in young children with sensory neuropathy can simulate child abuse (Makari et al. 1994). Pain insensitivity is not however always caused by a neuropathy, with mutations in the voltage-gated sodium channel genes causing congenital insensitivity to pain and other related phenotypes.

HSAN1
(SENSORY RADICULAR NEUROPATHY)

HSAN1 differs from all other HSANs in that the symptoms appear late, usually after the first decade, rather than in infancy. The transmission is autosomal dominant. The gene for the classic form, SPTLC1 (serine palmitoyltransferase long chain subunit 1), is involved in phospholipid biosynthesis and maps to 9q22.1–q22.3 (Dawkins et al. 2001). Symptoms appear in late childhood or adolescence with a progressive loss of sensation in the lower extremities, rapidly complicated by episodes of cellulitis and trophic ulcerations of the feet. Spontaneous stabbing pain may occur. There is loss of pain and temperature sensation with preservation of tactile sensation. Later, all sensation may disappear and the distal upper limbs may become involved. Sensorineural deafness is often present. Peroneal weakness often eventually develops. Motor nerve conduction velocities are mildly slow, and sensory action potentials are absent. The course is slowly progressive. Pathological examination shows a marked reduction in the number of unmyelinated fibres. Small and large myelinated fibres are decreased to a smaller but quite significant extent. The dorsal root ganglia and the spinal dorsal roots supplying the lower limbs are degenerate. Mutations in the gene for subunit 2 of the same enzyme SPTLC2 on chromosome 14q24 cause a phenotypically similar neuropathy without autonomic signs, designated HSAN1C. The mutations cause an alteration in the substrate specificity of the enzyme, and the accumulation of toxic deoxysphingolipids that are neurotoxic in vitro (Rothier et al. 2010). An l-serine enriched diet has shown improvement in a mouse model of the disease (Garofalo et al. 2011).

RAB7 mutations may cause a similar picture or a more typical CMT phenotype (CMT2B). Another similar autosomal dominant entity with later onset and prominent symptoms of gastro-oesophageal reflux and cough has been localised to 3p22–p24 (Kok et al. 2003). HSAN1D is caused by mutations in ATL1 (Atlastin GTPase 1) and is characterised by an adult onset of distal sensory axonal neuropathy (Guelly et al. 2011). Some patients have upper motor neuron involvement and ATL1 also causes spastic paraplegia 3A (SPG3A). HSAN1E is caused by mutations in DNMT1 (DNA methyltransferase 1), and characterised by a sensory neuropathy, dementia and hearing loss (Klein et al. 2011a).

HSAN2
(CONGENITAL SENSORY NEUROPATHY)

This is an autosomal recessive condition, caused by mutations in the WNK1 (with-no-lysine K-1) gene, with a congenital or
early onset (Shekarabi et al. 2008). Clinically, most patients have a universal absence of pain sensation resulting in burns and mutilations of the lips or fingertips and in painless fractures, especially of the metatarsals. Tactile sensation is also markedly impaired. Areas of normal sensation are preserved in some patients in whom the limbs and face are predominantly affected. Bladder sensation may be impaired with bladder distension (Verity et al. 1982). Deafness has been described in some patients. In most patients, the disease does not seem progressive or is only very slowly evolving (Ferreire et al. 1992). Motor conduction velocities are preserved but sensory action potentials are unobtainable. Cortical evoked somatosensory potentials were lacking in the lower limbs in some patients. Nerve biopsy often shows grossly atrophic nerves. Myelinated axons are severely reduced in number, but unmyelinated fibres are usually normal or at least not greatly diminished.

HSAN3 (FAMILIAL DYSAUTONOMIA OR RILEY-DAY SYNDROME)

HSAN3 is the most common of the sensory and autonomic neuropathies. The disorder is prevalent among Ashkenazi Jews, in whom the disease frequency is between 0.5 and one per 10,000 live births with an estimated carrier frequency of one in 50. Scattered case reports on non-Jewish patients can be found (Guzzetta et al. 1986). The disorder is transmitted as an autosomal recessive trait caused by mutations of the \textit{IKBKGAP} (inhibitor of kappa light polypeptide gene enhancer in B-cells, kinase complex-associated protein) gene, which maps to chromosome 9q31 (Slaugenhaupt et al. 2001). Histopathological findings include loss of neurons in the posterior root, Lissauer tract and intermediolateral grey columns (Pearson et al. 1978) and loss of unmyelinated and myelinated fibres in peripheral nerves where catecholamine endings are lacking (Pearson et al. 1974). Substance P-immune reactivity in the substantia gelatinosa of the spinal cord and in the medulla is consistently depleted (Pearson et al. 1982). Sympathetic ganglia are hypoplastic.

Clinical manifestations are mainly referable to the autonomic nervous system. Onset is congenital, and hypotonia, sucking difficulties, a poor cry and vomiting are present from birth. Growth retardation becomes evident later in life. Patients do not have overflow tears. Skin blotching, motor incoordination, unstable temperature and blood pressure, cyclic vomiting and drooling are variably present. Relative indifference to pain is usual (Axelrod et al. 1981). Temperature perception, sweating and cutaneous innervation have been studied by Hilz et al. (2004). Bouts of apnoea and pneumonia are common and are a usual cause of death in infancy and childhood. Oesophageal dilatation and impaired gastric motility are frequent findings. Postural hypotension is almost always present. Scoliosis is a major problem. The gag reflex is often poor. Diagnostic criteria include the absence of fungiform papillae on the tongue, diminished or absent deep tendon reflexes, lack of overflow tears, miosis following instillation of 2.5% metacholine chloride in the eyes and lack of an axon flare after intradermal histamine injection (Axelrod et al. 1974). None of these criteria is individually characteristic, and any of them can be found in other sensory neuropathies. Prenatal diagnosis is possible.

The course of familial dysautonomia is severe; in the early studies in the 1960s only 20% of patients survived to adulthood, although by the 1980s due to improvements in management this proportion had risen to 50% (Axelrod and Abularrage 1982). Digestive and respiratory complications are common and may be aggravated by the frequent occurrence of kyphoscoliosis. Emotional lability with repeated severe breath-holding spells is common. Intelligence remains normal. Treatment is symptomatic. The risk of aspiration pneumonia should be minimised by attention to posture and by meticulous precautions during feeding that may necessitate gavage, gastrostomy or fundoplication. Diazepam is effective in association with chlorpromazine for the treatment of acute crises and of hypertension. The management of scoliosis is difficult and only partial surgical correction of the curve can be achieved in many patients (Kaplan et al. 1997). Families of affected children need considerable psychological support.

HSAN4 (CONGENITAL INSENSITIVITY TO PAIN WITH ANHIDROSIS)

This rare disorder is caused by mutations in \textit{NTRK1}, which encodes TrkA, a nerve growth factor receptor. The condition is also known as congenital insensitivity to pain with anhidrosis and is a congenital neuronopathy with episodes of unexplained fever often related to environmental temperature and absence of sweating (anhidrosis). Insensitivity to pain is universal and leads to injuries, self-mutilation and osteomyelitis, especially of the lower extremities. Tongue biting is frequent. Blotching of the skin and pupillary hypersensitivity to metacholine chloride occur (Axelrod and Pearson 1984). Intellectual disability is the rule, measured IQ scores having varied from 41 to 78, the majority being in the sixties (Rosenberg et al. 1994). Motor and sensory nerve conduction velocities are normal or near normal. There is complete absence of unmyelinated and small myelinated nerve fibres in peripheral nerves (Goebel et al. 1980). The Lissauer tract and dorsal spinal roots are also affected.

HSAN5

HSAN5 presents as a congenital insensitivity to pain with decreased thermal sensitivity but with preservation of response to tactile and mechanical stimuli and retention of the deep tendon reflexes (Low et al. 1978). It is caused by mutations in the coding region of the \textit{NGFβ} (nerve growth factor beta
receptor) gene (Einarsdottir et al. 2004) that codes for nerve growth factor, the principal ligand for the TrkA receptor. The condition has been described in a single family, and is phenotypically similar to HSAN4, though patients may retain some pain sensation and have normal intelligence. It is characterised pathologically by an almost complete disappearance of small myelinated fibres and a moderate decrease of unmyelinated fibres. Routine motor and sensory nerve conduction studies are normal.

OTHER FORMS OF HSAN WITH INSENSITIVITY OR INDIFFERENCE TO PAIN

Several rare and/or controversial types of HSAN have been described. Additional types include HSAN with growth hormone deficiency (Libeरfarb et al. 1993), progressive pan-neuropathy with hypotension (Axelrod and Pearson 1984), congenital sensory neuropathy with ichthyosis and anterior chamber syndrome (Quinlivan et al. 1993), deafness, sensory neuropathy and ovarian agenesis (Linsen et al. 1994), and HSAN with cataracts, intellectual disability and skin lesions (Heckmann et al. 1995). HSAN associated with spastic paraplegia is caused by mutations in the CCT5 (cytosolic chaperonin-containing t-complex peptide-1) gene (Bouhouche et al. 2006). The acromutilating sensory neuropathy described in Navajo children, and rarely in other ethnic groups, is a mitochondrial depletion syndrome caused by recessive mutations in MPV17 (Spinazzola et al. 2006). The unexplained injuries in young children with sensory neuropathy can simulate child abuse (Makari et al. 1994).

The term insensitivity to pain in principle applies to patients in whom analgesia is the result of abnormalities of peripheral nerves, cutaneous nerve endings or central sensory pathways, whereas indifference to pain applies to those who have normal sensory pathways but fail to appreciate the painful nature of stimuli (Manfredi et al. 1981). Such a distinction may well be artificial, and Dyck et al. (1983) have emphasised the fact that precise analysis of cases of indifference to pain shows abnormalities of the peripheral sensory system when sophisticated methods are used. The term ‘congenital insensitivity to pain’ (CIP) is now used to describe all cases with absence of pain perception, irrespective of whether there is an abnormality in the number of myelinated or unmyelinated sensory fibres.

Recently, mutations in a number of genes encoding for sensory nerve ion channels have been shown to cause insensitivity to, or increased perception of pain (Bennett and Woods 2014). Autosomal recessive loss of function mutations in SCN9A, encoding voltage-gated sodium channel NaV 1.7; and rarely dominant gain of function mutations in SCN1A (NaV 1.9), CIP (Cox et al. 2006; Leipold et al. 2013). CIP is characterised by absence of nociceptive pain all over the body, congenital anosmia (in those with SCN9A mutations) and normal intelligence. Affected children chew their lips, tongue and fingers resulting in disfiguring injuries. Bruises, burns and scalds are common in the first decade. Large fibre sensations including vibration and proprioception remain normal and there is no autonomic dysfunction. Sural nerve biopsies are normal. Inherited erythromelalgia, characterised by episodic pain and erythema of the hands and feet, is caused by dominant gain of function mutations in SCN9A (Yang et al. 2004).

Paroxysmal extreme pain disorder (also known as familial rectal pain) is characterised by severe perineal and rectal, ocular or mandibular pain, often triggered by eating, defecation or emotional factors, and may be associated with other autonomic symptoms. It is caused by dominant gain of function mutations in SCN9A (Fertleman et al. 2006). Gain of function missense variants in SCN9A and SCN10A have been identified in a significant number of individuals with small fibre neuropathy (Fabre et al. 2012a, b). Finally, dominant gain of function mutations in TRPA1, which encodes the TRP channel TRPA1, and in SCN11A, have been identified in kindreds with familial episodic pain syndromes (Kremeyer et al. 2010; Zhang et al. 2013). Gabapentin, pregabalin, carbamazepine and mexiletine are currently used for the treatment of chronic pain associated with these ion channel mutations, but have limited efficacy. Specific sodium channel antagonists are in human trials.

The restless legs syndrome, which is a special type of sensory neuropathy frequent in adults, also exists in children (Kotagal and Silber 2004). The related syndrome of periodic limb movements in sleep has its onset before 10 years of age in 20% of cases.

RECOMMENDATIONS FOR GENETIC TESTING IN CMT

Classically, CMT and related disorders are classified on the basis of inheritance and nerve conduction tests and this classification is used to direct genetic testing. However, there are now more than 60 genes known to cause CMT and related disorders, and with mutations in the same gene sometimes causing different phenotypes and having different modes of inheritance, identifying the causative gene by traditional Sanger sequencing can be a time consuming and costly process, especially for rarer genetic causes. In specialist neuropa-thy clinics, around 62–67% of those with CMT will receive a genetic diagnosis (Saporta et al. 2011; Murphy et al. 2012). More than 90% of CMT where the molecular diagnosis is known, is caused by mutations in four genes (PMP22 including CMT1A caused by the 17p duplication, GJB1, MPZ and MFN2). The other genes individually make up less than 1% of genetically classified CMT.

There are flowcharts now available that help the clinician prioritise genes for sequencing (Saporta et al. 2011). In CMT1, especially with homogeneously reduced motor conduction velocities, testing for CMT1A should be done initially; this is usually done by MLPA or CGH microarrays.
the other common genes is then done on basis of nerve conduction findings and inheritance. However, next-generation sequencing technologies including neuropathy-specific panels, whole exome sequencing (WES) and whole genome sequencing (WGS) hold promise as faster and cheaper alternatives. Where appropriate, CMT1A should be excluded prior to the use of these techniques and many next-generation technologies may miss large deletions (though this is expected to change in the near future). It is then recommended that, if available, testing be done on a neuropathy-specific panel, as these are often optimised for complete coverage of the known neuropathy-causing genes. WES and WGS have been used successfully for the identification of novel disease-causing genes and phenotypes, but incomplete coverage of some neuropathy genes could cause disease-causing mutations to be missed in the clinical setting, though this situation is changing rapidly (Rossor et al. 2013).

Once common genetic causes have been excluded, patients should be referred to a specialised neuropathy clinic for assessment and diagnosis. As always, detailed family history, accurate clinical assessment and nerve conduction studies remain cornerstones of diagnosis, as they are often required to select among the many variants identified during next-generation sequencing.

### COMPLEX NEUROPATHIES ASSOCIATED WITH CENTRAL NERVOUS SYSTEM INVOLVEMENT AND METABOLIC NEUROPATHIES

Hereditary neuropathies may constitute a part of more complex neurological diseases involving the CNS (Table 25.2). Friedreich ataxia, a common cause of neuropathy with CNS involvement, is reviewed in Chapter 10.

### HEREDITARY MOTOR AND SENSORY NEUROPATHY WITH CNS INVOLVEMENT

‘Complicated’ forms of CMT/HMSN have been recognised that are associated with spasticity (HMSN V), optic atrophy (HMSN VI) and retinitis pigmentosa (HMSN VII) (Klein and Dyck 2005). HMSN type V features pyramidal tract signs associated with a motor and sensory neuropathy. This group includes a number of forms of complicated hereditary spastic paraplegia, many of which have an associated axonal neuropathy. Some families with HMSN V have mutations in MFN2 (Zhu et al. 2005). KIF5A mutations also cause a spectrum of disease from spastic paraplegia to CMT2 (Liu et al. 2014). The association of optic atrophy with CMT2, previously designated HMSN VI, is also caused by mutations in MFN2 (Zuchner et al. 2006). Periventricular white matter change may also be seen with MFN2 mutations (Chung et al. 2006). Mutations in the mitochondrial gene MTATP6 are the cause for neuropathy, ataxia, retinitis pigmentosa (NARP) syndrome. Recently, mutations in MTATP6 have been shown to be a rare cause of genetically undefined CMT2 (Pitceathly et al. 2012). HMSN IV or HMSN with phytic acid excess is Refsum disease.

Polyneuropathy can also be associated with optic-ocoustic degeneration as seen with syndromic causes such as CMTX5 (Rosenberg and Chutorian 1967) and riboflavin transporter deficiency as well as with sensorineural deafness in CMT due to mutations in GJB1, MPZ, PMP2 and NDRG1 and sometimes with HSAN types I and II (Hamiel et al. 1993; Stojkovic et al. 1999; Kalaydjieva et al. 2000).

Palmar–plantar keratoderma has been described in association with CMT (Tolmie et al. 1988) and with spastic paraplegia (Fitzsimmons et al. 1983; Isidor et al. 2013). The syndrome of cerebral dysgenesis, neuropathy, ichthyosis, and palmoplantar keratoderma is caused by a mutation in SNAP29 (Sprecher et al. 2005). Wright and Dyck (1995) described early-onset dementia and deafness in association with HSAN I. This has since been shown to be due to DNMT1 mutations (HSAN1E) (Klein et al. 2011a). Axonal neuropathy associated with juvenile parkinsonism and ophthalmoplegia is on record (van der Wiel and Staal 1981). Patients with SPG11 mutations, causing autosomal recessive hereditary spastic paraplegia with thin corpus callosum have been described with juvenile parkinsonism and an axonal neuropathy (Anheim et al. 2009). Axonal neuropathy may also be seen during the treatment of parkinsonism with levodopa. Neuropathy, early-onset parkinsonism and ophthalmoplegia may be seen in the mitochondrial depletion syndrome caused by POLG mutations. A special form of congenital neuropathy, with associated osseous fragility, intellectual disability and CNS involvement has been reported in one family by Neumann et al. (1976).

### GIANT AXONAL NEUROPATHY

This condition is characterised pathologically by the presence of massive axonal enlargements filled with neurofilaments. Normal sized axons may be demyelinated and show ‘onion bulb’ structures. The disease probably represents a disorder of cytoplasmic intermediate filament formation affecting both the peripheral and CNS (Treiber-Held et al. 1994). It is transmitted as an autosomal recessive trait. The affected gene, GAN, encoding gigaxonin, maps to chromosome 16q24 (Bomont et al. 2000).

The onset is in the first few years of life with motor deficit and areflexia. Progressive deterioration with ataxia, distal weakness and slow dementia ensue. Patients are usually wheelchair-dependent by late adolescence and many die in the third decade. Orthopaedic deformities include scoliosis and deformed feet.
Sensory abnormalities are usually present (Ouvrier 1989). Cranial nerves may be involved, and variable intellectual disability is the rule. System degenerations may be associated (Ben Hamida et al. 1990), and diffuse involvement with endocrinological abnormalities has been reported (Takebe et al. 1981).

One remarkable feature is the presence of ‘frizzy’ or ‘woolly’ hair (Treibert-Held et al. 1994), although milder variants, including the not-infrequent cases with absence of the characteristic ‘woolly’ hair have been described (Bruno et al. 2004).

Motor nerve conduction velocities are sometimes slowed and sensory action potentials are often absent. The EEG is often disorganised with increased slow activity and/or spike discharges, and brainstem auditory evoked potentials are altered. On MRI, a high signal from white matter may be present on T2 sequences.

**REFSUM DISEASE (HMSN IV) (HEREDOPATHIA ATACTICA POLYNEURITIFORMIS)**

Classic Refsum disease is rare in childhood, although some manifestations of the condition may appear early or even be congenital, e.g. bone deformities, especially short metatarsals (Skjeldal et al. 1987). Although Dyck classified Refsum disease as type IV of the HMSN5s, the condition deserves a special place because of its well-established metabolic disturbance, its remarkable symptomatology and its partially treatable nature. The disease is caused by an abnormal accumulation of phytanic acid (a C16 branched-chain fatty acid) whose beta-oxidation is blocked due to phytanic oxidase deficiency. Most phytanic acid...
is of exogenous origin so that reduction of intake, sometimes in association with plasma exchanges (Gibbend et al. 1985; Dickson et al. 1989), results in lowering of abnormally high plasma levels when patients are placed on a phytol-free diet. This treatment is accompanied by increased nerve conduction velocity, return of reflexes, and sensory and motor improvement.

The clinical manifestations of Refsum disease usually begin after 4–7 years of age but are often recognised much later as the progression of the disorder is slow. A few patients have presented in infancy with neurological features (Herbert and Clayton 1994). The picture is one of a chronic but sometimes fluctuating or remittent peripheral neuropathy in which the clinical expression is very variable (Skjeldal et al. 1987). A chronic relapsing picture and even an axonal neuropathy have been reported (Gelot et al. 1995). Ataxia is often marked. Atypical retinitis pigmentosa is present and hemeralopia (night blindness) may be the first symptom. Anosmia, deafness, ichthyosis and disorders of cardiac function are common. Nerve conduction velocities are usually markedly reduced, keeping with the pathological findings of a hypertrophic demyelinating neuropathy with large onion bulb formation. The CSF protein level is more than 1g/L but there is no excess of cells. The diagnosis can be confirmed by measurement of the plasma level of phytic acid, which is considerably increased (300–1600µmol/L instead of <10µmol/L). Mutations of the PHYH gene on chromosome 10p13 are responsible. This gene encodes for phytanoyl Co-A hydroxylase. Mutations of a second gene, PEX7, on chromosome 6q22–24 cause a mild form of the disorder (van den Brink et al. 2003).

A number of metabolic diseases feature a neuropathy that may be overshadowed by other neurological or systemic manifestations but may occasionally be the predominant or presenting feature. The main disorders in this group are shown in Table 25.2 and discussed below and in other chapters.

In some cases of metachromatic leukodystrophy, involvement of the peripheral nerves may be the only manifestation for periods of up to several months. Neuropathy with absence of deep tendon reflexes is common in Krabbe disease and has been reported in sialidosis type 1 (Steinman et al. 1980). Neuropathy due to inherited disorders of porphyrin metabolism is very rare in childhood. It can be observed with four diseases: variegate porphyria due to deficiency of protoporphyrinogen oxidase, acute intermittent porphyrina due to deficiency of porphobilinogen deaminase, hereditary coproporphyria due to deficient coproporphyrinogen oxidase, and delta-aminolaevulinic aciduria. These diseases are transmitted as autosomal dominant traits with variable penetrance. Prepubertal cases may occur. The symptoms and signs are similar to those in adult patients and are similar in the three types, except for the presence of photosensitivity in variegate porphyria and coproporphyria. The polynueopathy can involve both the lower and the upper limbs (Simon and Herkes 2011). The weakness is both proximal and distal and may involve the respiratory muscles. The neuropathy is a predominantly motor axonal neuropathy and sensory involvement is minimal. Acute attacks of colicky abdominal pain, dysautonomic signs such as hypertension, and psychiatric disturbances may be observed. Most cases remain asymptomatic. Bouts of paralysis are often precipitated by administration of drugs, especially barbiturates but also several antibiotics, oral contraceptives, oestro gens, imipramine and methyldopa, among others (Crimlisk 1997). Seizures may be more frequent in children than in adults, and this is of considerable importance as antiepileptic drugs including phenytoin, carbamazepine, ethosuximide and sodium valproate, and also some anaesthetic agents can also trigger attacks. Paraldehyde and chloral hydrate can be safely used, while gabapentin (Tatum and Zachariah 1995), magnesium sulphate (Sadeh et al. 1991) and levetiracetam (Zaatreh 2005) have also been reported to be safe.

The diagnosis is confirmed by the finding of an increased urinary excretion of porphobilinogen and delta-aminolaevulinic acid. Between attacks, excretion of these compounds may be

BROWN-VIALETTA-VAN LAERE SYNDROME DUE TO RIBOFLAVIN TRANSPORTER DEFICIENCY

Brown-Vialetto-Van Laere syndrome (BVVL) is characterised by a progressive pontobulbar palsy, sensorineural hearing loss and muscle weakness (Sathasivam 2008). Recently, homozygous and compound heterozygous mutations in the genes encoding the riboflavin transporters RFVT2 and RFVT3 have been identified in a significant number of patients with BVVL (Green et al. 2010; Johnson et al. 2012). There are three known riboflavin transporters. RFVT1, encoded by SLC52A1, and RFVT3, encoded by SLC52A3, are both responsible for riboflavin transport across the small intestine, while RFVT2, encoded by SLC52A2, is a neuronal riboflavin transporter (Yonezawa and Inui 2013).

Affected individuals with RFVT3 deficiency have sensorineural hearing loss, generalised lower limb predominant muscle weakness, bulbar weakness and tongue fasciculations, and respiratory weakness (Green et al. 2010). The phenotype of RFVT2 deficiency differs from that of RFVT3, with childhood onset of sensory ataxia (due to a sensory ganglionopathy) and sensorineural hearing loss. Affected individuals develop muscle weakness limited to the upper limbs, causing a ‘child-in-the-barrel’ phenotype (Foley et al. 2014). There is elevation of the medium-chain acylcarnitines on acylcarnitine profile, and this may be a useful screening test, though a number of affected children with normal acylcarnitine profiles have been described. It is important to recognise these phenotypes, as treatment with high-dose riboflavin (30–50mg/kg/day) results in stabilisation or improvement of the phenotype.

OTHER NEUROPATHIES WITH A KNOWN METABOLIC ABNORMALITY

A number of metabolic diseases feature a neuropathy that may be overshadowed by other neurological or systemic manifestations but may occasionally be the predominant or presenting feature. The main disorders in this group are shown in Table 25.2 and discussed below and in other chapters.
absent. Assay of erythrocyte porphobilinogen deaminase is the most accurate way of detecting acute intermittent porphyria, which is often signalled by a red discolouration of urine. Treatment includes prevention of attacks by avoidance of precipitating drugs. During attacks, intravenous haem in the form of haematin or haem arginate (3–4mg/kg/day for 4 days) should be given (Simon and Herkes 2011). Side effects (thrombophlebitis, coagulopathy) are frequent. Haem arginate (Crimlisk 1997) seems both effective and well tolerated. Avoidance of skin trauma and light is important only in variegated porphyria, in which transient polyneuritis is accompanied by increased skin sensitivity.

**Abetalipoproteinaemia (Bassen–Kornzweig disease)** or hypobetalipoproteinemia are autosomal recessive disorders of the synthesis of the beta-lipoprotein due to mutations of the MTTP (microsomal triglyceride transfer protein) or APOB genes respectively (Hooper and Burnett 2014; Lee and Hegele 2014). As a consequence, fat absorption is deficient. Lipids are not transported from the intestinal mucosal cells into the lymphatic system, because beta-lipoproteins are necessary for the formation of chylomicrons. Fat-soluble vitamins are also poorly absorbed, and levels of vitamins A and E in the serum are quite low. Neurological symptoms are the result of the deficit in vitamin E, resulting in peroxidation of the unsaturated myelin phospholipids. Pathologically, there is extensive demyelination of the posterior columns and spino-cerebellar tracts, with severe deprevement and segmental demyelination of large myelinated fibres in peripheral nerves and posterior roots. Involvement of the anterior horn cells and cerebellar cortex has been reported (Kane and Havel 1995).

The neurological picture is one of spino-cerebellar degeneration with progressive ataxia, loss of tendon reflexes, disturbances of deep sensation and pes cavus in association with pigmentary retinal degeneration that gives rise to decreased visual acuity and night blindness. Paralysis of vertical gaze is a frequent feature. Muscle weakness and atrophy may supervene. Indeed, the picture is highly suggestive of a primary spino-cerebellar degeneration and it is likely that many cases reported as Friedrich ataxia with retinitis pigmentosa were in fact cases of abetalipoproteinemia. Neurological manifestations may appear as early as 2 years of age and one-third of patients are symptomatic by 10 years. About the same proportion of patients have intellectual disability. A history of ‘coeliac syndrome’ during the first year of life with foul, bulky stools and abdominal distension is usually obtained, and most children exhibit growth retardation. The diagnosis rests on the presence of retinal lesions with an extinguished electoretinogram, on the finding of low serum cholesterol, triglycerides and vitamin E levels, on the presence of acanthocytosis on blood smears, and ultimately on low or absent apoB levels. The diagnosis can be confirmed on sequencing for MTTP and APOB mutations. EMG may show evidence of denervation, while sensory nerve action potentials and conduction velocities are diminished. Abetalipoproteinemia is a treatable condition, and is managed with dietary modification and supplementation of fat-soluble vitamins. The dietary fat intake is restricted to less than 30% of total caloric intake, particularly long-chain fatty acids, and medium-chain triglycerides are supplemented. The diet which is also supplemented with high-dose vitamin E (100–300mg/kg/day orally) prevents the development or progression of eye and nervous disease (Kane and Havel 1995; Lee and Hegele 2014). Intramuscular vitamin E is not superior. Administration of vitamin A (200–400IU/kg/day) and vitamin K1 (5mg every 2 weeks) is also advised.

Acanthocytosis is also observed in another dominantly inherited condition, known as **amyotrophic choreoacanthocytosis**, which includes symptoms of basal ganglia dysfunction, peripheral nerve involvement and other neurological features but is observed mostly in adults (Spencer et al. 1987), and in pantotenate kinase-associated neurodegeneration (PKAN)(see Chapter 19).

Vitamin E deficiency may be due, in addition to absence of betalipoproteins, to biliary insufficiency that prevents normal emulsion of fat in the bowel lumen and results in poor absorption, in association with steatorrhoea (Harding et al. 1982; Spencer et al. 1987). A similar result has been observed in a case of intestinal lymphangiectasia (Gutmann et al. 1986). The clinical picture, indistinguishable from that observed with abetalipoproteinemia, is observed in children with chronic liver disease, especially ductular hypoplasia (Sokol et al. 1985). The condition is amenable to the same therapy as abetalipoproteinemia.

Rare cases of a similar syndrome (Ataxia with vitamin E deficiency; AVED: Familial isolated vitamin E deficiency) mimicking spino-cerebellar degeneration have been described in children without liver disease or apparent fat malabsorption (Burck et al. 1981; Harding et al. 1985; Stumpf et al. 1987). For unknown reasons, these patients do not have retinopathy or ophthalmoplegia. This disorder is relatively frequent in Tunisia and results from mutations of the gene encoding the alpha-tocopherol transfer protein (Gotoda et al. 1995; Hentati et al. 1996).

**Tangier disease** is a rare condition characterised by a decrease of high-density lipoproteins and a low cholesterol level. Accumulation of cholesterol esters in Schwann cells produces a sensorimotor neuropathy that may remain subclinical. Two main syndromes are seen: a pseudosyringomyelic syndrome and a multiple mononeuropathy.

Neuropathies are a major manifestation of the various types of amyloidosis but this condition is exceptional before adulthood (Benson 2001).

**MITOCHONDRIAL NEUROPATHIES**

Mutations in genes responsible for mitochondrial fission, fusion and axonal transport, as with **MFN2** and **GDAP1** mutations, are known to cause CMT.

Recently, mutations in mitochondrial and nuclear genes encoding mitochondrial function, and usually causing classic multisystemic mitochondrial disease, have been shown to present with or cause predominantly a peripheral neuropathy (Pitcearthly et al. 2012; Echaniz-Laguna et al. 2013). A third of
Acquired neuropathies are most often inflammatory in origin but various toxins and undetermined processes may also cause them. Inflammatory disorders of the peripheral nervous system include two groups of diffuse diseases: the acute polyneuropathies, also termed polyradiculoneuropathies, and the much less common chronic progressive polyneuropathies. Localised inflammatory neuropathies are relatively common, although their mechanisms are poorly known.

**ACQUIRED DIFFUSE NEUROPATHIES**

Acute inflammatory neuropathies are among the most common acquired peripheral neuropathies. They are generally classified as either axonal or demyelinating, but there is often an overlap. Axonal neuropathies are characterised by the loss of axons, resulting in a reduction of conduction velocity and motor function. Demyelinating neuropathies, on the other hand, are characterised by the destruction of the myelin sheath, which results in a slower conduction velocity and often a more symmetrical involvement of the limbs.

Guillain–Barré syndrome (GBS) is the prototype of the acute inflammatory neuropathies. It is an acquired immune-mediated disorder that results in a rapid onset of ascending weakness and areflexia. The pathological changes seen in the acute inflammatory neuropathies are associated with the presence of immunoglobulins and complement on the outside of the associated Schwann cell. Interruption of the axon and the body of Schwann cells. Other cases develop vesicular myelin breakdown with the formation of a ‘soap-bubble appearance’ (Hafer-Macko et al. 1996). This appearance is associated with the presence of immunoglobulins and complement on the outside of the associated Schwann cell. In a minority of cases, macrophage-associated demyelination occurs despite a paucity of lymphocytes. These cases may be due to the action of an antibody rather than a T-cell autoimmune process (Honavar et al. 1991). Interruption of the axons with subsequent wallerian degeneration is present only in the most severe cases with intense inflammation. Proliferation of Schwann cells occurs later in the disease, probably as a first step in the remyelination process.

In the axonal forms, AMAN and AMSAN, Wallerian-like degeneration predominates with little evidence of demyelination or lymphocyte infiltration. In AMAN, sensory axons are largely spared. Apart from the axonal degenerative changes, the motor neurons show chromatolysis (Griffin et al. 1995; Visser et al. 1995).

**Pathogenesis**

The pathological changes seen in the acute inflammatory demyelinating form of GBS (AIDP) resemble those of acute allergic neuritis produced in experimental animals by immunisation with homogenates of peripheral nerves or heterologous myelin as well as by passive transfer of T cells activated to myelin proteins or peptides. In humans, both humoral and cellular factors play a role. Intraneuronal injection of sera from GBS patients produces demyelination in animals (Feasby et al. 1982). Anti-myelin antibodies have been demonstrated in GBS patients by fixation of the C1 component of complement and are especially high at onset of the disease (Koski et al. 1986). Some antibodies have been found in myelin sheaths and on Schwann cells but no single antigen has been identified in AIDP cases. Activated complement components C3a and C5a have been found in CSF (Hartung et al. 1987). The most attractive hypothesis remains that a pathogenic agent may damage the Schwann cell and myelin, with release of antigens triggering a cascade of events leading to segmental demyelination which, in turn, is responsible for multiple conduction...
blocks (Sumner 1981) that are the electrophysiological basis of the clinical manifestations of GBS. Molecular mimicry involving antigens shared between cell wall/capsular lipopolysaccharide or oligosaccharide of antecedent infective organisms and similar targets on the axons is a key element in the axonal forms of GBS. Several Campylobacter jejuni serotypes are associated with GBS, particularly Penner type HS/O19.

IgG anti-ganglioside antibodies to GM1, GQ1b, GD1a and GT1a, either as monomers or complexes, are associated with a number of the clinical variants of GBS. High titres of antibodies against gangliosides GM1 and GD1a are found in AMAN and AMSAN, especially when associated with Campylobacter infection (Gregson et al. 1993; Vriesendorp et al. 1993). More than 85% of Miller Fisher syndrome cases (see the Clinical Variants of the Guillain–Barré Syndrome and Related Disorders section) have anti-GQ1b antibodies (Yuki et al. 1993). The extraocular nerves, somatic nerve nodes of Ranvier and dorsal root ganglion cells bind anti-GQ1b antibodies, possibly explaining the specificity of the clinical manifestations. These antibodies are also found in AIDP with opthalmoplegia. Antibodies to GQ1b and GM1 have been shown to block neuromuscular transmission in vitro. Anti-GM1 antibodies interfere with nodal ion channel function (Takigawa et al. 1995). These findings may explain the rapid changes in strength sometimes seen early in the disorder and in response to immunoglobulin therapy.

Epidemiology

GBS occurs usually in children over 3–4 years of age but cases of early and even neonatal onset (al-Qudah et al. 1988) are on record. The overall frequency of GBS is 1.9 cases per 100,000 population (Larsen et al. 1985). The incidence was approximately 0.8 per 100,000 per annum in Australian children aged less than 15 years (Morris et al. 2003). The disease usually follows infection or immunisation by 2–4 weeks (Jones 1996). Among the identified infectious agents, a firm connection has been established with CMV, EBV, mycoplasma and C. jejuni (Jacobs et al. 1998; Hadden et al. 2001). Poliovirus infection is not a cause (Rantala et al. 1994) although Zika virus is. C. jejuni infection, often with diarrhoea, is the most common infection preceding GBS and, even more so, the Miller Fisher variant (Jones 1996). There has been no proven association with poliomyelitis, tetanus or measles immunisation, though a weak association with influenza vaccination has been recently reported, though greatly outweighed by the benefits from immunisation (Haber et al. 2009; Khandaker et al. 2012; Dodd et al. 2013).

Clinical Features of Guillain–Barré Syndrome

The onset of GBS is usually fairly rapid with symmetrical bilateral weakness generally affecting the lower limbs. The paralyses then follow an ascending course. Paralysis is generalised in half the cases, predominates in the distal parts of the limbs in 30%, and is rather symmetrical, although minor differences are not uncommon and gross asymmetry has been reported in rare patients (Jones 1996). Predominantly proximal involvement is present in 20% of cases. Neck, back, buttock and leg pain is often prominent at onset, and is important to recognise as an early presenting feature of GBS in young children who may refuse to weight-bear (Roodbol et al. 2011). Paraesthesiae and hypoaesthesiae are present only in a minority of older children.

The facial nerve is involved in approximately 50% of cases, often bilaterally (Hung et al. 1994). In very rare cases, affected children may present with loss of brainstem reflexes, quadriparesis and respiratory failure, and these severely affected children often have a poorer outcome (Medici et al. 2011). Ophthalmoplegia occurs in 3% of cases (Dehaene et al. 1986). Optic neuritis is uncommon (Behan et al. 1976). Papilloedema may also be associated due to increased intracranial pressure (Morley and Reynolds 1966). Objective evidence of CNS involvement is highly unusual (Willis and Van den Bergh 1988) and certainly uncommon in our experience. Deep tendon reflexes are abolished early in 85% of cases, even in nonparalytic territories (Winer et al. 1988) though preserved or exaggerated reflexes are rarely reported (Yuki et al. 2012). Loss of deep sensation is frequently found at examination later in the illness.

Paralysis of the respiratory muscles is a common complication of GBS and often requires ventilator support (Ropper 1992). Mild respiratory impairment is even more frequent with resulting hypercarbia. In a Sydney study of 71 childhood cases from 1988 to 2004, 21 (30%) had evidence of respiratory involvement but only five required ventilation. Autonomic involvement is present in many patients and may be responsible for hypotension, hypertension, cardiac arrhythmia and even cardiac arrest (Winer et al. 1988). Urinary retention or overflow incontinence may be present in up to 10% of cases. Ataxia, probably of sensory origin, is not uncommon and may dominate the clinical picture. Plantar responses are usually flexor but a Babinski response may be seen (Jones 1996).

The CSF is most often normal during the first days of the illness. Elevation of CSF protein appears between 2 and 15 days and reaches a peak by 4–5 weeks after clinical onset. The CSF total protein concentration and the IgG percentage seem to depend mainly on the degree of blood–brain barrier damage, which in turn correlates with the clinical course. Oligoclonal IgG bands are frequently present in the CSF but come essentially from serum. Oligoclonal IgG banding in GBS is transitory and correlates with the development of blood–brain barrier damage, the presence of cranial nerve involvement and the severity of the disease (Segurado et al. 1986). In occasional cases, the CSF protein may remain normal (Sullivan and Reeves 1977). In contrast to protein, cell content and the severity of the disease (Segurado et al. 1986).

In occasional cases, the CSF protein may remain normal (Sullivan and Reeves 1977). In contrast to protein, cell content and the CSF protein may remain normal (Sullivan and Reeves 1977). In contrast to protein, cell content and the severity of the disease (Segurado et al. 1986). In occasional cases, the CSF protein may remain normal (Sullivan and Reeves 1977). In contrast to protein, cell content and the severity of the disease (Segurado et al. 1986).
MRI of the spine is now being increasingly used in the initial assessment of children with suspected GBS. Enhancement after contrast and thickening of the anterior and posterior nerve roots, especially in the thoracolumbar spine and cauda equina are seen in most patients with GBS, though it is not specific for this disease (Mulkey et al. 2010; Yikilmaz et al. 2010; Zuccoli et al. 2011). An MRI is also important to rule out other sinister causes like discitis or transverse myelitis. There are well-established diagnostic criteria for GBS that remain useful in clinical practice (Asbury and Cornblath 1990). New criteria for GBS and MFS, based on results of clinical, EMG and CSF tests, have been proposed, and while these are effective to define cases for research studies, their value in the clinical setting remains to be evaluated (Sejvar et al. 2011).

Electrophysiology

Electrophysiological studies in AIDP (Cornblath et al. 1988; Ropper 1992) show marked slowing of motor conduction velocities, along with prolonged distal latencies consistent with demyelination in about 50% of the patients. Some abnormalities of motor or sensory conduction velocities are present in 90% of patients but, because of the patchy distribution of lesions, the probability of finding abnormalities increases with the number of nerves studied, and the degree of involvement can vary with the nerve studied. In 20% of cases, abnormalities are found in only one or two but not all nerves studied. The amplitude of the sensory action potentials and of the motor action potential is diminished. A conduction block could be demonstrated in at least one nerve in 74% of the cases of Bradshaw and Jones (Bradshaw and Jones 1992). Measurement of F-wave latency may detect abnormalities of proximal nerves or roots that escape routine examination. In AMAN and AMSAN, motor conduction velocities are normal or near normal but the amplitude of the compound muscle action potential is reduced or unmeasurable. In both forms of GBS, the amplitude of the mean compound muscle action potential bears a significant relationship to the prognosis (Cornblath et al. 1988). Signs of denervation and fibrillations indicate greater axonal involvement and may be of poor prognostic significance in adults but are less serious in children (Bradshaw and Jones 1992; Triggs et al. 1992).

Evoked potential studies have shown anomalies of both brainstem auditory evoked potentials and somatosensory evoked potentials (Ropper and Chiappa 1986).

Course of Guillain–Barré Syndrome

The initial phase of gradually increasing involvement lasts 10–30 days. Prolongation beyond 4 weeks suggests a diagnosis of subacute GBS (Hughes et al. 1992; Rodriguez-Casero et al. 2005) or chronic inflammatory polyneuropathy. In some forms (Ropper 1986), paralysis progresses very rapidly with complete quadriplegia in 2–5 days. Such patients often have severe respiratory involvement, and sequelae are more likely than in average cases. A plateau phase then follows. A long plateau phase was found, by some investigators (Billard et al. 1979) but not by others (Winer et al. 1988), to be associated with a relatively poor prognosis and the persistence of motor sequelae. Death is said to occur in 2–3% of childhood cases, although in some adult series (Winer et al. 1988) mortality was as high as 15%, mostly in older adult patients.

Recovery is usually complete. Motor sequelae, often mild, occur in 5–25% of patients. Relapses and late recurrences occur in about 3% of patients (Wijdicks and Ropper 1990). Late recurrences that supervene several years after the first episode probably have a different mechanism from those seen after discontinuation of plasma exchange or corticosteroid therapy and are usually only partial (Ropper et al. 1988). Factors giving an unfavourable prognosis include a rapid development of the paralysis, possibly a long duration of the plateau phase, a marked distal deficit, and the presence of fibrillation potentials and of low amplitude of the mean compound motor unit potentials (Ropper 1986). The prevalent impression that the disease has a better prognosis in children than in adults has been questioned by Kleyweg et al. (1989) and by Jansen et al. (1993) who found no difference in severity between 18 children and 50 adults and therefore recommended that the same treatments should be used in both groups. However, a large collaborative study (Korinthenberg and Monting 1996) confirmed the lesser severity of the disease in children. Rantala et al. (1995) found three major risk factors for more severe cases: onset of symptoms within 8 days of the preceding infection, cranial nerve involvement, and a CSF protein level more than 800mg/L during the first week of the disease.

Treatment of Guillain–Barré Syndrome

Symptomatic treatment is an essential part of the management of GBS. Careful monitoring of vital functions, avoidance of aspiration pneumonia, and tube feeding and respiratory assistance when needed have considerably lessened the mortality rate. Corticosteroid treatment has been shown in controlled studies to have no beneficial effects and even to prolong hospitalisation (Hughes 1991; Hughes et al. 2007). Plasmapheresis and intravenous immunoglobulin (IVIg) have both been shown to shorten the duration of hospital stay and hasten recovery in GBS (Hughes et al. 2012; Raphael et al. 2012). Both therapies are effective when administered within 14 days of symptom onset, though neither has been shown to improve the long-term outcome. Plasmapheresis has been used effectively in children more than 10kg in weight. The demonstration that high-dose (2g/kg) intravenous gammaglobulins (van der Meche and Schmitz 1992; Hartung et al. 1995) is effective opened a new avenue for therapy. Doses of 0.4g/kg per day for 5 days given during the first days of the disease give results similar to those of plasmapheresis (van der Meche and Schmitz 1992). Administration of the total dose in 2 days may be more effective than conventional fractionated therapy (Kanra et al. 1997) but has been
shown to result in more treatment-related relapses in children (Korinthenberg et al. 2005). IVIg infusion has largely replaced plasmapheresis in children because of the ease of administration and fewer side effects. The exact indications for either therapy remain variable: cases with rapid extension or impending respiratory insufficiency are obvious candidates but whether all incipient cases should be treated is often debated. The authors would treat patients who are rapidly evolving or who are non-ambulant on presentation. Rantala et al. (1995) suggested early administration at the time of diagnosis when risk factors are present. A number of ongoing studies (Second IVIg Dose in Guillain–Barre syndrome [SID-GBS] and International-SID-GBS as part of International Guillain–Barre syndrome Outcome Study trial) are evaluating the benefit of a second dose of IVIg on patients with GBS with a poor prognosis (van Doorn 2013).

Differential Diagnosis

GBS is a major cause of acute flaccid paralysis (Table 25.3). The diagnosis of GBS is easy in typical cases. Diagnostic criteria (Asbury and Cornblath 1990) include symmetrical weakness and areflexia, the presence of mild sensory symptoms and signs, progression of the symptoms lasting no more than 4 weeks after onset, absence of fever, sphincter dysfunction and no evidence of CNS involvement.

The conditions that may simulate GBS are common in children (Table 25.3) but only a few raise difficult problems. It is imperative to exclude conditions that require immediate specific treatment, especially spinal cord compression. Transverse myelitis can be distinguished by the finding of a sensory level and sphincter involvement. Rare cases of metabolic disease such as Leigh syndrome (Coker 1993) can closely simulate GBS. Poliomyelitis is now exceptional but some toxic neuropathies may be confused with acute polyneuritis. In adolescents, the possibility of volatile solvent abuse neuropathy should be kept in mind. Diptheritic neuropathy closely mimics GBS but is rare. Botulism and diphtheria cause pupillary involvement, which is rarely present in GBS. Tick paralysis can produce a very similar clinical picture but the finding of pupillary paralysis, or of an engorged tick, enables distinction. The clinical and neurophysiological findings are also distinctive (Grattan-Smith et al. 1997) (Table 25.3).

CLINICAL VARIANTS OF THE GUILLAIN–BARRÉ SYNDROME AND RELATED DISORDERS

Miller-Fisher syndrome is characterised by the triad of ophthalmoplegia, ataxia and areflexia which comes on rapidly and follows the same illnesses as classic GBS (Kohler et al. 1988; Lin et al. 2012). However, a history or serological evidence of C. jejuni infection is particularly common in this syndrome.
CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy (CIDP) is much rarer than GBS, with an annual incidence of one per 100,000, but cause up to 10% of cases of chronic childhood polyneuropathy (Ouvrier and Wilmshurst 2003; Rajabally et al. 2009) The diagnostic criteria for CIDP include: (1) a clinical course predominantly of weakness either monophasic, with an initial progressive phase lasting more than 8 weeks, or of a relapsing–remitting nature; (2) electrophysiological and pathological evidence of demyelination; and (3) the absence of systemic disease that may cause demyelinating neuropathy (Ouvrier 1992). Paediatric criteria were proposed by Nevo and Topaloglu (2002). An immunological origin to the condition is likely. There is evidence for both cellular and humoral involvement but molecular mimicry is less clearly involved than in GBS. No definite triggering antigen or pathogenic antibody has been proven to be associated with the disease. There is increased T-cell activation and cytokine release resulting in macrophage-associated peripheral nerve demyelination (Van den Bergh and Rajabally 2013).

Clinical Features of CIDP

The disease occurs predominantly in children aged between 5 and 15 years, but cases with infantile or early childhood onset are on record (Sladky et al. 1986; Pearce et al. 2005). Typically, there is a slow subacute onset over at least 2 months of a sensorimotor neuropathy involving the distal and proximal limbs. However, an acute onset as in GBS is possible. Cranial, especially facial, nerve involvement occurs in 10–40% of patients, and weakness of bulbar or respiratory muscles severe enough to necessitate assisted ventilation is present in about 10% of cases (Ouvrier 1992). Because of the usual predominance of weakness in the lower limbs, difficulties with ambulation are usually the first manifestation and in early cases may be responsible for delayed motor milestones. The weakness is not infrequently asymmetrical. It is associated with amyotrophy and sensory disturbances, although these are generally inconspicuous (McCombe et al. 1987; Barohn et al. 1989). Action or postural tremor is present in some patients. In contrast with adults who may have a slowly progressive course, children often have a monophasic disease with improvement, or a relapsing–remitting course (Simmons et al. 1997; Jo et al. 2010).

The CSF shows albumino-cytological dissociation as in GBS in most patients (Ware et al. 2014). The presence of a
monoclonal or of oligoclonal bands is frequent but the oligocl-onal proteins appear to be plasma-derived (Segurado et al. 1986). MRI is now increasingly used to assist with the di-gnosis of CIDP. MRI of the spine shows contrast enhancement in the majority of children, with the anterior nerve roots and the cauda equina being most affected. Enlargement of the nerve roots may also be seen (Wåre et al. 2014). Similar enhance-ment may also be seen with inherited neuropathies.

There is consistent electrophysiological evidence of demy-elination with slowed motor and sensory conduction veloc-ities, often varying in different segments of the same nerve, increased distal latencies, conduction block, temporal disper-sion and abnormal late responses. In contrast, most inherited neuropathies have a homogeneous slowing of motor con-duction velocities without temporal dispersion or conduc-tion block. Nerve biopsy (Fig. 25.4) shows endoneurial and sub-perineurial inflammatory oedema and mononuclear cell infiltration. Segmental demyelination and remyelination with less prominent axonal degeneration and fibre loss are seen. ‘Onion bulbs’ are present in about 50% of cases. While a nerve biopsy can provide supportive evidence for a diagnosis of CIDP, the absence of characteristic features, especially after the commencement of steroids does not exclude the diagnosis. The condition is aetiologically related to chronic dysimmune neuropathy (Maisonobe et al. 1996) but gammopathy-related cases are rarely, if ever, seen in childhood.

**Differential Diagnosis**

The main diagnostic difficulty is to distinguish CIDP from inherited neuropathy. Some of the distinctive features of CIDP, like rapid and asymmetrical development of weakness, proximal weakness, conduction block and temporal disper-sion on nerve conduction studies and response to immuno-therapy, have been documented in a number of inherited neuropathies including CMT1A and due to mutations in GJB1, SH3TC2, Fig4 and SPTLC1 (Ginsberg et al. 2004; Ryan and Jones 2005; Houlden et al. 2006; Houlden et al. 2009; Michell et al. 2009; Cottenie et al. 2013). Metabolic neuropathies, such as metachromatic leukodystrophy, may exhibit similar features with increased CSF protein.

CNS involvement in association with chronic demyelin-ating neuropathy has been described in some adult patients (Thomas et al. 1987; Ohtake et al. 1990) as well as in child-hood (Wåre et al. 2014).

Such cases raise the question of a relationship with multi-ple sclerosis. Systematic MRI imaging in adult patients with chronic neuropathy has shown the occasional presence of areas of abnormal white matter signal (Feasby et al. 1990). The significance of this finding is unclear.

**Prognosis and Treatment of CIDP**

The disorder does not usually threaten life, but its protracted course and the possible motor sequelae may make it a dis-abling condition. The prognosis in children is better than in adults and most achieve a full remission (Nevo et al. 1996; Simmons et al. 1997; Ryan et al. 2000; Connolly 2001). Both IVIg and corticosteroids are effective in the treatment of childhood CIDP (Rossignol et al. 2007; Sladky 2008; Teasley 2008). High-dose intravenous immunoglobulin is often the initial therapy of choice because of better side-effect profile, though it is more expensive. The response is often rapid and remission may occur even with only one or two doses of IVIg (2g/kg in total given over 2 or 5 days). Treatment with lower doses is maintained at 3–4 week intervals until a remission occurs or the patient is shown to be a non-responder. Plasma exchange is effective and has fewer side effects than protracted steroid therapy but is difficult in young children.

Therapy with corticosteroids is effective both in children and in adults and may be used if there is no response or only a partial response to IVIg. It is the authors’ practice to com-mence with 1mg/kg/day of prednisone and to increase to 2mg/kg/day if there is no response. Relapses following mini-mal decreases in dosage may occur so that prolonged treatment with careful monitoring is sometimes necessary (Wertman et al. 1988). After remission occurs, the steroids are cautiously tapered to minimise side effects. The absence of a response to the first-line agents is rare in childhood, and along with severe side effects, requires an add-on therapy. Immunosuppression with azathioprine, methotrexate, cyclophosphamide, cyclosporine and mycophenylate has been utilised, but no sys-tematic trials are available in children. A favourable response to rituximab has been reported in a small case series (Wåre et al. 2014).

**LEPROSY**

Leprosy is a systemic disease with a marked predilection for superfi-cial nerves, skin, the anterior third of the eye, the upper respiratory tract and the testes. Leprosy is still a major health problem in many resource-poor countries and together with vitamin deficiency is the main cause of neuropathy in many
regions. The disease is due to infection with *Mycobacterium leprae* and is transmitted by intimate person-to-person contact with only a small proportion of any given population being susceptible. HLA-linked genes control the susceptibility to the organism and the course of the illness. *M. leprae* is the only bacterium to invade peripheral nerves. The unique tropism of *M. leprae* for peripheral nerves (from large nerve trunks to microscopic dermal nerves) and certain immune-mediated reactional states are the major causes of morbidity in leprosy. Hosts with a low resistance to the organism develop lepromatous/multibacillary or nodular infection. Hosts with high resistance develop tuberculoid/paucibacillary infection. The most severe (lepromatous) form of leprosy is twice as common among men than women and is rarely encountered in children.

In lepromatous leprosy, most infiltrates consist of macrophages heavily infected by *M. leprae*. In tuberculoid leprosy, the lesions contain only remnants of bacteria surrounded by well-organised granulomas with epithelioid and giant cells. Borderline cases intermediate between lepromatous and tuberculoid leprosy occur frequently, and unstable cases can oscillate between the two forms. In lepromatous leprosy, neural damage may produce a purely sensory polynoeritis with loss of touch, pain and temperature sensation in a characteristic distribution while deep sensitivity is preserved. Sensory loss first appears in cool areas of the body (ears, dorsal sur-

endogenous and exogenous toxic neuropathies

Toxic neuropathies of both endogenous and exogenous origin are uncommon in childhood at least in symptomatic form (Gamstorp 1968; Evans 1979).

**endogenous toxic neuropathies**

**diabetes mellitus**

Subclinical neuropathy may not be rare in patients with juvenile diabetes as judged by electrophysiological findings. Ten per cent of children with chronic diabetes mellitus have symptoms and signs caused by peripheral neuropathy associated with diabetes (Gamstorp et al. 1966). Gallai et al. (1988) found decreased motor conduction velocity in the median nerve in 10%, in the posterior tibial nerve in 32%, and in the sural nerve in 44% of 50 juvenile diabetics with a mean age of 13 years. The neuropathy appeared to be more marked in poorly controlled diabetes. Compared with age-matched control children, impaired vibration perception was present in boys with diabetes in the absence of clinical symptoms of peripheral or autonomic neuropathy (Olsen et al. 1994). Mildly impaired autonomic nervous system function was found in 30–50% of children with diabetes when measured soon after diagnosis (Verrotti et al. 1995; Donaghue et al. 1996). The percentage involved did not change over 3 years (Donaghue et al. 1996). In another large prospective study of nerve conduction and autonomic nervous system function in children with diabetes, slowed sensory nerve conduction velocities and impaired autonomic function were present in 25% of children at the time of diagnosis (Solders et al. 1997). Clinically manifest diabetic neuropathy, however, is rare (Bastron and Thomas 1981; Fiçicioglu et al. 1994), even though the study of spinal sensory evoked potentials also confirms that subclinical involvement of neural transmission in young diabetic patients is common (Cracco et al. 1984). Cranial nerve palsies are exceptional in juvenile diabetes. Autonomic involvement with gastrointestinal features is sometimes apparent. A neurogenic bladder may be relatively common but usually remains asymptomatic (Faerman et al. 1971). Further, asymptomatic children with diabetes have diminished sensation of bladder filling (Barkai and Szabó 1993). Rare cases of mononeuritis multiplex have been recorded (Ouvrier et al. 1999).

**neuropathy of chronic renal failure**

Uraemic neuropathy is also subclinical in a large majority of cases. Seventy-six per cent of affected children had a significant slowing of peroneal nerve conduction velocity without other
evidence of neuropathy in a study by Mentser et al. (1978). Symptomatic patients may experience sensory abnormalities in the lower extremities that may evolve into a sensorimotor polyneuropathy with flaccid paraplegia or quadriplegia. Any type of neuropathy (purely axonal, mixed or predominantly demyelinating) may be observed (Saïd et al. 1983). A purely motor type of uraemic neuropathy (McGonigle et al. 1985) may occur. The neuropathy of uraemia may be related to chronic hyperpolarisation secondary to altered potassium levels (Krishnan and Kiernan 2007) and is usually reversed by successful renal transplant. A case of Miller-Fisher syndrome with a relapsing course and fluctuations temporally related to uraemia and haemodialysis sessions has been observed (Galassi et al. 1990).

ENDOCRINE NEUROPATHIES

Polyneuropathy may also occur in hypothyroidism (Nemni et al. 1987) and hypoglycaemia (Mohseni 2001).

EXOGENOUS TOXIC NEUROPATHIES

A vast number of chemicals can induce polyneuropathy (Table 25.4). Only the most important ones, especially drugs, are discussed here. Isoniazid can cause a distal mixed sensory and motor neuropathy through interference with the metabolism of pyridoxine. Supplementation with pyridoxine is therefore indicated in patients treated for tuberculosis. Excessive doses of pyridoxine, however, can cause a sensory neuropathy (Schaumburg et al. 1983). Vincristine is a relatively common cause of neuropathy in children with malignancies. The drug interferes with the formation of neurotubules. Abolition of reflexes starting with the ankle jerk is virtually constant following vincristine therapy. In more severe cases paraesthesiae develop, followed by sensory loss then by weakness that may be initially focal and may remain asymmetrical (Casey et al. 1973). Severe pain, in the parotid region, is frequent during vincristine treatment, and oculomotor palsies have been observed. An acute severe deterioration can occur in patients with CMT disease who are given vincristine (Igarashi et al. 1995).

Nitrofurantoin causes neuropathy mainly in children with renal insufficiency. Axonal involvement is the rule, and distal sensory symptoms are usually predominant. Differential diagnosis from uraemic neuropathy may be difficult. The resurgence of thalidomide has resulted in occasional cases of a toxic, mainly sensory, neuropathy in childhood (Fleming et al. 2005).

Most drug-induced neuropathies are reversible after discontinuation of treatment but recovery may be slow, especially when intoxication was prolonged. Phenytoin toxicity is almost always subclinical.

Accidental neuropathies due to heavy metals are rare. Insecticides should be suspected in rural communities, along with arsenic. N-hexane neuropathy may result from solvent abuse (‘glue-sniffing’), a practice that has become prevalent among adolescents and even children (Korobkin et al. 1975). A history of glue-sniffing should be routinely searched for in this

age group. Nerve biopsy characteristically shows changes of demyelination and giant axons packed with neurofilaments. Gasoline sniffing has also been associated with mononeuritis multiplex (Burns et al. 2001).

Biological toxins are rarely a cause. Most cases of tick paralysis are seen in Australia and the United States. It results in a flaccid, rapidly spreading paralysis involving the respiratory muscles, and may be lethal if the tick is not removed. Careful search is clearly imperative and removal leads to cure in a few hours to several days (Grattan-Smith et al. 1997). In Western Europe, paralysis following tick bite is due to Borrelia disease (see Chapter 11).

### NEUROPATHIES OF SYSTEMIC AND VASCULAR DISEASES

A neuropathy may be a manifestation of most vasculitides (see Chapter 12) including lupus erythematosus (McCombe et al. 1987a), rheumatoid arthritis, polyarteritis nodosa, anaphylactoid purpura (Ritter et al. 1983) and other, less well-defined, collagen disorders and vasculitides (Harati and Niakan 1986; Dyck et al. 1987). Such complications are rare in children. They may present as either mononeuritis multiplex or diffuse polyneuropathy (Parikh et al. 1995; Steinlin et al. 1995; Harel et al. 2002). Critical illness neuropathy and myopathy may occur in gravely ill children with multiple organ failure or following major surgery (Heckmatt et al. 1993; Tsao et al. 1995; Williams et al. 2007). They commonly cause generalised weakness and muscle wasting, with failure to wean from mechanical ventilation. There is significant clinical and neurophysiological overlap between the two conditions, such that the term critical illness polyneuropathy and myopathy is often applied. The precise cause of these conditions is obscure. They may entail sepsis, compression, hypoxia (Pfeiffer et al. 1990), toxic and other mechanisms. A similar polyneuropathy can occur in burn patients. Mononeuropathy is often related to electrical or deep thermal burns (Marquez et al. 1993; Kowalske et al. 2001).

### LOCALISED DISORDERS OF THE PERIPHERAL NERVES (EXCLUDING CRANIAL NERVES)

#### INFLAMMATORY LOCALISED NEUROPATHIES

These may involve a single nerve or branch or several nerves as in plexopathies. Transitional forms with the generalised neuropathies exist; for example, neuropathy with liability to pressure palsies or cases of familial brachial plexopathy that may also affect the lumbar plexus and presumably are the result of a more or less diffuse process.

#### PAINFUL BRACHIAL NEUROPATHY OR PLEXOPATHY, PARSONAGE–TURNER SYNDROME, NEURALGIC AMYOTROPHY

Brachial plexopathy occurs from infancy, although paediatric cases are much rarer than in adults (Charles and Jayam-Trouth 1980). It may follow a nonspecific respiratory infection, a specific viral disease such as infectious mononucleosis (Watson and Ashby 1976; Dussaix et al. 1986), parvovirus infection (Denning et al. 1987) or an immunisation (Hamati-Haddad and Fenichel 1997). In infants, associated osteomyelitis of the humerus must always be excluded. An autosomal dominant form of hereditary neuralgic amyotrophy is due to mutations in the gene SEPT1 encoding septin-9 which is involved in cellular microtubule function (Vassallo et al. 2010; Bai et al. 2013). Rare cases presenting with vocal cord paralysis have been reported in neonates and young children (Leshinsky-Silver et al. 2013).

Neuralgic amyotrophy usually begins with pain localised to the shoulder or involving the whole upper limb. Pain may last from hours to weeks and is often intense. It is followed by weakness which may, however, be the first manifestation in 5% of cases. Paralysis affects the upper brachial roots in over half the patients and the whole plexus in one-third, but may be limited to the hand and fingers in a small proportion. Amyotrophy sets in rapidly and objective sensory signs may be present (England and Sumner 1987). Recovery is virtually constant but it may take months or years and some residua may rarely persist (Zeharia et al. 1990; van Allen and van Engelen 2006). The diagnosis requires exclusion of spinal cord compression and transverse myelitis, which often demands an imaging study of the brachial plexus and cervical cord. The CSF is usually normal although a mild inflammatory reaction may be present at onset. EMG and nerve conduction studies are useful for determining the extent of involvement of the ipsilateral and, occasionally, the contralateral plexus. Treatment is based on analgesics and physiotherapy. Steroids do not modify the long-term outcome but may have a favourable effect in some cases. Rare cases in childhood may have a different phenotype with only mild or no pain but more extensive paralysis with less recovery than in adults (van Allen et al. 2000; Kotsopoulos et al. 2007). Involvement of only one nerve from the brachial plexus may be seen. The long thoracic nerve is commonly affected with consequent paralysis of the serratus
anterior, producing a unilateral winged scapula. A similar distribution of weakness, often with less pain but less benign prognosis, may occur in the Hopkins (asthma-amyotrophy) syndrome.

OTHER LOCALISED INFLAMMATORY NERVE DISORDERS

Lumbosacral plexopathy is the counterpart in the lower limb of neuralgic amyotrophy but is even rarer in children. Occasional cases are on record in adolescents (Evans et al. 1981) and even in 2–3-year-old children (Sander and Sharp 1981; Thomson 1993). Pain is located in a femoral or sciatic distribution and the children will limp or refuse to walk. Weakness of the leg follows in about a week. Recovery is almost universal although mild residual weakness may persist. When the lower plexus is involved, it may be confused with sciatica due to disc or vertebral disease. In some countries, schistosomiasis is an important cause of both brachial and lumbosacral plexopathy (Marra 1983).

Sacral radiculomyelitis (Elsberg syndrome) is observed mainly in young adults and presents with a tetrad of acute urinary retention, sensory deficit in sacral dermatomes, paraesthesiae in the same territory and pleocytosis of the CSF (Herbaut et al. 1987). Most cases are due to genital herpes simplex virus but other viral agents, for example, echovirus and cytomegalovirus, may be the cause (Vanneste et al. 1980; Michaelson et al. 1983; Gerber and Cromie 1996) (Fig. 25.5).

TRAUMATIC NERVE INJURIES

BRACHIAL PLEXUS INJURY

The incidence of brachial plexus injury in neonates has decreased in recent years probably because of improved obstetric techniques. Since 1980, the incidence varied from 0.37 to 0.87 per 1000 live births (Painter 1988; Evans-Jones et al. 2003).

Two Swedish studies found an incidence of 2.9 and 3.2 cases respectively per 1000 births (Lagerkvist et al. 2010; Lindqvist et al. 2012). Women over 35 years of age, those with pre-eclampsia or diabetes mellitus and those who had previously delivered children with brachial plexus injuries are more likely...
to have affected infants. In one series (Rossi et al. 1982), half of the affected children weighed more than 4000g at birth. Abnormal birth presentations are also a factor but the frequency of breech delivery varies with the series. Occasional cases of prenatal plexus injury due to deformation from uterine constraint, such as that of bicornuate uterus, are on record and are a possible cause of palsy in siblings (Paradiso et al. 1997).

Pathology
Lesions affect the upper plexus (C5 and C6 roots) – the Duchenne–Erb type of plexus paralysis – in 55–72% of cases; those of C5, C6 and C7 in 10–20%; and those of C8–T1 (Déjerine–Klumpke type) in less than 10%. Lesions of the entire plexus occur on an average in 10% of patients. Bilateral, but often asymmetrical, involvement is not rare. In most instances there is stretching of the upper cord of the plexus due to traction on the shoulder during delivery of the after-coming head or to turning the head away from the shoulder in difficult cephalic presentations. Injury to the lower cord seems to result from traction on the abducted arm during vertex delivery or from traction on the trunk with breech presentation. The most common lesions are haemorrhages and oedema within the nerve sheath of primary plexus cords. Actual avulsion of the roots from the spinal cord with segmental damage of the grey matter or tearing of the nerves is uncommon but occurs when the degree of traction is severe enough.

Clinical Manifestations
In the great majority of patients with upper plexus lesions, the paralysis is recognised from the first days of life. The affected arm hangs limply adducted and internally rotated, the elbow extended, the forearm pronated and the wrist variably flexed (Fig. 25.5). The grasp remains normal. The biceps and brachioradialis reflexes are absent. Weakness of the triceps and extensors of forearm and digits may complicate the picture when there is significant C7 involvement. In lower plexus lesions, intrinsic hand muscles are paralysed, the grasp is absent, and a Horner syndrome with ptosis and miosis is frequently present. If the Horner syndrome does not resolve, the iris fails to pigment and heterochromia iridis develops. Winging of the scapula and Horner syndrome generally herald a poor outcome. In some cases, there is significant sensory involvement with the possible appearance of whitlows on the fingers. Global palsy involving the upper and lower roots of the plexus carries a very poor prognosis for recovery. Involvement of the diaphragm, due to a lesion of the fourth–fifth cervical roots, is present in approximately 5% of cases and may produce symptoms of respiratory distress. This occurs most often in association with upper plexus palsy but may be present in isolation.

Diagnosis
The diagnosis of plexus paralysis is readily apparent. Study of the somatosensory evoked potentials may help distinguish between an avulsed root and a more distal lesion of better prognosis in older patients. MRI of the spinal cord and roots may also be used for the same purpose. EMG may be helpful in determining the extent of paralysis but can be misleading (Yilmaz et al. 1999). Signs of denervation may occur earlier than happens in adults (Swoboda et al. 2003).

Prognosis and Management
A majority of neonates with brachial plexus injury recover (DiTaranto et al. 2004; Strömbeck et al. 2007). This is partly due to the limited nature of the nerve damage but possibly also to the plasticity of the newborn spinal cord (Korak et al. 2004). Gordon et al. (1973) studied 59 such infants: examination showed recovery in 46/52 at 6 months of age, in 48/52 at 12 months, and in 53/56 at 4 years, with only three patients lost to follow-up. Similarly, Greenwald et al. (1984) found that 23 of their 38 patients had recovered by 1 week, 35 by 3 months, and 36 at several years. Children with residual deficits may continue to improve even during preschool years. Sequelae may affect various muscles depending on the lesions but tend to predominate in the proximal limb (Rossi et al. 1982). Sequelae include weakness, atrophy and sensory deficits. Contractures are often more marked than weakness. They are due to faulty re-innervation and result in paradoxical synkinesias. In particular, attempts at any movement of the upper limb tend to provoke contraction of the deltoid and biceps with abduction of the flexed limb. In virtually all cases there is internal rotation of the arm and pronation of the forearm. Subluxation of the humeral head may contribute to the disability (Hernandez and Dias 1988) and require surgery. The average case of plexus palsy in the newborn infant does not require more than range of motion exercises starting no sooner than 1 month after birth. Splinting is contraindicated as it may promote the development of contractures. For infants who have not significantly improved by age 6 months, the question of surgical therapy, including neural lysis, nerve anastomosis or grafting, arises (Gilbert and Tassin 1987; Gilbert et al. 1991). Laurent and Lee (1994) reported satisfactory results in 50 of 70 operated infants, but controversy persists in the absence of a prospective controlled study and no firm statement seems currently possible on the available evidence (Bodensteiner et al. 1994). Surgical intervention after 6–12 months of age is recommended by some groups but the precise indications are not agreed upon (Hunt 1988). Gilbert (2009) has repaired over a thousand infants with brachial plexus injuries who had not recovered biceps function after 3 months and considers that repair is always feasible and that its results are far better than spontaneous progression. In a long-term study, however, Strömbeck et al. (2007) reported that patients undergoing nerve reconstruction had a similar outcome of functional change as the non-operated group. Later orthopaedic surgical procedures on the shoulder appear often to be beneficial.

Postnatal injuries to the brachial plexus are mainly due to motor vehicle (especially motorcycle) and sports accidents
and consequently affect principally adolescents. The prognosis of these injuries is often guarded. Traumatic lesions of the lumbo-sacral plexus are rare. Both neonatal (Hope et al. 1985) and childhood (Egel et al. 1995) cases have been reported with a favourable outcome.

**SCIATIC NERVE INJURIES**

Injury to the sciatic nerve is now much less often the result of injections into the nerve or in its vicinity. Such accidents were particularly prone to occur in small preterm infants because of the small volume of the buttock allowing substances to diffuse right up to the nerve with resulting injury and dysfunction. Therefore, intramuscular injections into the buttocks of such infants are prohibited. The sciatic nerve can also be injured following injection of drugs into the umbilical artery. This is caused by thrombosis of the inferior gluteal artery and is accompanied by circulatory changes in the buttock (San Agustin et al. 1962; Wynne et al. 1978) or gangrenous skin areas in the leg. Similar changes may occur following injection of viscous substances into the buttocks. Paralysis may affect the whole territory of the sciatic nerve or only one of its two main divisions, most commonly the peroneal nerve. Foot drop, amyotrophy and growth disturbances of the leg are the most frequent manifestations. Surgical exploration of the nerve should be considered when no improvement occurs after a few weeks and/or when a granuloma is palpable at the site of injection. The prognosis is poor in severe cases especially as a result of trophic and growth disturbances. Breech delivery is a rare cause of neonatal sciatic palsy (Jones et al. 1988).

Sciatic neuralgia due to disc herniation is rare in childhood, and pain in the territory of the lower lumbar and upper sciatic roots is more commonly due to tumours than to disc pathology. In children above 10 years of age typical sciatica is occasionally observed. Spinal rigidity and scoliosis or kyphosis may be prominent manifestations (Kurihara and Kataoka 1980; Epstein et al. 1984).

Other causes of sciatic neuropathy in childhood include stretch injury after closed reduction of hip dislocation and due to braces, casts and prolonged abnormal lower extremity postures; compression by haematomas, tumours or lymphomas; and hypersensitivity vasculitis. In rare cases, a localised hypertrophy of the nerve, sometimes due to a perineuroma, or else no evident cause, is found (Jones et al. 1988; Ouvrier and Shield 1999). Perineuromas, occasionally multifocal, occur in other sites including the median and radial nerves (Nagappa et al. 2013).

**CARPAL TUNNEL SYNDROME AND OTHER ENTRAPMENT SYNDROMES**

Carpal tunnel syndrome is rare in childhood; Sainio et al. (1987) collected only 32 published cases and added three of their own. As in adults, the syndrome occurs most commonly in females. Motor symptoms tend to dominate the clinical picture in children with typical involvement of the thenar muscles but the latter can be congenitally hypoplastastic (Cavanagh et al. 1979). Pain and paraesthesiae are often less marked than in adults. Sensory and motor distal latencies are prolonged. Mucopolysaccharidoses types I-S, II and IV may cause the carpel tunnel syndrome through mucopolysaccharide accumulation under the flexor retinaculum and related structures. Other rare causes include neuropathy with liability to pressure palsies and the Schwartz–Jampel syndrome (Cruz Martínez et al. 1984). Occasional familial idiopathic cases presenting in childhood are on record (Danta 1975). An infant with suspected congenital insensitivity to pain associated with a family history of carpel tunnel syndrome was completely cured of self-mutilation of his hands by carpel tunnel release (Swoboda et al. 1998).

Other rare entrapment neuropathies of the upper extremities have been reviewed by Dawson (1993) and by Ouvrier and Shield (1999). Entrapment of the sciatic nerve due to a congenital iliac bony abnormality has been reported (Lester and McAlister 1970). Occasional childhood and adolescent cases of the thoracic outlet syndrome due to cervical ribs or fibrous bands are known (Smith and Trojaborg 1987). Radial neuropathies in childhood have been reviewed by Escobar and Jones (1996). MRI helps to diagnose the causes of such cases (Panegyres et al. 1993).

**OTHER TRAUMATIC NERVE INJURIES**

Neonatal injuries to the radial nerve as a result of subcutaneous fat necrosis of the upper arm (Eng et al. 1996) and of the median nerve as a result of attempts at catheterisation of the radial or humeral artery have been reported. Aicardi observed two infants with transient paralysis of the femoral nerve after difficult puncture of the femoral vein and two similar cases following herniorrhaphy and appendectomy. In the latter procedure (for retrocaecal appendicitis), nerve injury was probably due to trauma of the nerve along the psoas muscle. Similar cases are reported in the literature (Stulz and Pfeiffer 1982).

Traumatic palsy of the peroneal nerve may be due to direct penetration or orthopaedic procedures in the region (Jones 1986) and has been reported following infiltration of intravenous fluid (Kreusser and Volpe 1984). Radial paralysis following constraint of the forearm for intravenous infusion is relatively common and always transient.

Lumbar plexus injuries are rare and occur only following major trauma to the pelvis, especially as a result of motor vehicle accidents. Rare cases have been seen following difficult breech delivery (Hope et al. 1985).

Glossopharyngeal neuralgia and hypoglossal nerve paralysis following tonsillectomy have been exceptionally recorded (Ekbom and Westerberg 1966; Sharp et al. 2002). Occipital neuralgia is not rare especially in adolescents (Dugan et al. 1962). The neck–tongue syndrome (Lance and Anthony 1980; Hu and Dougherty 2016) is a headache disorder often
initiated by rapid axial rotation of the neck resulting in unilateral neck and/or occipital pain and transient ipsilateral sensory disturbance in the tongue. It may occur with degenerative or malformative abnormalities of the upper spine, although in many cases the cervical spine appears normal. It is usually treated conservatively with immobilisation in cervical collars, physiotherapy, analgesics and/or local injections. Surgery is not usually required.

Solitary nerve tumours are quite rare in children excepting the benign tumours of neurofibromatosis type I, which usually require no treatment unless they are disfiguring or causing compressive symptoms. Detection of malignant (Triton) nerve tumours is important, however, as effective treatment ing compressive symptoms. Detection of malignant (Triton) nerve tumours is important, however, as effective treatment should not be delayed.

### COMPLEX REGIONAL PAIN SYNDROME TYPE I (REFLEX SYMPATHETIC DYSTROPHY; REFLEX NEUROVASCULAR DYSTROPHY)

Reflex sympathetic dystrophy, now called complex regional pain syndrome (CRPS) type I, is a syndrome of unknown cause characterised by pain, tenderness, swelling, vasomotor disturbances and dystrophic skin changes typically affecting a single extremity (Schwartzman and McLellan 1987). Three diagnostic criteria have been suggested:

1. Diffuse pain often not localised to anatomical nerve territories and out of proportion to the cause;
2. Loss of function or impaired movements;
3. Some objective evidence of autonomic dysfunction such as skin changes, oedema or osteoporosis.

The disorder follows trauma, usually minor, in 40% of cases and typically occurs in young adolescent girls (Dietz et al. 1990; Gordon 1996). Pain may be so severe as to produce pseudo-paralysis. In children, symptoms tend to be self-limited but a significant minority have protracted and disabling illness. Trophic changes may persist in long-standing cases.

Patients often appear to have a large psychological component to their condition that may also require attention (Bruehl and Carlson 1992). Affected children may have a special psychological profile (Sherry and Weisman 1988) but other authors have denied this (Lynch 1992). Bone scan may help in diagnosing the condition by usually showing localised decrease rather than the increased uptake seen in affected adults. Study by cutaneous thermography of local vasomotor reflex or by monitoring of near-surface blood flow may be of diagnostic value (Gordon 1996). Numerous forms of treatment have been used (Schwartzman and McLellan 1987; Kesler et al. 1988; Dietz et al. 1990) with variable results, including steroids, beta-blockers, calcitonin, vasodilators, transcutaneous nerve stimulation and physiotherapy (Gordon 1996). Infiltration of the regional sympathetic ganglia may be helpful, although involvement of the sympathetic system in the disorder has been contested. Sympathectomy may be used when infiltration proves helpful. A Cochrane Collaboration analysis compared percutaneous radiofrequency thermal lumbar sympathectomy with lumbar sympathetic neurolysis using phenol in 20 participants with CRPS and concluded that sympathectomy should be used cautiously in clinical practice, in carefully selected patients, and probably only after failure of other treatment options (Straube et al. 2013).

Other rare overlapping autonomic disturbances of neural origin include Harlequin syndrome (unilateral diminished sweating and flushing of the face in response to heat or exercise) (Lance et al. 1988). It is sometimes associated with other dysautonomic syndromes such as Horner syndrome, Holmes Adie syndrome and Ross syndrome (anhidrosis, hyporeflexia, Adie pupil, syncope and other autonomic symptoms (Drummond and Lance 1993), which have been occasionally reported in children (Jain et al. 2013). The cause is often obscure but an adult case due to metastatic deposits has been reported (Guilloton et al. 2013). Beck et al. (1989) reported cases of isolated auriculotemporal syndrome in children, characterised by localised flushing of the face when eating.

### LOCALISED DISORDERS OF CRANIAL NERVES

The cranial nerves are affected, together with the rest of the peripheral nerves, in many diffuse nerve disorders. Certain conditions more specific to the cranial nerves, whether congenital or acquired, are described in this section (Table 25.5 and Figs 25.6, 25.7 and 25.8). Lesions of the optic, oculomotor and auditory nerves are described in Chapters 22 and 23.

### CONGENITAL FACIAL PARALYSES

#### Birth Injury to the Facial Nerve

The facial nerve is the one most commonly involved in birth trauma or prenatal compression. Congenital unilateral facial nerve palsy is observed in approximately 0.3 per 1000 live births (McHugh et al. 1969) but is more common in large infants in whom the incidence is up to 6.5–7.5 per 1000 (Levine et al. 1984). In a majority of cases injury to the nerve is probably the result of pressure on the facial nerve distal to its emergence from the stylomastoid foramen against the sacral prominence of the maternal pelvis. This is suggested by the consistent relationship between fetal position and side of palsy, with left and right palsies observed subsequent to, respectively, left and right occipital positions. Paralysis resulting from application of forceps is comparatively rare. The clinical expression of unilateral facial palsy even when it is complete is not always evident at birth and partial involvement
is not uncommon. In such cases, the orbicularis oculi is most often spared. This is because fibres that course upward just after leaving the foramen are not involved by compression over the parotid gland. When the orbital branches are affected, the palpebral fissure is wider on the affected side and the eye fails to close completely (Fig. 25.6). Finding a periauricular ecchymosis or a haemotympanum helps diagnose traumatic palsy with a likely recovery (Shapiro et al. 1996). In most cases, resolution of the paralysis is observed in a few weeks. Severe injuries with extensive disruption of the nerve seem to be rare. Surgical exploration of the nerve may be considered when no recovery is apparent after 3–6 months.

**Congenital Non-Traumatic Facial Palsy**

Congenital facial palsy can result from various anomalies of the nerve or its nucleus. Lesions of the inner ear may be associated with visible anomalies of the auricle and may be demonstrated by computed tomography (CT) studies showing osseous abnormalities. More often, the nucleus or the nerve itself is abnormal or interrupted (Zucker 1990). Such patients present with unilateral complete paralysis and have no tendency to spontaneous recovery. Electrical stimulation at the stylomastoid foramen in such infants shows no muscle contraction when performed within 48 hours of birth, in contrast to what obtains in traumatic palsy, and is of great value (Shapiro et al. 1996). Surgical exploration of the nerve may be indicated. Congenital facial palsies are also seen in the CHARGE (coloboma, heart defects, atresia choanae [also known as choanal atresia] and Goldenhar) syndromes. Cleidocranial dysostosis and other bony dysplasias of the base of the skull are unusual causes.

**Moebius Syndrome**

Moebius syndrome is characterised by facial diplegia, typically associated with bilateral abducens palsy (Fig. 25.7) and, occasionally, with involvement of several cranial nerves, especially the lower cranial pairs, with frequent tongue involvement (Sudarshan and Goldie 1985). Affectation of the IIIrd nerves is uncommon. The syndrome often results in speech and sometimes feeding difficulties. Intellectual disability is present in about 10–27% of affected children, although the immobile facies, drooling and speech difficulties often wrongly suggest subnormality. Unilateral Moebius syndrome has been reported. The mechanism of Moebius syndrome is probably multiple. A few cases may be of supranuclear origin; most are associated with abnormalities involving the rhombencephalon (Verzijl et al. 2005a) and may be due to absence of the brainstem nucleus (Towfighi et al. 1979).

| Table 25.5 Facial nerve paralysis: features associated with weakness as a function of lesion location |
|-----------|---------|--------|--------|---------|
| **Location** | **Taste** | **Hyperacusis** | **Lachrymation** | **Salivation** |
| Motor nucleus | Normal | Present$^a$ | Normal | Normal |
| Facial nerve trunk between pons and internal auditory meatus | Normal | Present$^a$ | Impaired$^b$ | Impaired$^c$ |
| Geniculate ganglion | Impaired$^d$ | Present$^e$ | Impaired$^b$ | Impaired$^d$ |
| Facial nerve trunk between geniculate ganglion and emergence of stapedius nerve | Impaired$^d$ | Present$^e$ | Normal | Impaired$^d$ |
| Facial nerve trunk between stapedius nerve and chorda tympani | Impaired$^d$ | Absent | Normal | Impaired$^d$ |
| Lower facial nerve below chorda tympani | Normal | Absent | Normal | Normal |

$^a$Function subserved by the stapedius nerve.
$^b$Function subserved by the greater superficial petrosal nerve (fibres originating from the solitary tract nucleus, coursing through the ganglion).
$^c$Function subserved by the chorda tympani (fibres originating from the solitary tract nucleus and joining the facial nerve through its anastomosis with the IXth cranial nerve).
It seems likely that many cases result from prenatal brainstem ischaemia with necrosis and sometimes calcification of the facial nuclei (Thakkar et al. 1977; Govaert et al. 1989; Fujita et al. 1991). Absence or hypoplasia of the facial nerve has been shown pathologically and by MRI studies (Verzijl et al. 2005b). Some cases may be due to congenital muscle aplasia or other muscle disorders (Hanson and Rowland 1971). Numerous cases have been caused by the use of misoprostol as an abortifacient (Marques-Dias et al. 2003). Bavinck and Weaver (1986) have speculated that Moebius syndrome and other regional malformations such as Klippel–Feil syndrome and the Poland anomaly might all be consequences of disrupted blood supply in the territory of the subclavian artery. Hamaguchi et al. (1993) separate three subgroups: children with only cranial nerve involvement, primarily of the VIth and VIIth pairs; patients with associated arthrogryposis; and those with absence or structural deformities of the extremities. The last type comprised 48% of 106 cases collected by Engler et al. (1979), who also encountered absence of the pectoralis major in 9% and micrognathia in 6% of their cases. Rare cases of familial Moebius syndrome are on record (García Erro et al. 1989). In some familial cases, other abnormalities such as Poland anomaly or arthrogryposis may be associated (Gadoth et al. 1979; Sudarshan and Goldie 1985). Genetic studies have not generated consistent involvement of particular genes, except for several case reports implicating the RYRI gene (Shaaban et al. 2013).

**Hypoplasia (or Paralysis) of the **Depressor Anguli Oris Muscle**

This is a common minor anomaly (Nelson and Eng 1972). The corner of the mouth on the involved side fails to move downward on crying (Fig. 25.8). The lower lip may be slightly everted on the same side. This anomaly has been thought to be associated with other manifestations, especially congenital heart disease (Levin et al. 1982; Raymond and Holmes 1993), the so-called cardio-facial syndrome. Some are associated with the velo-cardio-facial syndrome of Shprintzen (Puñal et al. 2001). Nevertheless, the vast majority of children with this anomaly do not have other problems and a referral bias is likely.

**Diagnosis of congenital facial palsies**

The major causes of facial weakness are shown in Table 25.6. Congenital palsies represent about 8% of cases of childhood facial paralysis (Manning and Adour 1972), but it is not always easy to distinguish acquired from congenital cases or to separate nerve involvement from weakness due to muscle diseases. Electroneurography may assist in elucidating the causation and prognosis. For all cases with paralysis lasting more than a few weeks without improvement, imaging studies of the base of the brain are indicated. In cases of Moebius syndrome, brain CT and MRI should be performed.
ACQUIRED FACIAL PARALYSES

Paralysis of Unknown Cause (Bell Palsy)

Bell palsy is an acute idiopathic paralysis involving the territory of one facial nerve. The pathological changes include considerable oedema but there are few inflammatory signs. The pathogenesis is still uncertain but auto-immune demyelination probably plays a major role. The incidence of Bell palsy is 2.7–4.2 per 100,000 in the first decade of life and 10.1–15.3 per 100,000 in the second decade (Katusik et al. 1986; Drack and Weissert 2013). Both sides of the face are equally involved. Approximately 1–2% of patients have a family history of the disorder. A history of prior viral infection is frequently recorded but its significance is undecided. Multiple viral infections, especially herpes simplex, have been suspected. Neuroborreliosis is a frequent cause in endemic areas (see Paralyses of known cause section). CSF studies in many cases have demonstrated pleocytosis, disordered blood–brain barrier and intrathecal immunoglobulin synthesis (Roberg et al. 1991). There is evidence that Bell palsy may be only the most striking manifestation of an auto-immune disorder affecting other cranial nerves, particularly the sensory trigeminal nerve, which may be involved in up to 50% of cases (Adour et al. 1978; Lapresle et al. 1980).

The first clinical manifestations may be pain or paraesthesiae in the ear or the face unilaterally but these are usually mild or absent. The paralysis reaches its maximum in a few hours and involves all muscles on one side of the face. The face is pulled to the side opposite the paralysis with efforts to use the muscles of expression. The eye cannot be fully closed, and drinking may become difficult. Lacrimation is preserved in many cases but taste sensation is lost in about half the patients (Table 25.5). Weakness remains maximal for 2–4 weeks and then begins to lessen spontaneously (Adour 1982). Complete recovery is the rule in children especially when palsy is partial. Wong (1995) found complete recovery in 21 of 24 children. When denervation is complete, the onset of improvement may be delayed and recovery may not be total, reaching its maximum within 6 months (Adour 1982). Drack and Weissert (2013) found a full recovery in 89% of children aged 16 years.
and under. Aberrant regeneration with ‘crocodile tears’ or auriculotemporal syndrome (Levin 1987) is exceptional in children. Recurrent paralysis is observed in around 6% of cases (Katusik et al. 1986). Electrical stimulation studies may be useful but are rarely necessary in childhood: incomplete denervation predicts complete recovery, whereas complete denervation may herald the persistence of some weakness. The CSF is abnormal in 10% (Weber et al. 1987) to 75% (Sandstedt et al. 1985) of patients, with increased protein and mononuclear cells, but lumbar puncture is rarely indicated. MRI is not usually indicated but, if performed, demonstrates contrast enhancement most commonly in the distal intra-canalicular and labyrinthine segments of the facial nerve (Sartoretti-Scheffer et al. 1994).

The treatment of Bell palsy is purely symptomatic. Protection of an exposed cornea (by lubrication and patching) is essential. Corticosteroids are often advocated for adult patients but they are usually not indicated for children and there is indeed no proof of their efficacy (Burgess et al. 1984; Salinas et al. 2004; Chen and Wong 2005). Since those children who will not recover well usually have a severe paralysis in the early stages, early steroid therapy can be justified in that group. It remains unclear whether antiviral agents are effective (Allen and Dunn 2004).

Paralyses of Known Cause

In endemic areas, facial palsy is frequently the only manifestation of Lyme disease, especially in summer and autumn (Markby 1989; Grundfast et al. 1990). Christen et al. (1993) found that 32.9% of their cases were due to Lyme disease whereas viruses were apparently responsible for 18.4%. Facial palsy in neuroborreliosis may be unilateral; the occurrence of bilateral palsy a few days after involvement of one side is highly suggestive of borreliosis (Keane 1994; Kindstrand 1995). A stiff neck may be found in a quarter of cases. The CSF in such cases consistently shows pleocytosis and increased protein and may contain antibodies against *Borrelia burgdorferi*.

Herpes zoster of the geniculate ganglion (Ramsay Hunt syndrome) is an uncommon cause of facial palsy in children. It may occur without any vesicular rash in the concha (Manning and Adour 1972). Other viruses may cause facial paralysis including Epstein–Barr, chickenpox and mumps viruses. Cases due to Kawasaki disease have been described (Bushara et al. 1997).

Otitis media and mastoiditis, although now uncommon causes, should always be thought of, as antibiotic and/or surgical treatment may be required and as local signs may be extremely subtle. X-rays or CT of the temporal bone are indicated if there is any doubt about the possibility of a local otogenic process.

Tumours, especially rhabdomyosarcomas, may compress the nerve and should always be considered.

Hypertension is an infrequent cause of facial palsy (Lloyd et al. 1966) but should be systematically looked for. Recurrent facial palsy may also be due to hypertension as well as to familial Bell palsy (Hageman et al. 1990).

Traumatic paralysis is easy to suspect but demonstration may also require X-ray investigation (May et al. 1981). It may lead to aberrant regeneration and contractures.

Facial palsy is also the most common manifestation of neurosarcoïtosis, a rare disorder in children (Scott 1993).

Melkersson–Rosenthal syndrome is characterised by recurrent facial palsy, associated with swelling of the lips, face or eyelids and furrowing of the tongue (Wadlington et al. 1984; Ziem et al. 2000). Facial swelling and palsy may occur in isolation or simultaneously. Often swelling is the initial manifestation. Lingual involvement is inconsistent. With repeated attacks, residual paralysis may appear and increase, leading to severe impairment. Histopathological examination reveals noncaseating granulomas on skin biopsy (Elias et al. 2013). Decompression of the facial canal appears to be more effective than steroid therapy (Feng et al. 2014; Tan et al. 2015).

Apart from neuroborreliosis, other causes of bilateral facial palsy in a mixed series of 43 children and adults (Keane 1994) included GBS (six cases), tumours of brainstem or meninges (nine cases), brainstem encephalitis and other miscellaneous causes. Ten cases were idiopathic (bilateral Bell palsy).

Hemifacial spasm-like seizures have been reported in a few infants and children (Al-Shahwan et al. 1994; Arzimanoglou 1996). The onset is usually in the first days of life with repeated attacks of unilateral tonic facial contracture lasting a minute or less and repeated many times daily. The syndrome is regularly associated with a small mass lesion in the cerebellum or in the region of the nucleus of the ipsilateral VIIth nerve that is hamartomatous or neoplastic in nature (Al-Shahwan et al. 1994; Arzimanoglou 1996; Harvey et al. 1996). Harvey et al. (1996) have recorded mass paroxysmal discharges synchronous with the attack that may thus be regarded as a form of subcortical epilepsy. Their patient remained free of attacks following resection of a ganglioglioma. Such attacks differ from true peripheral hemifacial spasm, a rare condition in childhood, which is usually attributed to vascular compression of the VIIth nerve trunk (Ronen et al. 1986). A case presenting in a newborn infant has been reported with a benign course (Zafeiriou et al. 1997).

LOWER CRANIAL NERVE PALSES

Congenital Lower Cranial Nerve Palsies

Impairment of function of lower cranial nerves VII to XII may occur in cases of Chiari I and II malformation (see Chapter 6). Involvement of the abductors of the vocal cords is particularly important as it often gives rise to severe respiratory insufficiency. Some cases are improved by treatment of the accompanying hydrocephalus.

Congenital traumatic laryngeal paralyses are probably related to intrauterine posture with rotation and lateral flexion of the head causing compression of the superior branch...
of the laryngeal nerve against the thyroid bone and that of the recurrent nerve against the cricoid cartilage. This produces a dual syndrome of the laryngeal nerve with both disturbances of swallowing due to sensory dysfunction of the superior laryngeal nerve and dysphonia due to involvement of the recurrent nerve (Chapple 1956). The prognosis of such cases is usually good (Narcy et al. 1978). Neurogenic stridor may also be of traumatic origin following forceps delivery or accidental trauma at birth (Maze and Bloch 1979). Other traumatic neonatal paralyses of the lower cranial nerves are uncommon.

Hoarseness due to paralysis of the left recurrent nerve is, in rare cases, a presenting or accompanying symptom of congestive heart failure in infancy or a manifestation of a congenital anomaly of the great vessels of the base of the heart, the cardiovocal syndrome (Condon et al. 1985).

Congenital dysfunction of the vocal cords may occur in isolation and may be genetically transmitted. The posterior cricoarytenoid muscle, which is the sole abductor of the vocal cords and the only laryngeal muscle innervated solely by neurons of the ventral division of the ipsilateral nucleus ambiguus, is affected, resulting in stridor and respiratory impairment. The condition may be familial (Cunningham et al. 1985). The course is towards spontaneous recovery in some cases, while other patients require a tracheostomy to maintain a free airway (Cohen et al. 1982).

Stridor may also be a feature of CNS involvement in infantile Gauchers disease and occurs in association with nystagmus in connatal Pelizaeus–Merzbacher disease (see Chapter 10).

In a family with six affected members from three generations with a point mutation in SEPT9, one of the patients presented in the neonatal period with vocal cord paralysis necessitating intubation and prolonged ventilation (Leshinsky-Silver et al. 2013).

Intracranial disorders that produce raised intracranial pressure can be responsible for unilateral or, more commonly, bilateral vocal cord palsy often requiring tracheostomy. Spontaneous regression occurred in four of seven cases reported by Chaten et al. (1991).

Laryngeal nerve palsies may improve significantly following various interventions including thyroplasty, laryngoplasty or re-innervation (Butskiy et al. 2015).

Congenital dysphagia is rarely due to peripheral nerve involvement and is more often a part of pseudobulbar palsy that may be due to brain malformations or vascular and degenerative disorders. Severe dysarthria is often present in such cases (Van Dongen et al. 1987). Prolonged congenital dysphagia was reported by Mbonda et al. (1995). One of their four patients had associated paralysis of the adductors of the vocal cords. Cine-radiographic study of swallowing showed major difficulties with the pharyngeal stage with only minimal involvement of the first oral stage. Two of the patients died; the others recovered in 20 and 40 months respectively. This syndrome is to be distinguished from benign transient pharyngeal dysfunction observed usually in preterm infants with recovery in a few weeks. EMG of the tongue and pharyngeal muscle confirms the peripheral involvement and helps predict the outcome.

Other Lesions of the Lower Cranial Nerves

A few cases of glossopharyngeal paralysis variably associated with involvement of the Xth and XIIth cranial nerves are on record (Greenberg et al. 1987). Glossopharyngeal neuralgia is exceptionally rare in children. Recurrent laryngeal and hypoglossal palsies accompanied by brachial plexus injury or inflammation have also been reported (Haenggeli and Lacourt 1989; Nagappa et al. 2013).

Isolated neuropathies probably related to viral or post-viral diseases may raise serious diagnostic problems in children. Some may affect only one nerve; for example, the hypoglossal nerve (Edin et al. 1976; Wright and Lee 1980), the recurrent nerve (Blau and Kapadia 1972) or the vagus nerve (Berry and Blair 1980). Others may involve both the IXth and Xth nerves, usually on one side, and produce an isolated temporary paralysis of the pharynx that may raise the suspicion of brainstem disease (Aubergé et al. 1979; Roberton and Mellor 1982; Suarez-Zeledon and Brian-Gago 1995). The onset is sudden, often following an upper respiratory infection, more rarely after a specific viral infection such as infectious mononucleosis (Wright and Lee 1980; Sugama et al. 1992; Connelly and De Witt 1994), with nasal reflux and/or dysphagia. Examination shows unilateral paresis of the soft palate and of the posterior pharyngeal wall. Spontaneous recovery occurs in a few days or weeks. Such cases are probably related to post-infectious abducens palsy. XIIth nerve palsy is rare in children (Keane 1996).

MULTIPLE CRANIAL NERVE PARALYSES

As indicated above, multiple involvement of cranial nerves may be more frequent than suspected, and Bell palsy is often the visible part of a subclinical multiple neuropathy. Such multiple nerve involvement in adults may be of vascular origin (Lapresle and Lasjaunias 1986). Affected nerves are few in such cases and belong to a localised arterial territory. In children, multiple cranial neuropathy is more often a manifestation of acute polynuropathy akin to the Guillain–Barré syndrome (Ropper 1986; Waddy et al. 1989). In occasional cases, a known virus is implicated; for example, the varicella-zoster virus (Mayo and Booss 1989).

Idiopathic cranial polyneuropathy is observed mainly in adults (Hokkanen et al. 1978; Juncos and Beal 1987; Uldry and Régli 1988) but may also affect children. Various patterns of multiple cranial nerve involvement can obtain. The most commonly involved nerves are the facial nerves, the oculomotor nerves and the lower cranial nerves, but optic nerve involvement has been reported. The course of multiple cranial neuropathies is often recurrent, and such cases pose differential
diagnostic problems with myasthenia gravis, recurrent facial palsy, the syndrome of Tolosa–Hunt (Sorensen 1988), and some mitochondrial diseases. A migrating course is sometimes observed (Takahashi 1978). The condition may be familial (Sorensen 1988) but little is known about its mechanism. A few cases have been linked to antiganglioside antibodies (Matsubara et al. 1997).

A similar picture may be produced by tumours invading the base of the skull or basal meninges; hence the necessity of a careful radiological examination of such patients. Brainstem gliomas and encephalitis may also pose a diagnostic problem although they commonly produce signs of long tract involvement. Osseous diseases (hyperostosis cranialis interna) (Manni et al. 1990) may be a rare cause of multiple cranial nerve entrapment.

Muscle Disorders

Monique M Ryan, Francesco Muntoni and Kathryn N North

The last few decades have seen an explosion in our understanding of the genetic and pathological basis of neuromuscular conditions, although at this time their treatment remains largely symptomatic.

The genetic and inflammatory myopathies, muscular dystrophies, congenital and acquired myasthenic and neuropathic syndromes of childhood all present with weakness, hypotonia and motor delay. Distinction between these syndromes is based on age at onset, pattern of weakness, associated neurological findings, baseline biochemical and neurophysiological testing. Targeted genetic testing can then be used to confirm diagnosis and guide treatment.

This chapter will describe these conditions in detail and will focus on our current understanding of treatment and management issues in these disorders, looking towards diagnostic and therapeutic challenges for the future.

CONGENITAL MYOPATHIES

Congenital myopathies are characterised clinically by hypotonia and weakness, usually from birth, as well as by characteristic morphological changes on histological and/or electron microscopic examination of muscle. There is wide variation in clinical severity within each form of myopathy and marked clinical overlap with other neuromuscular disorders including the muscular dystrophies, congenital myasthenic syndromes, metabolic myopathies including Pompe disease and spinal muscular atrophy, which can all present in the newborn period with marked hypotonia and weakness (the ‘floppy infant’ syndrome). The differential diagnosis also encompasses other conditions such as Prader-Willi syndrome and neurometabolic disorders in which children may appear profoundly hypotonic without a primary involvement of the skeletal muscles or nerves.

Clinical findings suggestive of congenital myopathies include prominent facial weakness with or without ptosis, a hypotonic (‘frog-leg’) posture with hyporeflexia and weakness of the respiratory and bulbar muscles. The extraocular muscles may be involved in some forms, either at presentation or later in the course of the disorder. Sensation is intact and intelligence usually normal. Histopathological signs of muscle dystrophy are not present, creatine kinase levels are normal or only mildly elevated and the electromyography (EMG) is either normal or myopathic. Muscle ultrasound and magnetic resonance imaging (MRI) are increasingly used to recognise primary myopathies and differentiate between different forms of congenital myopathy. Selective muscle involvement on MRI can be suggestive of a specific disease gene but not all myopathy subtypes have unique MRI signatures. Imaging is usually interpreted in conjunction with the clinical phenotype and results of muscle biopsy, to prioritise or interpret results of gene testing.

Historically, the congenital myopathies have been classified on the basis of the morphological features seen on muscle biopsy – for example, rods (nemaline myopathy), cores (central core disease and multiminicore disease), central nuclei (centronuclear/myotubular myopathy) and selective hypertrophy of type 1 fibres (congenital fibre type disproportion). Over the past 15 years the genetic basis of many of the different forms of congenital myopathy has been identified but it is clear that there are still many additional genes to be discovered. The known genetic causes for the congenital myopathies are summarised in Table 26.1. As demonstrated in the table, the relationship between each congenital myopathy (as defined on histological grounds) and the genetic cause(s) is complex. Many congenital myopathies resulting in an apparently similar muscle pathology phenotype can be caused by mutations in more than one gene (genetic heterogeneity). For example, there are currently ten known genetic loci for nemaline myopathy. In addition, mutations in the same gene can cause different muscle pathologies. Mutations in the ryanodine receptor 1 (RYR1) gene can be autosomal dominant or recessive and may be associated with central core disease, core-rod myopathy, multiminicore disease, centronuclear myopathy and congenital fibre type disproportion. Clinical features can provide valuable clues to help distinguish between different genetic disorders with overlapping pathology (North et al. 2014). The increasing use of next generation sequencing as a diagnostic tool in clinical practice is likely to reduce the need for muscle biopsy as a first-line investigation in the future.

*Continued*
There are currently no curative treatments for the congenital myopathies but a multidisciplinary approach to the management of affected individuals can greatly improve both quality of life and longevity, in particular physical and occupational therapy, orthopaedic intervention, anticipatory respiratory care and management of feeding difficulties. While progression of muscle weakness is usually only very slow or even absent, some complications (scoliosis; respiratory insufficiency) are very common in congenital myopathies and if untreated can lead to death. In severely affected infants survival into childhood can be very challenging. Prenatal diagnosis is available for many of these disorders once their genetic cause is identified.

### NEMALINE MYOPATHY

The ‘typical congenital’ form of nemaline myopathy usually presents at birth or during the first year of life with hypotonia, weakness and feeding difficulties. Some children present later with delayed motor milestones, a waddling gait or speech abnormalities however occasionally some will not present till adulthood. Facial weakness is common while there is often distal as well as proximal weakness, which may be a clue to genetic subtype. The respiratory muscles are always involved and hypoventilation may be subclinical; many children require active ventilatory support. Cardiac involvement is rare with muscle weakness often static or only very slowly progressive: most patients are able to lead an active life.

The ‘severe congenital’ form of nemaline myopathy presents at birth with severe hypotonia and muscle weakness, fetal akinesia and little spontaneous movement postnatally, difficulties with sucking and swallowing and respiratory insufficiency. Death due to respiratory insufficiency or recurrent pneumonia is common during the first weeks or months of life although occasional patients survive and achieve the ability to walk (Ryan et al. 2001).

The diagnostic feature of nemaline myopathy is the presence of distinct rod-like inclusions – nemaline bodies – in skeletal muscle fibres. Rods are not visible on haematoxylin and eosin (H&E) staining but appear as red or purple structures against the blue-green myofibrillar background with the modified Gomori trichrome stain and are derived from the lateral expansion of the Z-line. Additional pathological features of nemaline myopathy include type I fibre predominance, fibre atrophy and/or fibre hypertrophy (Ryan et al. 2003).

Adapted from North et al. (2014).

AD, autosomal dominant; AR, autosomal recessive.
new dominant mutations). To date, disease-causing mutations have been identified in ten genes (reviewed in Romero et al. 2013; North et al. 2014). Seven of these genes encode protein components of the thin filament of muscle: α-tropomyosin, tropomyosin, troponin T, coflin and leiomodin 3 (Table 26.1). Three genes (KBTBD13, KLHL40, KLHL41) are likely to be involved in regulating the turnover or breakdown of proteins in the sarcomere although their exact function is as yet unknown. Recessive mutations in nebulin are likely to account for up to 50% of individuals affected by nemaline myopathy. Sporadic or new dominant mutations in the skeletal α-actin gene (ACTA1) account for 20–25% of individuals (and up to 50% of newborn lethal presentations). The other genes are relatively rare causes of nemaline myopathy and there are further genes to be identified.

**CENTRAL CORE DISEASE**

Central core disease (CCD) usually presents in infancy with weakness, hypotonia and poor muscle bulk, primarily affecting the proximal musculature and lower extremities. Most affected individuals achieve ambulation but motor milestones are typically delayed and muscle weakness generally static or only slowly progressive. There may be mild facial and neck muscle weakness and extracocular muscles are usually spared. Musculoskeletal deformities such as kyphoscoliosis, congenital hip dislocation, pes cavus, pes planus and thoracic deformities occur frequently. Significant respiratory insufficiency is unusual, cardiac abnormalities are not part of the condition and intellectual performance is not impaired (Shuaib et al. 1987). Although most patients display the ‘typical’ clinical phenotype, central cores on muscle biopsies may be found in children who are asymptomatic and have isolated hyper-CK-emia as well as in patients with mild weakness or skeletal deformity (Shuaib et al. 1987; Quinlivan et al. 2003). At the other end of the spectrum severe and fatal infantile variants have also been described.

The characteristic pathological abnormality of CCD is the presence of central cores: central single, well-circumscribed circular regions in the majority of type 1 fibres which represent zones of reduced oxidative enzyme activity staining negatively for phosphorylase and glycogen (Quinlivan et al. 2003). Cores are devoid of mitochondria and sarcoplasmic reticulum (Quinlivan et al. 2003). In most individuals there is type 1 fibre predominance, and type 1 fibres are typically smaller than type 2.

Central core disease has traditionally been regarded as an autosomal dominant disease with variable penetrance. De novo mutations are relatively common. Recessive inheritance is now also recognised, particularly when individuals are affected severely (Ferreiro et al. 2002; Romero et al. 2003). Where histological changes and clinical features are typical of CCD, most patients have dominant changes in the ryanodine receptor gene (RYR1) (Wu et al. 2006), but there is significant clinical and pathological overlap with other variants of RYR1-related myopathy, including the fact that ‘typical’ pathological changes can evolve with time in the same patient from multiminicore to central core so that these group of conditions are increasingly referred to as ‘RYR1-related core myopathies’. The RYR1 gene encodes the skeletal muscle ryanodine receptor 1 which allows release of calcium from the sarcoplasmic reticulum into the sarcoplasm, triggering muscle contraction and in anybody with undiagnosed muscle weakness with possible autosomal dominant inheritance. Some patients with malignant hyperthermia susceptibility have cores on muscle biopsy and mutations in RYR1, despite having normal muscle strength.

The clinical spectrum of RYR1-related myopathies has recently been expanded with identification of children with dominant or recessive core myopathies (CCD or multiminicore disease) presenting with arthrogryposis, severe weakness and respiratory failure in the neonatal period (Romero et al. 2003); see Multiminicore Disease section below. Ophthalmoplegia and ptosis are present in some affected children who may require ventilatory support from birth, however surviving children can demonstrate considerable improvement in respiratory and peripheral muscle strength with increasing age.

**MULTIMINICORE DISEASE**

Multiminicore disease is a clinically and genetically heterogeneous disorder. Two main forms are recognised, one characterised mainly by rigidity of the spine and early respiratory insufficiency (RSMD1) with the other allelic to CCD, caused by recessive mutations in RYR1 and often associated with ophthalmoplegia.

The rigid spine syndrome phenotype of multiminicore disease is caused by recessive mutations in the gene for selenoprotein N (SEPN1), presenting in the first year of life. Affected infants are hypotonic and weak, with joint hyperextensibility and delayed motor development. Weakness is predominantly axial; the neck flexors are usually the most affected muscles, resulting in poor or absent head control in infancy. Facial weakness is common and the extraocular muscles are spared: intelligence is normal. Kyphoscoliosis and spinal rigidity are common and can progress rapidly during periods of rapid skeletal growth, particularly adolescence (Ferreiro et al. 2000; Jungbluth et al. 2000). This is almost invariably associated with progressive respiratory insufficiency (Ferreiro et al. 2000; Jungbluth et al. 2000). Most patients develop respiratory insufficiency in late adolescence or early adulthood (Ferreiro et al. 2000) although most remain independently ambulant.

R recessively inherited RYR1-related core myopathies with multiminicores show a similar distribution of weakness and wasting but additional extracocular muscle involvement, most pronounced on abduction and upward gaze (Ferreiro et al. 2000). Respiratory impairment is usually milder than in the classic form although bulbar involvement may be pronounced. This variant is far more common than the SEPN1–associated RSMD1 (Maggi et al. 2013).
Minicores are seen as multiple focal defects in oxidative enzyme activity in the majority of muscle fibres on histochemical preparations; they occur in both type I and type II fibres (Ferreiro et al. 2000; Jungbluth et al. 2000). Associated features include increased fibre-size variability, central nuclei, hypotrophy of type I fibres and type I fibre predominance (Jungbluth et al. 2000).

Other genes are also rarely associated with core myopathies (both central and multiminicores): in individuals with associated cardiomyopathy mutations in MYH7 (Cullup et al. 2012) and titin (TTN) (Carmignac et al. 2007) should be considered.

Core-rod disease is characterised by the presence of both central cores and nemaline bodies on muscle biopsy; these may be in the same or separate muscle fibres. The most common cause of true core-rod myopathy is mutations in the RYR1 gene; both dominant and recessive mutations have been described (Scacheri et al. 2000; Ferreiro et al. 2002). Nebulin mutations are an uncommon cause of recessive core-rod disease (Romero et al. 2000).

**CENTRONUCLEAR MYOPATHIES**

There are three groups of centronuclear myopathies (CNMs) based on clinical and genetic features. The X-linked recessive form (also known as myotubular myopathy) usually has onset in utero and the pregnancy is complicated by polyhydramnios. Affected males present at birth with severe floppiness and weakness, facial diplegia, and difficulties with respiration and feeding. Additional features include thin ribs, contractures of the hips and knees, ophthalmoplegia and contractile disorder. Many affected boys die in the neonatal period, but a minority survives longer, often requiring permanent respiratory support (McEntagart et al. 2002). The gene for X-linked myotubular myopathy, MTM1 (Laporte et al. 1996), is thought to be involved in a signal transduction pathway necessary both for late myogenesis and excitation-contraction coupling. The characteristic histological feature is predominance of small type 1 fibres with centrally placed nuclei that occupy a large volume of the fibre, resembling fetal myotubes. The major differential diagnosis, congenital myotonic dystrophy, must be excluded by genetic testing. Obligate carriers of the X-linked form of myotubular myopathy are usually asymptomatic but as many as 50% have changes on muscle biopsy. Manifesting carriers may have skewed X-inactivation and more severe weakness on a rare basis.

The autosomal dominant form of CNM due to mutations in the gene encoding dynamin 2 (DNM2) has a wide range in severity from congenital- to adult-onset weakness (Bitoun et al. 2005). Features suggesting this diagnosis include relative weakness of neck flexors, facial weakness, external ophthalmoplegia and ptosis. De novo mutations are relatively common, particularly in patients with severe phenotypes. Centrally placed nuclei and strands radiating from the centre of the fibre (radial sarcoplasmic strands) on the oxidative stains are characteristic findings on muscle biopsy in DNM2- and BIN1-related CNM, although they may be less apparent in younger children (Romero 2010).

Ryanodine receptor (RYR1) mutations are another cause of autosomal recessive centronuclear myopathy presenting in infancy or early childhood with respiratory distress, hypotonia, a weak cry and difficulty sucking (Romero 2010). Ophthalmoplegia, ptosis and facial diplegia are common. The clinical course is characterised by delayed motor milestones, slowly progressive weakness as well as development of contractures and scoliosis. Amphiphysin 2 (BIN1) mutations also cause a rare variant of autosomal recessive centronuclear myopathy (Nicot et al. 2007). Recessive mutations in the SPEG gene have recently been shown to cause a centronuclear myopathy with dilated cardiomyopathy (Agrawal et al. 2014).

**CONGENITAL FIBRE-TYPE DISPROPORTION**

Fibre-size disproportion occurs as a secondary phenomenon in a wide range of skeletal and neuromuscular conditions including CNS disorders, peripheral neuropathy, muscular dystrophy and other congenital myopathies such as nemaline myopathy, multiminicore disease and centronuclear myopathy. Congenital fibre-type disproportion (CFTD) is a diagnosis of exclusion, which is best reserved for patients who have clinical features of a congenital myopathy with reduction in type 1 (slow twitch) fibre size relative to type 2 (fast twitch) fibres (at least 35–40%) as their only significant histological abnormality (Clarke and North 2003).

CFTD is genetically heterogeneous and may be associated with autosomal dominant or recessive inheritance. De novo dominant mutations have been identified in skeletal α-actin (ACTA1), α-tropomyosin SLOW (TPM3) and β-tropomyosin (TPM2), all of which are also associated with nemaline myopathy (Table 26.1) (Laing et al. 2004; Clarke et al. 2008; Brandis et al. 2008). Recessive mutations have been identified in the gene encoding selenoprotein N (SEPN1), (Clarke et al. 2006) and the ryanodine receptor (RYR1) (Clarke et al. 2010). The clinical presentation is variable depending on the genetic subtype (Table 26.1).
progressive although some children have an essentially static course (Bonnemann et al. 2014).

In recent years the number of identified discrete clinical and genetic causes of CMD has increased markedly. Previous classifications of the CMDs, which were based mainly upon the presence or absence of concomitant structural central nervous system abnormalities in addition to the muscular dystrophy, have largely been replaced by systems reflecting the underlying genetic abnormality and/or muscle pathology.

Infants with CMD usually present with neonatal hypotonia, often with arthrogryposis. MRI of the brain is often abnormal in the CMDs, showing changes suggestive of specific conditions. Muscle biopsy shows typical dystrophic changes while immunostaining may reflect deficiency of alpha-2 laminin (merosin) or alpha-dystroglycan (Godfrey et al. 2011).

Genetic testing may enable definitive diagnosis. In many individuals negative testing suggests additional genetic heterogeneity to that already identified. Most of the CMDs are recessively inherited, exceptions being the dominantly inherited forms of collagen 6A1, A2 and A3 muscular dystrophy (in ~50% of patients with Ullrich CMD) as well as LMNA MD.

Laminin alpha-two congenital muscular dystrophy (merosin-deficient CMD, merosin-deficient congenital muscular dystrophy [MDC1A]) was defined relatively early as a cause of CMD without structural brain or eye abnormalities – ‘classic’ CMD. Children with MDC1A have severe muscle weakness with onset in infancy, often with early joint contractures and scoliosis. Nocturnal hypoventilation is common. Most sit but few walk unsupported, while intelligence is normal (Pegoraro et al. 1998). This form of CMD is frequently associated with cerebral dysmyelination – seen on MRI – and with peripheral nerve demyelination. The associated gene, LAMA2, encodes the alpha-2 chain of laminin, also known as merosin, which is a part of the dystrophin-associated glycoprotein complex. Staining for this protein is absent or decreased on muscle biopsies of children with MDC1A (Mercuri and Muntoni 2012).

Other forms of ‘classic’ CMD include the collagen VI-related CMDs (Ullrich and Bethlem CMD, UCMD and BM) which are characteristically associated with proximal joint contractures, striking distal hyperlaxity, sandpaper-like skin on the face and limbs, a characteristic facies and early-onset scoliosis. Children with Ullrich congenital muscular dystrophy are generally wheelchair-dependent by the end of the first decade; Bethlem myopathy has a similar but less severe phenotype. These conditions are on a phenotypic spectrum of ‘collagenopathies’ (Bushby et al. 2014). UCMD is caused in ~50% of individuals by recessive mutations in type VI collagen genes (COL6A1, COL6A2 and COL6A3), and Bethlem CMD generally dominantly inherited, although inheritance of both UCMD and BMD is variable (Giusti et al. 2005).

Recessive mutations in the selenoprotein N1 gene (SEPN1) cause rigid spine CMD associated with spinal rigidity and often with development of respiratory failure even while patients remain ambulant (Mohgadaszadeh et al. 2001), while that associated with LMNA mutations often presents with severe weakness particularly affecting the neck extensors, and can be associated with life-threatening cardiac arrhythmias and cardiomyopathy as well as chronic respiratory insufficiency (Quijano-Roy et al. 2008).

The alpha-dystroglycanopathies are a genetically heterogeneous group of muscle disorders, all of which are associated with hypoglycosylated alpha-dystroglycan (ADG) on muscle biopsy. These conditions cause a range of phenotypes ranging from severe syndromal CMDs to later-onset limb-girdle muscular dystrophies (LGMDs) (Mercuri et al. 2009; Godfrey et al. 2011). The severe CMDs are often associated with developmental abnormalities of the eyes and brain, as seen in Walker-Warburg syndrome (WWS), muscle-eye-brain disease (MEB), and Fukuyama congenital muscular dystrophy (FCMD). Weakness in the alpha-dystroglycanopathies tends to be more pronounced in the upper than lower extremities. Concomitant structural brain and ocular abnormalities, where present, often cause cognitive deficits, epilepsy and visual loss. Cardiac involvement is variably present and tends to be more severe in Fukuyama CMD, Walker-Warburg syndrome and muscle-eye-brain disease (Finsterer et al. 2010; Pane et al. 2012).

The serum creatine kinase is almost always markedly elevated in the dystroglycanopathies. Muscle biopsy shows classic dystrophic changes with absent or decreased staining for alpha-dystroglycan. A specific genetic diagnosis is often contingent on testing of multiple genes, which can most easily be achieved through next generation sequencing techniques.

The various genes involved in the dystroglycanopathies are listed in Table 26.2. Recent studies have shown that individual genes are commonly associated with different CMD phenotypes. Similarly, the defined clinical phenotypes are often associated with many different genes (Mercuri et al. 2009; Godfrey et al. 2011; Meilleur et al. 2014).

Fukuyama CMD (FCMD) is a severe disorder most often seen in Japan. Affected individuals have severe weakness, cognitive deficits, developmental delay, seizures and cardiomyopathy. Developmental brain anomalies in FCMD include occipital pachygyria and polymicrogyria, pontine hypoplasia and cerebellar abnormalities. Milder phenotypes are less commonly seen in children with FKTN mutations (Mercuri et al. 2006). In WWS muscle weakness is associated with severe brain and eye malformations, and hydrocephalus: this phenotype may be caused by mutations in the POMT1, POMT2, FKTN, FKRP, POMGNT1, LARGE, ISPD, GTDC2 and DAG1 genes (Mercuri and Muntoni 2012). Other mutations in POMT1 cause milder forms of congenital muscular dystrophy or an autosomal recessive form of LGMD. MEB, which has a milder phenotype than WWS, is also caused by mutations in a number of alpha-dystroglycanopathy genes (see Table 26.2).

Management of the CMDs follows guidelines for other neuromuscular disorders and is focussed on maintenance of strength and range of motion, with anticipatory monitoring for and treatment of disease-specific complications such as joint contractures, scoliosis, bulbar, respiratory and cardiac muscle involvement.

**DYSTROPHINOPATHIES**

**DUCHENNE AND BECKER MUSCULAR DYSTROPHIES**

**Duchenne muscular dystrophy** (DMD) is the most common muscular dystrophy of childhood, affecting one in 5000 boys (Darras et al. 2015). Affected individuals present between 3 and 5 years of age with motor delay, gait abnormalities, frequent falls and difficulty arising from the ground. Less common presentations include language or global developmental delay, or an incidental finding of raised serum creatine kinase (creatine kinase) levels or hepatic transaminases. Boys with DMD lose the ability to walk by age 13 years.

**Becker muscular dystrophy** (BMD), a less common, milder phenocopy of DMD, is caused by mutations in the same gene – dystrophin – but is associated with independent ambulation beyond the age of 16 years. Other conditions caused by dystrophin mutations – ‘dystrophinopathies’ – include X-linked cardiomyopathy and isolated quadriceps myopathy (reviewed in Darras et al. 2015).

Weakness in DMD initially primarily affects the proximal lower limbs and trunk with later involvement of the upper limbs and distal muscles. Neck flexor weakness is usually present at presentation. Untreated boys with DMD cannot jump, with examination features including a waddling gait, prominent calves and a positive Gowers’ sign, the latter being a non-specific sign of proximal weakness after the age of 3 years. Most boys with DMD increase in strength and motor skills (albeit to a lesser extent than their peers) until about 6 years of age; after this stage progressive weakness is seen, to the point that most are wheelchair dependent by 13 years of age (Darras et al. 2015). Boys and men with BMD have more variable onset of weakness, some remaining ambulant throughout life.

Respiratory muscle involvement in DMD causes chronic restrictive lung disease which first manifests from around 12 years, causing a progressive decrease in lung capacity after that age (Khirani et al. 2014), which is exacerbated in those with severe scoliosis (Smith et al. 1989). Sleep-disordered breathing (SDB) in DMD may be caused by obstructive sleep apnoea in the first decade with invariable development of nocturnal hypoventilation in the second decade, followed by SDB with nocturnal hypcapnia then, finally, diurnal hypcapnia (Ragette et al. 2002).

Cardiac manifestations of the dystrophinopathies include dilated cardiomyopathy and arrhythmias. The first sign of cardiac involvement in DMD is a resting tachycardia which occurs as result of de novo mutations (Kunkel et al. 1986; Hoffman et al. 1987; Darras et al. 2015). Fractures are common, especially in boys treated with steroids, and can precipitate permanent loss of independent ambulation (King et al. 2007; Darras et al. 2015). Most female carriers of dystrophin mutations are asymptomatic. As many as 20% have mild to moderate muscle weakness and creatine kinase levels are raised in 50–60% (Hoogerwaard et al. 1999). Cardiac involvement may occur; up to 8% of carrier females develop a dilated cardiomyopathy in adulthood (Hoogerwaard et al. 1999a).

DMD is caused by mutations in dystrophin (DMD) gene on chromosome Xp21. The DMD gene is one of the largest genes known, containing 79 exons; the size of the gene makes it susceptible to mutations. Two-thirds of individuals affected by DMD inherit the gene maternally, one-third occurring as result of de novo mutations (Kunkel et al. 1986; Hoffman et al. 1987; Darras et al. 2015). Dystrophin localises to the skeletal muscle sarcolemmal membrane, complexing with the dystrophin-associated glycoprotein complex, and acting as a link between the cytoskeleton and the extracellular matrix (Rando 2001). Loss of dystrophin in DMD causes degeneration of muscle fibres and is likely to be as a result of cytoskeletal instability as well as abnormal calcium homeostasis (Deconinck and Dan 2007).

Mutations in DMD result in a truncated, unstable dystrophin protein product. The ‘reading frame rule’ explains the majority of the phenotypic differences between DMD and BMD; mutations disrupting the open reading frame cause a lack of any functional dystrophin, causing DMD, while those maintaining the open reading frame, with production of a lower molecular weight protein product retaining some protein function, cause BMD and the other dystrophinopathy phenotypes (Aartsma-Rus et al. 2006). Most (65–70%) patients with DMD have deletions; 10–15% have point mutations and about 5–7% have partial duplications of the dystrophin gene (Darras et al. 2015).

Serum creatine kinase levels are markedly raised in DMD, with levels 10–20 times the upper limit of normal seen from overall, boys with DMD have a lower average IQ than their peers. Cognitive involvement in DMD and BMD affects verbal IQ more than performance IQ and is static throughout life (Liebowitz and Dubowitz 1981). DMD is also associated with a higher incidence of attention-deficit–hyperactivity disorder and autism spectrum disorders (Hendriksen et al. 2008).

Orthopaedic complications are virtually invariable in DMD. In the first decade of life a typical pattern of contractions commonly develops at the ankles, knees, iliotibial bands and hips, causing a characteristic lumbar lordosis and predisposition to toe-walking while affected boys remain ambulant. Scoliosis may develop in adolescence and can progress rapidly once boys are confined to a wheelchair, however it is now much less common than was the case before steroid treatment became the standard of care for DMD (Smith et al. 1989; Lebel et al. 2013). Fractures are common, especially in boys treated with steroids, and can precipitate permanent loss of independent ambulation (King et al. 2007; Darras et al. 2015).
Chapter 26 Muscle Disorders

birth. Serum alanine transaminase and aspartate transaminase levels are also raised; in boys with DMD these enzymes are muscle- (rather than liver-) derived; this can sometimes cause confusion (Bushby et al. 2010a). Deletions and duplications in the dystrophin gene can usually be detected by multiplex ligation-dependent probe amplification (MLPA) or high-resolution chromosomal microarray. Where these tests are negative, direct sequencing is required to identify point mutations in dystrophin; this method is relatively expensive and not available at all centres. Muscle biopsy is not required for diagnosis of DMD where genetic testing is conclusive but may be performed when genetic testing is negative. Typical muscle histology in DMD includes focci of muscle fibre necrosis and regeneration, with increased fibre size variability, mild inflammatory changes and replacement of muscle by fat and connective tissue. Immunostaining and/or Western blot analysis demonstrates a complete absence of dystrophin in DMD; milder changes are seen in BMD (Darras et al. 2015).

The multidisciplinary management of boys and young men with DMD revolves around symptomatic and rehabilitative management, monitoring for and treatment of the respiratory, cardiac, orthopaedic and nutritional issues associated with DMD and resulting corticosteroid treatment as well as genetic counselling. Advances in DMD management over the past two to three decades have improved both life expectancy and quality of life (Eagle et al. 2007; Passamano et al. 2012; Rall et al. 2012). International standards of care for the diagnosis and management of DMD were published in 2010, providing a benchmark for centres internationally and a basis for best practice care preparatory for clinical trials (Bushby et al. 2010a, b).

Maintenance of independent ambulation prevents development of contractures and scoliosis, while also helping to maintain independence (Darras et al. 2015). Regular physiotherapy and provision of orthotics prevent development or progression of contractures. Bone health assessments include monitoring of calcium, phosphate and 25-OH vitamin D levels, as well as bone densitometry in the steroid-treated and/or non-ambulant. Dietary supplementation of calcium and vitamin D should be considered in all boys, while boys with DMD should be monitored for development of scoliosis – both clinically and radiologically – once they become non-ambulant. Spinal fusion is considered in boys with a spinal curvature of greater than 20 degrees if they are still growing (Lebel et al. 2013). Patients with DMD have an increased risk of malignant hyperthermia-like reactions if exposed to inhalational anaesthetics and depolarising muscle relaxants; their parents and physicians must be aware of this risk (Hayes et al. 2008; Birkkrant 2009).

Monitoring of respiratory function in DMD should begin at 5–6 years of age, with consideration of annual overnight pulse oximetry or sleep studies once boys are non-ambulant. Acute respiratory infections require early management with antibiotics and chest physiotherapy (Birkkrant et al. 2009; Bushby et al. 2010a). Patients should be taught airway clearance techniques and offered support with nocturnal non-invasive ventilation (NIV) when they develop sleep-disordered breathing complicated by hypoventilation and/or hypercapnia. Benefits of NIV include fewer respiratory infections and hospital admissions, improved life expectancy and quality of life (Eagle et al. 2007; Young et al. 2007).

Cardiac surveillance in DMD includes regular electrocardiograms and echocardiograms, monitoring for arrhythmias and development of dilated cardiomyopathy (Nigro et al. 1990). Angiotensin converting enzyme inhibitors and/or beta blockers are increasingly used for treatment of left ventricular dysfunction (Angelini 2015). Boys on corticosteroids may require treatment for steroid-induced hypertension.

Supportive therapy for DMD includes appropriate attention to nutrition (Davidson and Truby 2009). Constipation, gastro-oesophageal reflux and dysphagia are common late in the disease course (Darras et al. 2015). Physical fitness is important for cognitive health and maintenance of cardiopulmonary function (Bushby et al. 2010a). Cognitive and mood issues may require input from a psychologist (Henriksen et al. 2008) while involvement of a palliative care team can help address social isolation, depression and pain towards the end of life (Bushby et al. 2010a).

Corticosteroids are the only pharmacological agent proven effective in DMD. Steroids improve muscle strength within 10 days of initiation of treatment; this improvement is maximal by 3 months (Gloss et al. 2016). Ongoing corticosteroid therapy prolongs independent ambulation by up to 3 years, preserves cardiopulmonary function, reduces the risk of scoliosis and improves life expectancy in DMD (Balaban et al. 2005; Biggar et al. 2006; Manzur et al. 2008). The most commonly used corticosteroids are prednisolone and prednisone, at a dose of 0.75mg/kg/day. Deflazacort (0.9mg/kg/day), a synthetic corticosteroid, is used in some countries; the choice of corticosteroid used largely depends on availability, cost, formulation and side-effect profile (Gloss et al. 2016).

The optimal age to begin treatment with corticosteroids is not clear. The current consensus is to start corticosteroid treatment at 4–6 years of age, prior to the onset of motor decline from DMD. Daily corticosteroid dosing is more effective than alternate daily dosing (Bushby et al. 2010a). Many centres continue corticosteroid treatment after loss of ambulation with the aims of preserving upper limb and cardiopulmonary function, as well as limiting progression of scoliosis (Pane et al. 2015). Long-term corticosteroid therapy has significant side-effects which should be monitored for and managed appropriately. The most common are excessive weight gain and behavioural problems; these can sometimes respond to a change in the steroid used (Gloss et al. 2016). Growth suppression and delayed puberty are virtually universal, with boys treated with steroids at greater risk of vertebral and long bone fractures (Gloss et al. 2016).

All affected families and possible carriers should be referred for genetic counselling. Prenatal diagnosis is available for carrier mothers who should also undergo cardiac monitoring in adulthood (Nolan et al. 2003; AAP 2005).

Recent clinical trials in DMD have focussed on gene therapies, stem cell therapies and dystrophin restoration approaches (Darras et al. 2015). Agents such as ataluren (Bushby et al. 2014) and antisense oligonucleotides (Mendell et al. 2013;
Voit et al. 2014) remain under study but have shown promise in increasing muscle dystrophin expression in specific genetic subtypes of DMD.

**FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY**

Facioscapulohumeral muscular dystrophy (FSHD) is an autosomal dominant myopathy characterised by progressive, frequently asymmetrical weakness involving the face, scapular muscles, proximal limb muscles and peronei (Tawil and Van der Maarel 2006). Typical initial symptoms are wasting of the shoulder girdle, winging of the scapulae, facial involvement with inability to purse the lips and close the eyes tightly, as well as a transverse smile. In the lower extremities there is generally a tendency to foot drop, with variable weakness of the hip girdle muscles. Respiratory function is usually normal while progression of weakness is insidious; many patients remain ambulant and life expectancy is usually unaffected. The respiratory muscles are usually only mildly affected.

The age at onset of FSHD is variable. Most patients first experience symptoms in the second decade but some remain asymptomatic throughout their lives. A small minority experience symptoms in the second decade but some remain asymptomatic while progression of weakness is insidious; many patients remain ambulant and life expectancy is usually unaffected. The respiratory muscles are usually only mildly affected.

The genetics of FSHD are complex. Two (clinically indistinguishable) genetic subtypes are defined – FSHD1 and FSHD2 (Tawil et al. 2010; Lemmers et al. 2012). Only some haplotypes are pathogenic with respect to FSHD; contractions involving other 4qA and 4qB haplotypes are not pathogenic (Lemmers et al. 2002). A small minority of individuals with FSHD has DNA hypomethylation on both D4Z4 alleles, a condition called FSHD2, caused by mutations in the *SMCHD1* gene (Lemmers et al. 2012). It is likely that both the D4Z4 deletion in FSHD1 and *SMCHD1* mutations in FSHD2 affect *DUX4* expression, leading to the development of FSHD by a toxic gain of function mechanism (Tawil and Van Der Maarel 2006; de Greef et al. 2010; Lemmers et al. 2012).

About 10–30% of individuals with FSHD have the disorder as the result of a de novo D4Z4 deletion; in the remainder there is a family history consistent with autosomal dominant inheritance (Bakker et al. 1996). The inheritance of FSHD2 is unclear but most cases appear to be sporadic (de Greef et al. 2010).

The distribution of weakness is an important clue to the diagnosis of FSHD, although similar findings may be seen in myotonic dystrophy, the congenital and mitochondrial myopathies, as well as some of the LGMDs (particularly LGMD 2A) (Tawil et al. 2010).

Management is primarily symptomatic, based on maintenance of strength, function and range of motion. Affected children need neuropsychological support for their cognitive deficits, and monitoring for ophthalmological, auditory, respiratory, cardiac and orthopaedic complications of their condition. Myalgia and joint pain are relatively common in FSHD and may respond to analgesics, physiotherapy as well as targeted exercise programmes (Tawil et al. 2010). Restrictive lung disease is more common in those with significant weakness while all persons with FSHD should be screened for retinal vascular disease at diagnosis; children require repeat studies until they are mature enough to report any visual loss (Statland et al. 2013). Children with FSHD should undergo regular audiological and ophthalmological reviews (Tawil et al. 2010).

**EMERY-DREIFUSS MUSCULAR DYSTROPHY**

Emery-Dreifuss muscular dystrophy (EDMD) is an uncommon, genetically heterogeneous muscle disease with a characteristic clinical phenotype. Genes most frequently involved in this condition include *EMD*, encoding emerin and *FHL1* (filamin-1), which cause X-linked EDMD. Autosomal dominant EDMD is caused by mutations in *LMNA*, the gene encoding lamins type A and C and by mutations in *TMEM43*, encoding LUMA. Mutations in two further genes, *SYNE1* (nesprin 1) and *SYNE2* (nesprin 2), may also cause rare variants of AD EDMD. Emerin, LUMA, lamin A and lamin C,
nesprin 1 and nesprin 2 are all proteins of the nuclear envelope (Puckelwartz and McNally 2011; Durmus et al. 2015).

Most children with EDMD present between 2–15 years although some develop symptoms later. The cardinal features of this condition include slowly progressive humeroperoneal muscle weakness and wasting, with early ankle and elbow contractures and back and neck stiffness (Durmus et al. 2015). Muscle weakness usually begins in the biceps and triceps, with subsequent development of peroneal muscle weakness and foot drop. Progression is slow but more than 10% of patients become non-ambulant in the third to fifth decades; their weakness may be exacerbated by spinal rigidity and joint contractures (Merlini et al. 1986). Disease severity can vary significantly within families.

Cardiac involvement in EDMD is often severe, particularly in those with LMNA mutations (Carlin et al. 2013). The ECG shows varying degrees of atrioventricular block with small T waves and atrial arrhythmias. Complete heart block often develops later and patients are at risk of atrial fibrillation, atrial flutter and atrial paralyzis. Later, dilated cardiomyopathy and ventricular tachyarrhythmias can cause sudden death, even in those with minimal previous signs of cardiac disease (Sakata et al. 2005). The severity of cardiac involvement does not correlate with skeletal muscle weakness in EDMD (Durmus et al. 2015).

Creatine kinase levels are elevated, usually two to ten times normal. EMG shows typical myopathic changes. Muscle MRI can be useful in demonstrating selective muscle involvement. Muscle histology in all genetic subtypes shows a combination of myopathic and dystrophic changes, with type 1 fibre predominance and angular, atrophic fibres. Immunohistochemistry shows absence of staining for emerin in 95% of patients with X-linked EDMD (Yates and Weinert 1999). Molecular diagnosis of EDMD should be guided by use of defined algorithms given the genetic heterogeneity (Darras 2015).

Treatment is largely supportive. Contractures should be addressed with physiotherapy and orthopaedic interventions. All patients – even those with minimal muscle weakness – known carrier and at-risk family members should undergo regular cardiac surveillance with Holter monitoring and echocardiography. Development of a junctional bradycardia should prompt insertion of a pacemaker and implantable cardiac defibrillator. Patients with severe ventricular failure may be candidates for cardiac transplantation (Bonnet al. 2015). Respiratory involvement is significant in some individuals with EDMD; a minority develop nocturnal hypoventilation and require nocturnal ventilatory support.

Limb-girdle muscular dystrophies

The limb-girdle muscular dystrophies (LGMDs) are a heterogeneous group of disorders characterised by weakness and wasting of the pelvic and shoulder girdle muscles, with dystrophic muscle histology showing ongoing degeneration of muscle fibres, increased fibre size variability, fat and connective tissue. Even within specific genetic subtypes the clinical course of LGMDs varies markedly, from severe forms with rapid progression and onset in the first decade (similar to the clinical presentation of DMD) to milder forms with slower progression and later onset (for useful reviews see Bushby 2009; Pegoraro and Hoffman 2012). Most LGMDs cause predominantly proximal weakness, sparing the facial, extraocular and distal limb muscles.

The more common forms of LGMD are shown in Table 26.3. Most are recessively inherited (LGMD type 2) – a minority is inherited in an autosomal dominant fashion (type 1). The overall prevalence of LGMDs has been estimated at 2.27 per 100 000 persons (Norwood et al. 2009).

Most LGMDs involve proteins related to, or interacting with, dystrophin, such as the dystrophin-associated proteins (DAPs), α-, β-, δ- and γ-sarcoglycans. It is hypothesised that deficiency of any single component of the DAP complex disrupts binding of the extracellular matrix to the cytoskeleton, rendering the sarcolemmal membrane unstable and resulting in ongoing fibre necrosis (Zatz et al. 2003; Laval and Bushby 2004). Other LGMDs (LGMDs 2I, 2K, 2N, 2O and 2P) relate to aberrant glycosylation of α-dystroglycan, again resulting in loss of the link between the extracellular matrix and cytoskeleton, destabilising muscle fibres and predisposing to chronic dystrophic changes. A minority of LGMDs relate to other structural muscle proteins; dysferlin is involved in vesicle fusion in skeletal muscle (Bansal and Campbell 2004) while calpain is a calcium-sensitive intracellular protease; caveolin-3, a component of membrane lipid raft domains; lamin A/C and emerin, nuclear envelope proteins; telethonin and myotilin are sarcomeric proteins while TRIM32 is a putative ubiquitin ligase (Zatz et al. 2003). Abnormalities in these proteins may lead to disruption of cellular pathways, central to disease pathogenesis, rather than causing dystrophic changes in muscle by a direct effect on the structure and integrity of the sarcolemmal membrane.

Clinical Correlates and an Approach to Diagnosis

A detailed review of all of the different forms of LGMD is beyond the scope of this text but there are some clues that can aid the clinician in diagnosis (Table 26.3). The pattern of muscle involvement is important as can be the identification of additional findings such as joint contractures, cardiac and central nervous system involvement. A family history may suggest dominant or recessive inheritance and there is commonly significant inter- and intra-familial phenotypic variability in the LGMDs. Calf hypertrophy can occur in all groups but is rare in LGMD2B, in which calf atrophy may occur. Cardiac involvement (cardiomyopathy) is common in the sarcoglycanopathies and LGMDs type 2I, 2J and 1B. Early onset and more severe weakness (a Duchenne-like phenotype) can be seen in the sarcoglycanopathies and in LGMDs 2A and 2I while later childhood onset is suggestive...

</table>

The differential diagnosis of the LGMDs includes Duchenne and Becker muscular dystrophies, myotonic dystrophy and FSHD. Affected females should be considered possible manifesting carriers of DMD. Other differential diagnoses such as juvenile acid maltase deficiency should be excluded by specific testing.

The creatine kinase is almost always raised in the LGMDs; the degree of creatine kinase elevation may be a clue to diagnosis. MRI may demonstrate specific muscle group involvement. Often the different forms of LGMD cannot be distinguished clinically, a specific diagnosis resting on protein studies on the muscle biopsy (immunohistochemistry and Western blot) to identify deficiency of a specific muscle protein, followed by mutation analysis to confirm the deficiency is due to a primary mutation in a specific gene (Table 26.3).

Abnormalities seen on immunohistochemistry are not always specific and this semiquantitative test should be interpreted with caution; for example, dysferlin is abnormally localised...
in up to 40% of LGMDs although complete deficiency as demonstrated by immunohistochemistry (IHC) is usually due to a primary dysferlin mutation (Bansal and Campbell 2004). Primary mutations in any one of the sarcoglycan genes can result in deficiency of all members of the sarcoglycan complex on IHC. Calpain deficiency demonstrated by Western blot is about 70% specific but can occur in other dystrophies; conversely, patients with mutations in the calpain gene have been identified in whom Western blotting for calpain is normal.

A specific diagnosis in the LGMDs is best made by molecular genetic testing, which is now most often done as part of a next-generation sequencing, panel or by whole exome sequencing which enable multiple genes to be tested in one iteration. These techniques may miss mutations involving large deletions or duplications.

### MYOTONIC DISEASES AND RELATED CONDITIONS

Myotonia is both a symptom and a sign. Clinically, myotonia manifests as delayed muscle relaxation which may be associated with a sensation of stiffness and/or discomfort. On electromyography myotonia is characterised by repetitive discharges producing classic ‘dive bomber’ (crescendo-decrescendo) discharges. Myotonia is caused by skeletal muscle fibre hyperexcitability, is purely of muscular origin and can be seen in a number of genetic diseases and syndromes including myotonic dystrophy and the ‘channelopathies’ or ion channel disorders.

#### MYOTONIC DYSTROPHY (DYSTROPHIA MYOTONICA, DM1, STEINERT DISEASE)

Myotonic dystrophy is the most common myotonic myopathy, affecting around one in 7000 people. Milder cases are often undiagnosed. This multisystem disorder, transmitted as an autosomal dominant trait, affects skeletal and smooth muscle as well as the eye, heart, endocrine and central nervous systems. Findings in myotonic dystrophy span a continuum from mild to very severe and have been categorised into three (overlapping) phenotypes: mild, classic and congenital.

Myotonic dystrophy type 1 is caused by a CTG trinucleotide expansion in the untranslated region of the dystrophia myotonica–protein kinase gene (DMPK) on chromosome 19q13.3. The length of this trinucleotide expansion may increase dramatically between generations (Harper 2001). Myotonic dystrophy type 2 (DM2, previously termed proximal myotonic myopathy) is a much less common disorder, which is not generally seen in childhood (Udd and Krahe 2012).

#### CLASSIC MYOTONIC DYSTROPHY

Classic myotonic dystrophy has very variable clinical severity. The age at onset of classic myotonic dystrophy is typically in the twenties or thirties, although subtle early signs – facial weakness and the onset of myotonia – may be evident in childhood. Individuals with classic myotonic dystrophy type 1 (DM1) may have only cataracts, mild myotonia or diabetes mellitus (Harper 2001).

The distribution of muscular atrophy and weakness in myotonic dystrophy is characteristic. Atrophy of the facial muscles, especially the masseters and temporalis muscles, results in a long, thin face and hollowed temporal fossae, with the sternocleidomastoid and shoulder girdle muscles also involved. The brachioradialis muscles, hand intrinsics and muscles of the anterior compartment of the leg are also wasted, resulting in foot drop. In some patients weakness is mild, but those with significant symptoms in childhood tend to have progressive weakness in adult life, sometimes to the point of wheelchair confinement (Harper 2001; Echenne et al. 2008).

Muscle pain is often prominent in myotonic dystrophy. Myotonia, slowing of muscle relaxation after volitional contraction, is often best seen in the eyelids or after hand grip. Elicited myotonia is demonstrated by percussion of muscle (e.g. the thenar eminence, the thumb remaining opposed for several seconds after percussion).

Respiratory muscle compromise and aspiration may occur in individuals with advanced disease (Udd and Krahe 2012). Smooth muscle involvement in myotonic dystrophy may present with dysphagia, constipation, diarrhoea or incontinence. In adults frontal balding, hypogonadism and insulin resistance may occur (Hudson et al. 1987) with cardiac conduction defects the most important complication because of the risk of conduction block, cardiac arrhythmia and sudden cardiac death (Lund et al. 2014; Petri et al. 2014). Posterior cataracts develop after the first decade and may be the presenting feature of the disease. Intellectual impairment is common in patients with classic myotonic dystrophy; avoidant, obsessive-compulsive and passive-aggressive personality traits are also often seen (Serra et al. 2014). Hypersomnia and sleep apnoea are other well-recognised manifestations of the diseases (Udd and Krahe 2012). A reduced lifespan may be due to pneumonia and respiratory failure or cardiovascular complications such as arrhythmias (Groh et al. 2008).

#### MILD MYOTONIC DYSTROPHY

Children with mild myotonic dystrophy may present with static cognitive issues prior to their later development of relatively mild, proximally-predominant muscle weakness.
Part X  Neuromuscular Diseases

1276

(Ekstrom et al. 2009; Angeard et al. 2011). Myotonia may not be reported by patients when mild and has to be specifically looked for on examination.

**CONGENITAL MYOTONIC DYSTROPHY**

Congenital myotonic dystrophy is a severe myopathy of early childhood. The onset is prenatal with decreased fetal movement reflected in polydramnios, talipes equinovarus deformities and breech presentation. At delivery affected infants are hypotonic and weak, with facial diplegia and a tented upper lip (Fig. 26.1).

Children with congenital myopathies and congenital muscular dystrophies may look very similar to those with myotonic dystrophy although the overall appearance of the infant, especially distribution of facial weakness, is suggestive. Examination of the mother, for mild weakness and for myotonia, is the best clue to diagnosis.

Respiratory insufficiency due to diaphragmatic and intercostal muscle involvement occurs in about as many as 80% of individuals, necessitating ventilatory support and often leading to early death (Campbell et al. 2013). Most affected infants require gavage feeding (Campbell et al. 2013). Surviving infants gradually improve and usually eventually walk although they later develop a progressive myopathy, as in the classic form, and are at risk of cardiac arrhythmias and cardiomyopathy in the first decade of life (Igarashi et al. 1998; Bassez et al. 2004). Myotonia is never observed, even by EMG, before 3–4 years of age (often much later). Most children with congenital myotonic dystrophy have severe static cognitive deficits (Harper 2001; Echenne et al. 2008).

**Diagnosis and Treatment of Myotonic Dystrophies**

Serum creatine kinase is usually mildly to moderately elevated in DM1. In older children EMG is useful in identifying myotonic discharges which are most likely to be seen in distal muscles. Muscle biopsy is not generally required for diagnosis but when undertaken shows markedly increased internal nuclei and atrophic fibres with limited dystrophic changes. This can lead to the misdiagnosis of centronuclear myopathy.

DM1 is caused by expansion of a CTG trinucleotide repeat in the *DMPK* gene on chromosome 19q13.3 (Brook et al. 1992). The normal DMPK allele contains 5–34 CTG repeats. Adults with 35–49 repeats have a mutable normal (premutable) allele with their children at risk of inheriting a larger repeat size (Harper 2001). As is usual with disorders associated with DNA expansion, anticipation and a sex bias in genetic transmission are observed. The length of the repeat usually increases in successive generations, especially when maternally transmitted. There is a good correlation between the length of the expansion and the clinical severity and age at onset (Jaspert et al. 1995). Classic DM1 is associated with a repeat size of 100–1000 while congenital myotonic dystrophy is associated with repeat sizes >2000. Congenital DM1 is almost always inherited from the mother (Harper 2001).

Molecular genetic testing detects mutations in nearly 100% of affected individuals and enables pre- and postnatal diagnosis. The expanded CTG repeat leads to the abnormal processing of RNA transcripts that affect the alternative splicing and levels of expression of other genes, resulting in multisystem disease manifestations (e.g. chloride channel leading to myotonia, insulin receptor leading to diabetes) (Day and Ranum 2005).

Regular multidisciplinary disease surveillance is important for patients with myotonic dystrophy. Affected patients should undergo annual ECG and/or Holter monitoring to detect cardiac conduction defects as well as regular monitoring of pulmonary function and swallowing function. Many children require nutritional support and gavage feeding. Myotonia is rarely severe enough to require treatment while myalgia may require symptomatic treatment. Some children with DM1 experience excessive daytime sleepiness; this responds well to treatment with modafinil in adults but has not yet been formally studied in children (Annane et al. 2006).

Life expectancy is reduced in patients with congenital and childhood-onset myotonic dystrophy. Causes of death include pneumonia, sudden cardiac death and progressive respiratory failure (Mathieu et al. 1999; Groh et al. 2008) and as many as 25% of children with congenital myotonic dystrophy die before the age of 5 years, with only 50% surviving into their mid-thirties (Reardon et al. 1993). Very few achieve independent living as a result of the cognitive involvement.
Chapter 26 Muscle Disorders

1277

ION CHANNEL DISORDERS

A number of ion channel disorders affect skeletal muscle, variably producing myotonia and/or weakness. In diagnosing these conditions it is important to distinguish between myotonia and paramyotonia, with the former decreasing with repeated muscle contraction, known as the ‘warm-up’ phenomenon, while in paramyotonia or ‘paradoxical myotonia’ muscle relaxation becomes slower with repeated contractions (Cannon 2015).

This group of disorders can be considered as follows (Table 26.4):

1. Patients with clinical and neurophysiological evidence of myotonia who have dystrophic or non-dystrophic muscle disorders, with or without fixed muscle weakness.
2. Patients with electrical but not clinical evidence of myotonia, with this subset including a number of genetic and medication-induced myopathies.
3. Patients with suggestive symptoms but no clinical or electrical evidence of myotonia (Heatwole et al. 2013).

Myotonic muscle diseases causing weakness, myotonia and/or muscle hypertrophy are described briefly below.

CHLORIDE CHANNEL DISORDERS

Myotonia congenita can be transmitted as either an autosomal dominant or autosomal recessive trait, or can occur sporadically as a result of de novo chloride channel gene mutations (Cannon 2015). Myotonia is present at the beginning of a movement after a period of rest, making movements difficult to initiate, but resolves after repeated movements. The severity of myotonia varies from mild symptoms causing no functional limitations to severe stiffness which significantly limits daily activities. Symptoms are often present from early childhood but may not be recognised until late adolescence or adulthood and are usually more significant in the legs and face than the arms. The recessive (Becker) form of this disease usually begins slightly later but is more severe than the dominant (Thomsen) form. Many patients have generalised muscle hypertrophy as a consequence of continuous muscle contraction. Stiffness is usually painless and increased by intense emotion or exposure to cold. Myotonic contraction can be elicited by percussion of muscles while serum creatine kinase may be normal or mildly elevated (three to four times upper limit of normal). Neither type of myotonia congenita is associated with the systemic features seen in myotonic dystrophy.

The clinical diagnosis is confirmed by EMG, which demonstrates repetitive discharges on insertion and with voluntary contraction: muscle biopsy is rarely necessary. Both the dominant and the recessive forms are caused by mutations in the voltage-gated chloride channel gene ($\text{CLCN1}$) on chromosome 7q (Koch et al. 1992). Sequencing of the $\text{CLCN1}$ gene detects more than 95% of mutations in both forms of myotonia congenita.

Myotonia may be avoided by brief frequent periods of exercise and by avoidance of cold environments. In patients with problematic symptoms muscle stiffness may respond to...

AD, autosomal dominant; AR, autosomal recessive.
a variety of sodium-channel blocking agents including mexiletine, procainamide, tocainide and phenytoin (Heatwole et al. 2013). Depolarising muscle relaxants, adrenaline, beta-adrenergic agonists and propranolol may aggravate myotonia (Farbu et al. 2003). Malignant hyperthermia is reported in patients with myotonia congenita (Heiman-Patterson et al. 1988).

**SODIUM CHANNEL DISORDERS**

Several dominantly-inherited myotonic syndromes and periodic paralyses are caused by point mutations in the *SCN4A* gene on chromosome 17q23, encoding the voltage-gated skeletal muscle sodium channel (reviewed in Heatwole et al. 2013; Cannon 2015).

**Paramyotonia Congenita**

In this condition, myotonia is present from infancy and involves the eyelids, facial and hand muscles, as well as sometimes the pharyngeal muscles; all of these muscles are susceptible to the effects of cold (Cannon 2015). Characteristically, patients may be unable to reopen the eyes after several forceful closures in rapid succession. The myotonia may be increased by exercise (i.e. *paradoxical* myotonia). Many patients also experience episodic weakness and may develop muscular atrophy. Weakness is of two types: generalised episodes which can be brought on by cold, and localised weakness, provoked by exercise alone, which may occur in heat or cold.

Hyperkalaemic Periodic Paralysis is characterised by recurrent episodes of flaccid limb weakness, associated with an increase in the serum potassium during an attack of weakness, with normal muscle strength and serum potassium levels between episodes (Cannon 2015). Most patients are symptomatic before age 20 and the first presentation may be as early as infancy. Episodes of weakness are often triggered by moderate exercise and can last as short as a number of minutes or as long as a number of hours. Episodes may also be precipitated or worsened by potassium-rich food, rest after exercise, a cold environment, emotional stress or glucocorticoids. Mild myotonia is present between episodes in approximately 50% of individuals and is most readily observed in the eyelids, thenar muscles and finger extensors. The presence of myotonia suggests the diagnosis of hyperkalaemic periodic paralysis rather than other forms of familial periodic paralysis (Cannon 2015).

Elevation of the plasma potassium during episodes may be difficult to document. Identification of myotonia on EMG supports the diagnosis but myotonia is detectable in only 50% of individuals affected – diagnostic yield is increased by testing at the onset of a symptomatic episode (Venance et al. 2006; Cannon 2015). The serum creatine kinase may be elevated to five to ten times normal concentration between episodes. Oral administration of potassium chloride after exercise may provoke an attack. Mutations in *SCN4A* account for only 60–70% of individuals, suggesting genetic heterogeneity.

The differential diagnosis includes other causes of hyperkalaemia such as adrenal insufficiency, medications (e.g. spironolactone, ACE inhibitors) and rhabdomyolysis. Andersen–Tawil syndrome is caused by mutations in the potassium channel gene *KCNJ2* (Venance et al. 2006) and characterised by episodic muscle weakness, ventricular arrhythmias and characteristic dysmorphic features (Tawil et al. 1994).

Episodes can be prevented or aborted by sustained mild exercise or carbohydrate loading at the onset of weakness. Other preventative measures include frequent carbohydrate-rich meals and avoidance of foods rich in potassium, fasting and exposure to cold. If episodes are frequent treatment with thiazide diuretics or acetazolamide may be considered (Heatwole et al. 2013).

**Other Potassium-Aggravated Myotonias**

These disorders are characterised by the development of stiffness following strenuous exercise or ingestion of potassium; all are associated with mutations in *SCN4A*. *Myotonia fluctuans*, the mildest form, resembles Thomsen disease with stiffness that is sometimes painful, precipitated by inactivity and resolving with continued exercise. Weakness is not a significant feature (Heatwole et al. 2013). In *acetazolamide-responsive* myotonia muscle pain may be induced by exercise (Heatwole et al. 2013). Myotonia permanens is a severe disorder associated with continuous myotonic activity on EMG which results in generalised muscle hypertrophy and may be confused with Schwartz–Jampel syndrome (Lehmann-Horn et al. 2004). Normokalaemic periodic paralysis resembles both hypo- and hyperkalaemic periodic paralysis but serum potassium levels during episodes are normal.

**CALCIUM CHANNEL DISORDERS**

Hypokalaemic periodic paralysis has two different forms, paralytic and myopathic, which may occur separately or together, with the pure version of the former more common. Most individuals present between age 5 and 16 years of age with infrequent episodes of weakness which are often precipitated by meals rich in carbohydrate or by exercise following rest and thus commonly occur in the early morning (Statland and Barohn 2013); exposure to cold may also be a trigger. The intensity and extent of weakness are very variable, with only the proximal limb muscles affected in some patients while others have diffuse paralysis; the facial muscles are rarely affected while the extra-ocular and respiratory muscles are usually spared. Some individuals have only one episode in a lifetime while crises occur more commonly on a repeated basis, often daily, weekly, or less frequently: most episodes last a few hours while some a day or more. In individuals affected severely the tendon reflexes are absent and muscles can be swollen. The episodes tend initially to increase in frequency then decrease after 25–30 years and may even disappear. The myopathic form of hypokalaemic periodic paralysis develops in approximately 25% of affected individuals, causing increasingly severe fixed muscle weakness that begins as exercise intolerance predominantly in the lower limbs. It occurs
independently of the episodic paralysis and may be the sole manifestation of hypokalaemic periodic paralysis, however is not usually observed in children.

The diagnosis rests on the characteristics of paralysis and the family history. Potassium levels during episodes may be only slightly lowered and the creatine kinase is transiently elevated. The ECG reflects changes consistent with hypokalemia: there is no myotonia, clinically or on EMG. Episodes may be provoked by administration of glucose and insulin, but a negative test does not exclude the diagnosis, with these tests not generally recommended in children.

Molecular genetic testing identifies mutations in the CACNA1S gene in about 70% of individuals (Cannon 2015), with about 12% of patients having mutations in the SCN4A gene (Jurkat-Rott et al. 2000). Mutations in these two genes are not found in around 20% of patients, raising the possibility of further genetic heterogeneity.

Hypokalaemic periodic paralysis is the most frequent cause of periodic paralysis but needs to be differentiated from causes of secondary hypokalaemia such as primary hyperaldosteronism, renal tubular defects and recurrent vomiting. In Asian patients hypokalaemic periodic paralysis is often associated with hyperthyroidism (Oh et al. 1990).

Treatment of acute episodes is by oral potassium administration, 5–10 g per dose, which may be repeated. Prevention of episodes may be achieved by a low-carbohydrate and low-sodium diet and treatment with acetazolamide where necessary (Statland and Barohn 2013). Hypokalaemic periodic paralysis may be associated with an increased risk of malignant hyperthermia (Marchant et al. 2004).

CONDITIONS MIMICKING MYOTONIC MYOPATHIES

A number of unusual conditions present in childhood with muscle stiffness, hypertonia or pain without myotonia. These conditions are reviewed briefly below.

Cramps are involuntary painful contractions of a muscle or part of a muscle. When cramps occur in normal individuals they are usually confined to the distal lower extremities and characterised on EMG by the repetitive firing of normal motor unit potentials. Cramps are not associated with other symptoms or signs of neurological disease and are often precipitated by vigorous exercise or by excessive loss of fluids and electrolytes: stretching the involved muscle usually relieves the cramp. Night cramps are also physiological events although they occur much more frequently in children with neuropa-thies (Blyton et al. 2011).

Pathological cramps occur in association with a variety of metabolic disorders and secondary to disorders of the anterior horn cell, peripheral nerve or muscle itself (Taglia et al. 2015). Exercise-induced myalgia, with or without tenderness, exercise intolerance, weakness, cramps and myoglobinuria can occur in metabolic myopathies as well as in association with congenital myopathies, muscular dystrophies, inflammatory myopathies as well as toxic and endocrine myopathies.

Myokymias are rippling fascicular contractions that occur spontaneously in healthy children and adults, especially about the eyes but also in other muscles. They are a physiological phenomenon unless excessively diffuse and intense.

RIPPLING MUSCLE DISEASE

Rippling muscle disease (RMD) is characterised by ‘mounding’ produced by percussion of muscles and rolling muscle movements occurring after contraction followed by stretching, with muscle contractions being electrically silent: other clinical symptoms include muscle stiffness, cramps and pain on exercise. Although calf hypertrophy has been reported in RMD, muscle weakness and wasting is usually absent. Most individuals are affected as a result of autosomal dominant mutations in the gene encoding caveolin-3, which is also associated with LGMD type 1C (Milone et al. 2012).

BRODY DISEASE

Brody disease is a rare genetic myopathy that usually begins in childhood with progressive exercise-induced stiffness and myalgia (Karpatic et al. 1986; Danon et al. 1988). The main clinical manifestation is difficulty in muscle relaxation which is different from myotonia in being electrically silent and increasing with continued exercise. Muscle biopsy shows only atrophy of type 2 fibres, with both autosomal recessive (Karpatic et al. 1986) and autosomal dominant (Danon et al. 1988) kindreds described. The autosomal recessive form is now known to be due to mutations in the SERCA1 gene which encodes the sarcoplasmic reticulum calcium-activated ATPase of fast twitch muscles (Odermatt et al. 1996). Brody disease may be associated with malignant hyperthermia susceptibility (see below) (Sambuughin et al. 2014).

PERIPHERAL HYPEREXCITABILITY AND ISAACS SYNDROME

The terminology and nosology of the peripheral nerve hyperexcitability syndromes (PNH) are confusing. Hart et al. (2002) point out that many terms are used to describe the clinical manifestations of PNH such as neuromyotonia, Isaacs syndrome and cramp–fasciculation syndrome. All refer to a clinical phenomenon of abnormal, continuous muscle fibre activity of primary neural origin. Characteristic clinical accompaniments are muscle rippling or twitching, cramps, stiffness or delayed relaxation following voluntary muscle contraction (pseudo-myotonia). One electrical accompaniment is the neuromyotonic discharge, a burst of rapidly firing (150–300Hz) motor unit action potentials often starting or stopping abruptly with waning of the wave amplitude but not the waxing and waning pattern of myotonia. The discharges may occur spontaneously or be initiated by needle movement, voluntary effort or percussion of a nerve and can be abolished by nerve blocks. PNH is a feature of several rare diseases and syndromes for which pathogenetic mechanisms are progressively being defined; some are presumed auto-immune while others are clearly genetic (Kleopa 2011; Zimon et al. 2012).
**Isaacs syndrome** is a rare disorder of continuous motor unit activity, which in most individuals is an acquired channelopathy associated with antibodies against voltage-gated potassium channels (Hart et al. 2000). There is an association with other autoimmune disorders and neoplasms, notably myasthenia gravis and thymoma. The main clinical features are muscle stiffness, cramps and sweating; myokymia may also be seen, with the limbs and trunk most affected. This most affects adolescents but there are rare reports of onset in infancy with stiffness and respiratory difficulty (McGuire et al. 1984; Thomas et al. 1994; Gonzalez et al. 2008). The EMG shows continuous activity which appears to originate in the distal part of axons as it is not abolished by proximal nerve blocks, while there is neurophysiological evidence of a polyneuropathy in up to a third of patients (Hart 2000). Treatment with anticonvulsants and immunotherapy may ameliorate symptoms (Hart 2000).

**Stiff person syndrome**

Stiff person syndrome is ordinarily a sporadic disease of adults with rare reports of childhood and adolescents being affected (Udani et al. 1997; Clardy et al. 2013; Jun et al. 2015). Progressive rigidity and painful muscle spasms develop primarily in the trunk and proximal limb muscles (Clardy et al. 2013), while there is also excessive sensitivity to external stimuli. Rigidity is always present except in sleep, with EMG of affected muscles showing continuous muscle fibre activity. There is an association with diabetes mellitus and other auto-immune disorders, with up to 80% of patients having autoantibodies to glutamic acid decarboxylase (GAD) which concentrates in GABAergic nerve terminals and in pancreatic cells. Benzodiazepines and baclofen provide symptomatic relief, longer-term amelioration being provided by immunotherapy with plasma exchange or intravenous immunoglobulin (Clardy et al. 2013; Jun et al. 2015).

**Hyperkplexia**

Hyperkplexia (see Chapter 9), sometimes referred to as the stiff baby syndrome, is characterised by severe stiffness and excessive startle which may be associated with prolonged apnoea in response to external stimuli (Mine et al. 2015). Most individuals affected by hyperkplexia present in the neonatal period. It is caused by mutations in the gene encoding the α1-subunit of the glycine receptor (GLRA1) on chromosome 5q31.2 and responds to treatment with clonazepam (Harvey et al. 2008).

**Schwartz–Jampel syndrome**

Schwartz–Jampel syndrome is an autosomal recessive condition featuring chondrodysplasia, short stature and continuous muscle contraction causing blepharophimosis, pursing of the mouth and puckering of the chin as well as stiffness of the limbs (Arya et al. 2013). The serum creatine kinase is normal or only mildly increased with EMG demonstrating abnormal muscle fibre activity and muscle histology usually normal. Treatment with sodium channel blockers may ameliorate symptoms (Arya et al. 2013). Schwartz-Jampel syndrome is caused by recessive mutations in the gene encoding perlecan (HSPG2), a heparan sulphate proteoglycan expressed in basement membranes and cartilage (Nicole et al. 2000).

**Malignant Hyperthermia**

Malignant hyperthermia is a pharmacogenomic disorder in which volatile anesthetic agents (e.g. halothane) or depolarising muscle relaxants such as succinylcholine trigger uncontrolled muscle contraction, potentially leading to life-threatening hyperthermia, muscle rigidity, acidosis, rhabdomyolysis and cardiac arrhythmias (Nelson and Litman 2014). In nearly all individuals the first manifestations of malignant hyperthermia (masseter spasm, tachycardia and tachypnea) occur in the operating room but it may also feature in the early post-operative period. As the first exposure to these substances elicits an event in only 50% ofalignant hyperthermia-susceptible patients, a previous history of tolerance of halothane or succinylcholine does not ensure these agents can be used safely in future anaesthesia. Malignant hyperthermia is still the most frequent cause of death during anaesthesia.

The disorder is inherited as an autosomal dominant trait so a family history of suggestive incidents during anaesthesia is of extreme diagnostic importance. The syndrome may occur in two different settings: in patients with a genetic predisposition and those with specific muscular diseases. Malignant hyperthermia is most commonly associated with mutations of the skeletal muscle ryanodine receptor gene (RYRI) encoding the Ca$^{2+}$ release channel of the sarcoplasmic reticulum (Robinson et al. 2006). Central core disease, King-Denborough syndrome and multifacimico myopathy, which can be caused by RYRI mutations, are associated with an increased risk of malignant hyperthermia (McCarthy et al. 2000; D’arcy et al. 2008; Brislin and Theroux 2013). On rare occasions mutations have been identified in CACNA2D1, encoding dihydropyridine-sensitive L-type calcium channel alpha-2/delta subunits and in CACNA1S encoding the skeletal muscle calcium channel (Monnier et al. 1997): further loci have been mapped but the genes have not been identified while molecular genetic testing for RYRI and CACNA1S is clinically available. Other conditions much less commonly linked to malignant hyperthermia include nemaline myopathy (Asai et al. 1992), Schwartz–Jampel syndrome (Seay and Ziter 1978), myoadenylate deaminase deficiency (Fishbein et al. 1985) and STAC3 myopathy (Dowling et al. 2014).

Because the underlying diagnosis is unknown in many patients undergoing muscle biopsy, malignant hyperthermia precautions should be taken in all patients prior to definitive diagnosis (Hayes et al. 2008; Racca et al. 2013; Rafique et al. 2013). Siblings and relatives of patients with malignant hyperthermia should be screened for high creatine kinase levels (Brandom and Muldoon 2013). Contracture testing, the standard diagnostic test for malignant hyperthermia since the mid-1970s, relies on the in vitro measurement of contractual
response of biopsied muscle to graded concentrations of caffeine and the anaesthetic agent halothane. The sensitivity of the test approaches 100% with specificity between 80% and 97% (Allen et al. 1998). The in vitro contracture test requires a fresh muscle biopsy and is not well standardised in children.

The differential diagnosis of malignant hyperthermia includes sepsis, hyperthermia, pheochromocytoma crisis and thyrotoxicosis. Anaesthesia-induced rhabdomyolysis can occur in patients with dystrophinopathies but has a different pathophysiology from malignant hyperthermia (Hayes et al. 2008). Patients with myotonic syndromes can also develop muscle rigidity following succinylcholine administration.

Treatment for malignant hyperthermia includes termination of the anesthetic agent. Dantrolene and intravenous injection of dantrolene at an initial dose of 1–2mg/kg, which may be repeated every 5–10 minutes up to a total dose of 10mg/kg (Racca et al. 2013).

**Neuroleptic Malignant Syndrome**

This syndrome shares several features with malignant hyperthermia. Affected children develop muscle rigidity, high fever and a raised serum creatine kinase after treatment with antipsychotic agents, including phenothiazines, clozapine and risperidone (Rasimas and Leibelt 2012). Sweating, tachypnoea, tachycardia, hypertension as well as altered consciousness develop over hours or days and can be complicated by development of renal failure secondary to rhabdomyolysis (Ty and Rothern 2001). Optimal treatment consists of early recognition, withdrawal of triggering medications and active supportive therapy. Bromocriptine and dantrolene reverse muscle hyperexcitability; levodopa and benzodiazepines are sometimes used (Halleron and Bernard 2004). Serotonin syndrome, secondary to treatment with selective serotonin reuptake inhibitors, can cause similar symptoms (Kant and Liebelt 2012): further molecular genetic testing may well clarify this possible association.

**Rhabdomyolysis and Myoglobinuria**

Myoglobinuria secondary to rhabdomyolysis is a rare phenomenon with a wide range of aetiologies but with potentially fatal physiological consequences irrespective of the acquired or inherited cause (Table 26.5, Fig. 26.5) (Chan et al. 2015).

Potential complications of rhabdomyolysis include acute renal failure, cardiac arrhythmias due to hyperkalaemia, bulbar muscle dysfunction, respiratory insufficiency and encephalopathy. The development of pigmenturia, sometimes with muscle pain and swelling, in a child with or without a previously recognised neuromuscular disorder therefore requires urgent medical attention. Apart from identifying myoglobin as the cause of the dark urine (reflected by a positive urine dipstick test for blood, but no red blood cells) a critically high creatine kinase level, often >100 times the upper limit of normal, is the cardinal clue to the nature of the problem. Although dipstick urine testing is sensitive, depending on timing, a negative test does not rule out myoglobinuria (Coco and Klasner 2004).

Exogenous causes such as direct or indirect injury, animal toxins (e.g. snake bite) and drugs are usually but not always obvious. The long list of causative drugs includes those of abuse and those associated with the neuroleptic malignant syndrome (Coco and Klasner 2004). Even after extensive investigation no cause may be found in many individuals but children have been classified into two broad groups on the basis of precipitating factors (Tein et al. 1990): exertion-triggered myoglobinuria in which a metabolic cause is often found, and ‘toxic’ myoglobinuria, precipitated by fever and infection. The latter group is generally younger, acutely tends to be more critically unwell and more often remains idioopathic even after investigation. If there is no specific clinical clue to an aetiological diagnosis muscle biopsy after recovery from the acute episode of rhabdomyolysis may point in the direction of lipid storage, glycogen-related or mitochondrial myopathies (see Fig. 26.2).

**INFLAMMATORY MYOPATHIES**

The inflammatory myopathies are a heterogeneous group of acquired muscle disorders, all of which are individually rare in childhood.

**DERMATOMYOSITIS**

Dermatomyositis is a rare systemic microangiopathy mainly affecting capillaries of muscle, skin, connective tissue and gastrointestinal tract. The trigger for development of dermatomyositis is not known but immunopathogenesis hinges on activation of complement, with deposition of the membrane attack complex on the endomysium of small blood vessels and a localised microvasculitis.

Most individuals present between 5–15 years. Presentation is acute to subacute in one-third of individuals with fever, muscle pain and weakness. In the remaining patients the onset is more insidious with weakness, fatigue, anorexia and behavioural changes (Robinson and Reed 2011). Weakness in dermatomyositis dermatomyositis is generally proximally predominant and symmetrical: the bulbar muscles may be involved, causing hoarseness and swallowing difficulties (Robinson and Reed 2011; Kishi et al. 2013) while joint contractures may develop early and can be severe. Cutaneous manifestations of dermatomyositis include a photosensitive reddish lavender (‘heliotrope’, or violaceous) discoloration of the skin of the upper eyelids, the periorbital and malar regions, with or without periorbital oedema. A similar rash, often scaly, may appear on the extensor surfaces of the knuckles (‘Gottron papules’), elbows, knees and malleoli of the ankles (Guseinova et al. 2011). A generalised

Adapted from Chan et al. (2015). CPT, carnitine-palmitoyl transferase; VLCAD, very long chain acylcoenzyme a dehydrogenase; MELAS, myopathy, encephalopathy, lactic acidosis, and stroke-like episodes; FKRPR, fukutin-related protein.
rash is rarely seen: the rash of dermatomyositis may be evanescent with diagnosis more difficult when cutaneous manifestations of dermatomyositis are not prominent or absent. Examination of the nailfold capillaries often shows dilated, tortuous vessels reflecting a generalised microangiopathy, especially in those with longstanding dermatomyositis (Smith et al. 2004).

Gastrointestinal symptoms are present in about 20% of patients, with bowel ulcerations being potentially fatal (Robinson and Reed 2011). Respiratory function is usually normal but occasional children experience respiratory distress from parenchymal lung disease (Robinson and Reed 2011).

Longstanding paediatric dermatomyositis may be associated with severe contractures, generalised wasting and chronic skin changes with thickened discoloured skin over the knuckles, generalised or focal lipodystrophic changes, osteoporosis and calcinosis of subcutaneous tissues.

In one series the median interval between onset of symptoms and diagnosis was 3 months with a range of 0.5–20.0 months (Pachman et al. 1998). Diagnosis is often delayed where cutaneous signs are absent, weakness is absent or not recognised, or presentation is with behavioural change.

Unlike adults, childhood dermatomyositis is not associated with malignancy (Robinson and Reed 2013).

The diagnosis of paediatric dermatomyositis is primarily clinical, based on the presence of acquired proximal weakness and the characteristic cutaneous findings (Smith et al. 2006). Tests used to confirm the diagnosis include nailfold capillaroscopy, muscle enzyme levels, magnetic resonance imaging (MRI) of the muscle, EMG and muscle biopsy.

Diagnostic criteria for dermatomyositis are based on the Bohan and Peter criteria (Bohan and Peter 1975), including a combination of clinical and laboratory findings as described above.

The serum muscle-derived enzymes (creatine kinase), lactate dehydrogenase (LDH), spartate aminotransferase (AST) and/or alanine aminotransferase (ALT), which are markers of muscle damage, are often but not always elevated in paediatric dermatomyositis. Screening for myositis-specific autoantibodies such as the anti-Jo1 antibody generally adds little to the diagnosis of juvenile dermatomyositis.

Nerve conduction studies are normal. EMG shows increased insertional activity with fibrillations and positive sharp waves and myopathic motor unit action potentials. These changes can be patchy and may be most obvious superficially within muscle bellies.
Muscle imaging by ultrasound or MRI can be helpful, with muscle inflammation appearing as increased signal on ultrasound or T2-weighted fat-suppressed images (Tzaribachev et al. 2009).

Muscle biopsy is usually required to confirm the clinical diagnosis, even in apparently typical cases, prior to committing to potentially long-term immunosuppressive therapy. Capillary injury in dermatomyositis causes microinfarcts within muscle, causing muscle fibre injury, necrosis and regeneration, with a distinctive pattern of perifascicular atrophy (Robinson and Reed 2001). There may be perivascular mononuclear cell infiltrates within the muscle with endothelial necrosis. Immunocytochemical studies may demonstrate deposition of the membrane attack complex within muscle (Sakuta et al. 2005).

The differential diagnosis of paediatric dermatomyositis includes dystrophies such as Duchenne and Becker muscular dystrophy, as well as LGMDs. Some metabolic myopathies are associated with myalgia and exercise intolerance (see below). Other forms of myositis are rare in childhood; viral illnesses occasionally cause focal myositis which is generally self-limiting. Other rheumatological disorders are sometimes associated with myositis (see below).

The general aims of treatment are management of muscle inflammation, maximisation of function and prevention of contractures and calcinosis. Most data on prognosis in paediatric dermatomyositis are based on small observational studies; there are few prospective studies of outcome in paediatric dermatomyositis (Huber and Feldman 2005).

Most clinicians initiate treatment with high-dose corticosteroids (prednisolone, up to 1mg/kg/day), with or without concomitant treatment with intravenous immunoglobulin (IVIg). Methotrexate or cyclosporine are usually also used for longer-term control of dermatomyositis, increasing the effectiveness of treatment and limiting steroid-related side-effects (Stringer et al. 2010; Ruperto et al. 2016). Intravenous methylprednisolone may be initially substituted for prednisolone in some individuals with refractory weakness, severe gastrointestinal or respiratory involvement or rapidly progressive calcinosis (Rouster-Stevens et al. 2008), but should not be used for long-term treatment in the place of oral prednisolone (Klein-Gitelman et al. 2000). Severe ulcerating skin disease or severe systemic involvement (interstitial lung disease, gastrointestinal ulceration) may be treated emergently with intravenous cyclophosphamide or immunoglobulin. Other agents less commonly used in refractory juvenile dermatomyositis include rituximab and other biological agents.

Supportive therapy for paediatric dermatomyositis includes the use of sunscreen, topical agents for dermatomyositis-related rash (corticosteroid, tacrolimus or pimecrolimus creams), physiotherapy, occupational therapy as well as dietary supplementation of calcium (1000mg/day) and vitamin D (1000 units/day) to prevent osteoporosis. Calcinosis of soft tissues is best prevented by immunosuppressive therapy of dermatomyositis; no consistently effective treatments have been identified.

Typical disease courses in paediatric dermatomyositis include a monophasic illness with sustained response to therapy, a relapsing-remitting course or (most commonly) a chronic illness with increasing deficits over time. Response to treatment is determined by evaluating muscle strength, changes in rashes, and muscle enzyme testing. Serial muscle strength testing is best done using standardised scales such as the MMT8 or Childhood Myositis Assessment Scales (Lovell et al. 1999; Rider et al. 2010). Muscle MRI also shows some promise as a means of following disease progression in dermatomyositis (Malattia et al. 2014).

The prognosis of paediatric dermatomyositis has improved markedly in the last 3–4 decades. Prognosis is poorer in those with greater severity at presentation, ulcerating skin lesions and gastrointestinal involvement (Huber and Feldman 2005).

**OTHER MYOSITIDES OF CHILDHOOD**

Macrogranular myofasciitis is a rare inflammatory myositis presenting in infants and young children with delayed motor milestones, hypotonia and high creatine kinase. It is thought to be connected to aluminium hydroxide-containing vaccines which have usually been administered in the 1–2 months before the onset of symptoms. Muscle biopsy shows large collections of perimysial macrophages (Gruis et al. 2006; Lach et al. 2008).

Polymyositis, another inflammatory myopathy, albeit without skin rash and with a different immunological basis to dermatomyositis, is very rarely, if ever, seen in children. In those children experiencing progressive muscle weakness (especially distal weakness) without rash, in whom apparently inflammatory changes are seen on biopsy, diagnostic efforts should be directed towards facioscapulohumeral muscular dystrophy and other genetic myopathies in which such pathological findings may be seen (D’Arcy et al. 2009; Tarnopolsky et al. 2016).

**INFLAMMATORY MYOPATHIES ASSOCIATED WITH SYSTEMIC DISEASE**

Some systemic connective disorders can be associated with a myopathy in childhood.

Rheumatoid arthritis, scleroderma-myositis, systemic lupus erythematosus-myositis, mixed connective disease-myositis, Churg-Strauss syndrome and Sjögren syndrome-myositis can all be associated with proximal weakness which can be severe and may be associated with calcinosis, interstitial lung disease, arthritis and sclerodactyly (Mason and de Vivo 2015). Treatment is of the underlying condition but morbidity can be severe.

Other auto-immune disorders uncommonly associated with myositis in childhood include Kawasaki disease, Behcet syndrome and Wegener granulomatosis.
EOSINOPHILIC MYOPATHIES

A number of eosinophilic myopathies have been reported in childhood. Idiopathic eosinophilic myositis can be focal or generalised, presenting with myalgia, muscle swelling and weakness, sometimes in association with systemic upset. In eosinophilic myositis muscle weakness can be associated with pericarditis, myocarditis, cardiac arrhythmias and skin involvement (angioedema and subcutaneous induration). There may be peripheral blood eosinophilia in addition to elevated creatine kinase levels and localised myopathic EMG changes (Pickering and Walport 1998).

Eosinophilic myopathies are also associated with parasitic infections (Taenia solium and Trichinella spiralis), ingestion of toxic oils (Alonso-Ruiz et al. 1993) and dietary supplementation with tryptophan (Hertzman et al. 1990).

FOCAL MYOSITIS

Focal myositis is a rare syndrome in which children develop localised swelling and pain in a single muscle group, sometimes after trauma, often raising the question as to a neoplastic or infectious process (Isaacson et al. 1991). Imaging studies define the extent of the lesion (Galloway et al. 2001) but muscle biopsy is generally required to confirm the diagnosis, showing increased fibre size variation with atrophic fibres and focal dense fibrosis (Forcucci et al. 2016). Lesions may resolve spontaneously or may require surgical excision (Forcucci et al. 2016).

INFECTION MYOSITIS

VIRAL MYOSITIS

Epidemic pleurodynia (Bornholm disease) due to Coxsackie virus B infection is a well-recognised disease involving the intercostal muscles (Huang et al. 2010). Myalgia is common in some other viral diseases, especially influenza. A more diffuse picture of acute diffuse polymyositis is uncommon and individuals affected severely by myoglobinuria are rare (Moon et al. 2013). Other viruses (adenoviruses, paramyxoviruses) rarely produce myositis.

Benign acute childhood myositis (Mackay et al. 1999) is an easily recognisable syndrome of mid-childhood affecting boys more than girls. A concurrent or preceding (1–4 days) upper respiratory infection is typically followed by the sudden onset of calf pain and tenderness, with refusal to walk or difficulty walking. The gait pattern is usually either toe-walking with resistance to passive ankle dorsiflexion or walking in extreme recurvatum at the knees, possibly to minimise stretch of the gastrocnemius-soleus complex. More proximal lower limb and upper limb muscles may also be involved but it is the calf muscle predilection that gives the syndrome a recognisable pattern. Weakness and difficulty eliciting deep tendon reflexes are commonly described but generally relate to difficulty in examining a child with severe discomfort (Mackay et al. 2009; Mall et al. 2011): an erroneous diagnosis of Guillain–Barré syndrome is often made. The child may be febrile and there may be elevation of the acute phase reactants while the serum creatine kinase may be only mildly elevated or increased to levels as high as 60 times the upper limit of normal. The creatine kinase level returns to normal in the convalescent period with most children recovering fully within days and only a minority experiencing repeated episodes which may raise the question of an underlying myopathy, a disorder occurring sporadically or in epidemics. Associated viruses include influenza A and B as well as less commonly parainfluenza, adenovirus and coxsackie infection. Muscle biopsy may show inflammatory and other non-specific changes but should not be required for diagnosis. The importance of recognising this syndrome is in avoiding unnecessary investigation and signalling a good prognosis to the family.

BACTERIAL MYOSITIS (PYOMYOSITIS)

Purulent myositis is common in tropical countries and is becoming more common in temperate climates, for reasons which are unclear (Unnikrishnan et al. 2010; Moriarty et al. 2015). Most individuals are affected as a result of infection with Staphylococcus aureus, with abscess formation occurring following a phase of muscle induration. Early diagnosis and differentiation from other conditions such as septic arthritis and rhabdomyosarcoma has become easier with the use of modern imaging technologies, especially MRI. Surgical drainage may be necessary, in addition to antibiotic treatment, with the course usually favourable (Pannaraj et al. 2006; Moriarty et al. 2015). Non-suppurative myositis is also observed in individuals affected by Borrelia burgdorferi infection (Holmgren and Matteson 2006).

PARASITIC MYOSITIS

Trichinosis is the most common cause of parasitic myositis (Pickering and Walport 1998). Muscle involvement in cysticercosis can present with myalgia, nodular lesions or muscle pseudohypertrophy. Ultrasound or X-rays may show nodules or calcified cysts while muscle biopsy reveals cysterci within the muscle (Venkataraman and Vijayan 1983). Toxoplasmosis is an unusual cause of inflammatory myopathy (Paspalaki et al. 2001).
Metabolic myopathies are conditions in which disordered energy production by muscle results in weakness and often myalgia. Disorders of glycogen or lipid metabolism or mitochondrial function may involve muscle, either as an isolated phenomenon or as part of a multisystem syndrome. The associated myopathy may be permanent with progressive weakness or may be intermittently symptomatic with episodes of myalgia, rhabdomyolysis and myoglobinuria often being triggered by exercise or other factors. Although the clinical features may be easily identified the underlying metabolic defect may be difficult to establish because of the complexity of the laboratory analyses required (see also Chapter 9). Despite detailed knowledge of the biochemical and genetic basis of some of these disorders effective treatments are still quite limited.

**ACID MALTASE DEFICIENCY**

Acid maltase (acid α-glucosidase); (GSD-II) is a lysosomal enzyme present in all tissues which catalyses the hydrolysis of α-1,4 and α-1,6 linkages, breaking glycogen down into glucose. Deficiency of this enzyme results in glycogen accumulation in the tongue, heart and skeletal muscles. The clinical syndromes associated with this condition included a severe infantile form (Pompe disease) and a milder form of acid maltase deficiency presenting in childhood or adulthood. Both conditions result from autosomal recessive mutations in the same gene, *GAA* (chromosome 17q25.2–q25.3) (Kishnani and Howell 2004).

The infantile form of acid maltase deficiency, known as Pompe disease or type IIa glycogenosis, presents at around 1–2 months of age with profound hypotonia, failure to thrive, weakness, macroglossia, progressive cardiomyopathy and cardiac failure which may be the presenting feature. Areflexia is present in one-third of patients at presentation as a result of anterior horn cell involvement. Most infants never achieve the ability to roll. The serum creatine kinase level may be normal but is usually elevated while the ECG shows a short P-R interval, giant QRS complexes and left or biventricular hypertrophy, often with inverted T waves and/or ST depression. Most children die from cardiorespiratory failure before the age of 12 months (Kishnani and Howell 2004).

In the later-onset form patients present with slowly progressive trunk and proximal limb weakness. Mild hypertrophy of the calves may cause confusion with one of the muscular dystrophies. The respiratory muscles are involved relatively early, often causing respiratory failure by the second or third decade, but the heart is spared in this form of acid maltase deficiency. Many affected individuals ultimately become wheelchair-dependent and require ventilatory support (Laforet et al. 2013) while late complications of this condition in adulthood may include large vessel aneurysms and smooth muscle involvement (Angelini and Semplicini 2012; Laforet et al. 2013).

The creatine kinase is elevated in both forms of acid maltase deficiency. EMG generally shows a myopathic interference pattern, often with complex repetitive discharges and myotonic discharges in the paraspinal and proximal limb muscles. Muscle MRI can be helpful in identifying typical patterns of muscle involvement (Carlier et al. 2011). Biopsy shows a vacuolar myopathy and decreased α-glucosidase levels (<10% normal activity) are seen on assay of muscle, leukocytes or fibroblasts. A large number of mutations have been found in the α-glucosidase gene: prenatal diagnosis is possible on trophoblasts or amniotic cells.

Enzyme replacement therapy with recombinant human α-glucosidase has been shown to result in improved walking distances and stabilisation of respiratory function in late-onset patients (de Vries et al. 2012). Infants with Pompe disease have prolonged survival with ERT but generally remain very weak and ventilator-dependent and there are concerns about their long-term cognitive outcome (Elbink et al. 2016).

**DEBRANCHER DEFICIENCY AND BRANCHER DEFICIENCY**

Debrancher deficiency (GSD-III and Brancher deficiency (GSD-IV) are usually characterised by predominant liver disease, presenting as hepatomegaly, growth failure and fasting hypoglycaemia. Affected infants may be hypotonic with motor

---

**DISORDERS OF GLYCOGENOLYSIS AND GLYCOLYSIS – THE GLYCOGEN STORAGE DISORDERS**

Disorders of glycogenolysis and glycolysis generally present with one of two clinical syndromes. Some cause progressive weakness of the extremities and trunk: these include disorders of the glycogen synthetic pathway and lysosomal glycogenolytic pathway (glycogenoses types II, III and IV and occasionally rare disorders such as muscle phosphoglucomutase deficiency) and muscle fructose diphosphatase deficiency (Darras and Friedman 2000a, b). Others present with exercise intolerance, intermittent weakness, myalgia and/or myoglobinuria. These symptoms tend to be associated with disorders of glycolysis (deficiencies of phosphoglucomutase, phosphofructokinase, aldolase, beta-enolase, phosphoglycerate kinase (Aasly et al. 2000), phosphoglycerate mutase and lactate dehydrogenase as well as glycogenolysis (phosphorylase kinase and myophosphorylase deficiency (McArdle disease). There are exceptions to these syndromes with some patients presenting with fatal infantile organ dysfunction (causing hepatomegaly, hypoglycaemia, haemolytic anaemia and jaundice) or later development of painless fixed weakness (Darras and Friedman 2000a).
delay or muscle weakness, that is, may not be seen until later in life without a preceding history of liver disease. Affected children have generalised weakness with exercise intolerance and cramps while adults tend to have predominantly distal weakness. Muscle biopsy shows a vacuolar myopathy while sequencing of the AGL gene on chromosome 1p21 is diagnostic. Dietary management may include frequent meals, administration of uncooked cornstarch and continuous gastric drip feeding (Sentner et al. 2016).

Glycogen storage disease type IV (GSD-IV), is an autosomal recessive disorder due to mutations in the glycogen branching enzyme gene (GBE1, chromosome 3p12). An amylopectin-like polysaccharide known as polyglucosan is accumulated. The perinatal form presents as fetal akinesia deformation sequence (FADS) with multiple joint contractures, hydrops fetalis and perinatal death (Escobar et al. 2012). The congenital form (FADS) with multiple joint contractures, hydrops fetalis and perinatal death (Escobar et al. 2012). The congenital form includes hypotonia, hyporeflexia, cardiomyopathy, ventilator dependence and cardiorespiratory death in early infancy (Bruno et al. 2004; Giuffrè et al. 2004). Later-onset forms present with hepatic disease and progressive cirrhosis with variable myopathy or cardiomyopathy (Bruno et al. 2004).

**McARDLE DISEASE**

Muscle phosphorylase initiates glycogen breakdown by removing 1,4-glucosyl residues from the outer branches of the glycogen molecule, releasing glucose-1-phosphate. The deficiency causes McArdle disease (myophosphorylase deficiency; GSD-V), the prototype of the glycogenoses manifesting with intermittent symptoms. McArdle disease, which shows autosomal recessive inheritance, is caused by many different mutations of the PYGM gene on chromosome 11q13. The incidence of the disease is one per 50 000 births (Tsujino et al. 1993).

The onset, frequently not recognised as such for many years, is usually in the first two decades. The cardinal clinical features are exercise intolerance with fatigue, muscle pain and cramps developing soon after initiating exercise. Exercise precipitating symptoms is generally either brief and intense or sustained and less intense. Most patients experience a characteristic ‘second wind’ phenomenon: if they rest briefly after the onset of symptoms; they can then resume without redeveloping myalgia or fatigue. This phenomenon largely results from the switch from use of glucose to free fatty acids as a substrate of muscle metabolism. Episodic weakness after exercise can be associated with rhabdomyolysis leading to myoglobinuria and, if severe, acute renal failure. In children, however, easy fatigability can be the only symptom: most children reduce their overall level of physical activity as a result of pain. Permanent weakness may be observed after many years, particularly if there are repeated episodes of rhabdomyolysis.

Rare patients have variant phenotypes such as a congenital myopathy presenting with delayed milestones (Cornello et al. 1983) or slowly progressive proximal weakness with onset in childhood but without myalgia or myoglobinuria (Abarbanel et al. 1987). A fatal infantile type has been described (Milstein et al. 1989; El-Schahawi et al. 1997) while occasional asymptomatic patients are identified as a result of elevated creatine kinase levels (Oldfors and DiMauro 2013).

The creatine kinase is moderately increased in most patients at rest but may rise dramatically after exercise, particularly in the context of myoglobinuria. The EMG may be normal or myopathic while the non-ischaemic forearm exercise test can be used as a screening test, showing failure of the usual rise in the serum lactate level with an increase in ammonia (Chan et al. 2015). Muscle biopsy shows a moderate increase in subsarcolemmal glycogen and the absence of phosphorylase can be demonstrated histochemically (Darras and Friedman 2000a). Gene testing is generally available.

There are no specific treatments for McArdle disease. Patients with residual enzyme activity may benefit from dietary vitamin B6 supplementation; pyridoxal phosphate binds to myophosphorylase (Oldfors and diMauro 2013). Low-dose creatine (60mg/kg/day for adults) and oral sucrose taken 30 minutes before exercise may alleviate some symptoms. A carbohydrate-rich diet while regular moderate exercise improves metabolic capacity and exercise tolerance (Quinlivan et al. 2014).

**PHOSPHOFRACTOKINASE DEFICIENCY, OR TARUI DISEASE**

Phosphofructokinase deficiency (GSD-VII) is due to mutations in the M (muscle) subunit of the phosphofructokinase enzyme, for which the gene PFKM is located on chromosome 12q13.3; in muscle only M subunits are present. Both M and L subunits are found in erythrocytes; hence, in addition to muscle symptoms, M subunit deficiencies may also present with bouts of haemolytic anaemia and hyperuricaemia. Impaired glycolysis leads to cramps on exercise and myoglobinuria (Di Mauro 2007) similar to McArdle disease but these patients are unable to achieve a spontaneous second wind under conditions that consistently produce one in patients with McArdle disease. In addition, their symptoms are often worsened rather than ameliorated by high carbohydrate intake (Haller and Vissing 2004).

A severe neonatal form is marked by hypotonia, weakness, respiratory insufficiency and joint deformities. Cerebral involvement is present and death supervenes during the first year (Servidei et al. 1986; Amit et al. 1992). There is no specific therapy for PFK deficiency (Musumeci et al. 2012).

**PHOSPHORYLASE B KINASE DEFICIENCY**

Phosphorylase B kinase (PBK) (GSD-VIII) regulates glycogen breakdown by activating glycogen phosphorylase in response to humeral (neural or hormonal) stimuli; this enzyme has four subunits. Muscle involvement is described with mutations of the beta subunit of the PHKB gene on chromosome 16q12–q13. PBK deficiency is uncommon; onset of symptoms may
be in infancy or early childhood with weakness and delayed motor milestones or later in childhood or adolescence with exercise intolerance, cramps and episodic myoglobinuria (DiMauro 2007). There may be liver involvement while severe myopathy presenting in the neonatal period has been described (Sahin et al. 1998; Bühler et al. 2000). Creatine kinase levels, non-ischaemic exercise testing and muscle histology are sometimes normal, which is likely to cause diagnostic difficulty (Wilkinson et al. 1994).

OTHER GLYCOGENOSES
Myopathy presenting with intolerance to exercise and associated myoglobinuria has been reported in phosphoglycerate mutase deficiency (GSD-X) (PGAM-M gene, chromosome 7p12–p13) (Vita et al. 1994; Hadjigeorgiou et al. 1999), lactate dehydrogenase deficiency (GSD-XI) (LDHA gene, chromosome 11p15.4) (Oldfors and DiMauro 2013) and phosphoglycerate kinase deficiency (GSD-IX) (PGK1 gene, chromosome Xq13) (Sugie et al. 1989; Aasly et al. 2000).

MYOADENYLATE DEAMINASE DEFICIENCY
Myoadenylate deaminase deficiency (MADA) (AMPD1 gene, chromosome 1p13–p21) is an autosomal recessive trait found in 1–2% of the population. Most carriers are asymptomatic but some experience myalgia, exercise intolerance and weakness: this variability is not yet well explained (Sabina 2000). The diagnosis is suggested by non-ischaemic forearm exercise testing showing normal lactate production with failure of the blood ammonia level to rise (Chan et al. 2015), confirmed on muscle biopsy.

DISORDERS OF LIPID UTILISATION AND METABOLISM
Fatty acids are very important fuels for skeletal muscle, particularly during sustained exercise and under fasting conditions (see also Chapter 9). Defects in fatty acid oxidation cause progressive myopathies, recurrent rhabdomyolysis, neuropathies and cardiomyopathy in addition to hypoglycaemic hypoketonotic episodes and seizures. At least 16 genetic disorders of fatty acid oxidation are recognised, with a combined incidence of about one in 9300: all are inherited in an autosomal recessive fashion (Tein 2013). Carnitine is an essential cofactor in the transfer of long-chain fatty acids into the mitochondrion where fatty acids of long, medium and short chain are metabolised by beta-oxidation.

CARNITINE DEFICIENCY
Carnitine deficiency is often secondary to other metabolic disorders (Chapter 9) but can occur as a primary defect.

Primary Carnitine Deficiency
Primary carnitine deficiency is an autosomal recessive disorder with progressive proximal limb weakness, often associated with cardiomyopathy and fasting hypoglycaemia. Muscle biopsy shows lipid storage and reduced carnitine content. Dietary treatment with L-carnitine is generally effective (Tein 2013).

DEFICITS IN CARNITINE-PALMITOYL TRANSFERASE
The carnitine-palmitoyl transferase (CPT) system includes two enzymes, defects of which limit entry of long-chain fatty acids into mitochondria. CPT I deficiency is rare but has been identified in a few patients presenting with episodes of severe hypoglycaemia without ketosis, triggered by fasting or intercurrent illnesses.

CPT II deficiency, a much more common disorder, may present as a lethal neonatal form limited to muscle (Land et al. 1995) or associated with CNS malformations (Isackson et al. 2008) in infancy with hepatic and cardiac involvement as well as non-ketotic hypoglycaemia, or as a clinically quite different later onset form (Sigauke et al. 2003). The late-onset (classic) form of CPT II deficiency, which is the most common, is dominated by episodic weakness, myalgia and myoglobinuria and very high creatine kinase levels. Muscle strength and the serum creatine kinase are usually normal between episodes and there is no ‘second wind’ phenomenon. Onset is usually in late childhood or early adulthood but presentation in the first few years of life has been described (Hurvitz et al. 2000; Gempel et al. 2001). Prolonged exercise, fasting, fever or infections may trigger symptoms while the respiratory muscles may be involved: death during an attack in childhood has also been reported (Kelly et al. 1989). There is a marked reduction or complete absence of CPTII enzyme activity in muscle as well as in leukocytes, platelets and cultured fibroblasts.

Many mutations have been described in the CPT II gene on chromosome 1p32 (Sigauke et al. 2003). A similar clinical picture to that of CPT II deficiency may be seen with mitochondrial trifunctional protein (long-chain 3-hydroxyacyl-CoA dehydrogenase) deficiency (Schafer et al. 1996; Miyajima et al. 1997).

Treatment consists mainly of avoidance of fasting or other triggering factors and ingestion of a high-carbohydrate, low-fat diet. Treatment with bezafibrate shows promise in reducing biochemical and physical manifestations of CPT II deficiency (Bonnefont et al. 2010). Valproic acid can trigger acute rhabdomyolysis in CPT II deficiency (Kottlors et al. 2001).

OTHER DEFECTS OF LIPID METABOLISM
Defects of mitochondrial (beta) oxidation are clinically heterogeneous but myopathic presentations occur in older children and adults (Lafont and Vianey-Saban 2010). Recurrent myalgia, rhabdomyolysis and myoglobinuria precipitated by
exercise and fasting may occur in very long chain acyl-coenzyme A dehydrogenase (VLCAD) deficiency (Andresen et al. 1999). Short chain acyl-coenzyme A dehydrogenase (SCAD) usually presents in the first few months of life with a lipid storage myopathy, failure to thrive, hypotonia as well as seizures and may later cause a minicore myopathy with progressive external ophthalmoplegia (Tein et al. 1999). Other lipid storage myopathies presenting in childhood include multiple acyl-CoA-dehydrogenase defect (glutaric aciduria type II) (Olsen et al. 2004; Domizio et al. 2005) and long-chain 3-hydroxyacyl-CoA dehydrogenase (trifunctional protein) deficiency (Korenke et al. 2003; Tein 2013).

The management of patients with disorders of lipid metabolism is discussed in Chapter 9.

MITOCHONDRIAL MYOPATHIES

Mitochondrial cytopathies are relatively rare but within this group of disorders involvement of the CNS and neuromuscular system is common (Thorburn 2004; DiMauro et al. 2013). The distinction between purely myopathic and more complex forms is to some extent artificial because of the ubiquitous cellular presence of mitochondria. Skewed heteroplasmy, whereby skeletal muscle might have a predominance of pathogenic mitochondrial mutations compared to other tissues, may account for apparent preferential muscle tissue involvement in some conditions.

Clinical Features

Mitochondrial myopathies may present from birth to adulthood and are extremely variable in their symptoms, severity and outcome (DiMauro et al. 2013). Some are part of complex encephalomyopathies while others are purely or essentially limited to skeletal muscle. If the presentation is that of a clinically pure myopathic process with predominantly proximal muscle weakness then symptoms such as fatigue, myalgia, exercise intolerance and episodic exercise-related myoglobinuria, although not diagnostic, give a clue to the myopathy being due to a metabolic condition. Ptosis and progressive external ophthalmoplegia are highly important clues (Moraes et al. 1989), as are other deficits such as such as cardiomyopathy, cognitive deficits, deafness, retinitis pigmentosa, ataxia and seizures. Like other inborn errors of metabolism, mitochondrial conditions may present during times of physiological stress, such as intercurrent illnesses, surgery or anaesthesia.

Investigation

If an obvious syndrome is not recognised clinically then early clues to a respiratory chain defect come from an elevated blood or CSF lactate or imaging abnormalities in the basal ganglia (Jackson et al. 1995). In some recognisable mitochondrial syndromes (e.g. MELAS, MERRF, NARP) mutations may be found in circulating lymphocytes, thereby avoiding the need for a biopsy (Taylor et al. 2004).

Even in the absence of significant weakness, histological and histochemical assessment of muscle tissue often gives the initial or the confirmatory clue to a mitochondrial disorder. The characteristic morphological abnormality, seen best on staining with Gomori trichrome, is the so-called ‘ragged red fibre’ due to accumulation of subsarcolemmal mitochondria. Electron microscopy may show abnormal mitochondrial structures which may contain paracrystalline inclusions (Fig. 26.3), with further assessment involving histochemical staining for the enzymes succinate dehydrogenase (SDH) which demonstrate mitochondrial proliferation and cytochrome c oxidase (COX). COX is encoded for by both nuclear as well as mitochondrial DNA (mtDNA) and a mosaic pattern of reactivity suggests a heteroplasmic mtDNA disorder, while an overall decrease suggests a nuclear DNA mutation (Taylor et al. 2004). Ragged red fibres are usually COX-negative but they can also be COX-positive (Taylor et al. 2004; DiMauro and Hirano 2005). An excess of lipids or glycogen is seen in some individuals affected by mitochondrial myopathy while, biochemical analysis of respiratory chain complex activity can point to defects in a single respiratory chain complex or multiple complexes. Further delineation is undertaken by molecular genetic studies of both mitochondrial (mt) and nuclear DNA (DiMauro and Hirano 2005).

CLINICAL MYOPATHIC SYNDROMES

Marked clinical heterogeneity, lack of phenotype–genotype correlations and the multisystem nature of mitochondrial disorders have meant that while a number of encephalopathic syndromes that involve muscle have been defined (e.g. MERRF, MELAS), there are very few predominantly or entirely myopathic phenotypes. Some exceptions are discussed below.
Cytochrome C Oxidase Deficiency
Cytochrome C Oxidase (COX) deficiency may present with severe congenital lactic acidosis, weakness and hypotonia which can be isolated or associated with renal and/or cardiac involvement. Infants become symptomatic before 3 months of age; weakness is usually progressive and fatal (Zeviani et al. 1985; Darin et al. 2003). A reversible form of COX deficiency presenting in the newborn period with severe weakness, ptosis, areflexia, increased creatine kinase and lactic acidosis relates to transient impairment of mitochondrial translation (Horvath et al. 2009; Mimaki et al. 2010; Uusimaa et al. 2011).

Coenzyme Q10 Deficiency
Deficiency of coenzyme Q10 (ubiquinone) presents in infancy as a multisystem disorder with encephalopathy, ataxia, nephropathy and myopathy (Trevisson et al. 2011). Later-onset cases have a myopathic presentation with exercise intolerance, progressive proximal muscle weakness and exercise-related myoglobinuria which may be associated with seizures, neuropathy and/or ataxia (Gempel et al. 2007). This disorder is important to recognise because it is potentially treatable with coenzyme Q10 replacement (Trevisson et al. 2011).

Mitochondrial DNA Depletion Syndromes
The mitochondrial depletion syndromes are often multisystemic but can be tissue specific. The myopathic form presents in infancy or early childhood with progressive weakness, hypotonia, areflexia, early onset of respiratory failure and death in the first decade (Martin-Hernandez 2016). Mutations in the thymidine kinase 2 (TK2) gene cause severe generalised muscle weakness, sometimes presenting as a dystrophic condition in early infancy (Chanoprasert et al. 2013). Mutations in the SUCLA2 gene are also associated with mitochondrial DNA depletion and progressive muscle weakness, often with prominent multisystem features (Ostergaard et al. 2007).

Other Mitochondrial Myopathies
Development of sideroblastic anaemia during adolescence may give a clue to the syndrome entitled myopathy and sideroblastic anaemia (MLASA), which commences with exercise intolerance during childhood. Mutations have been found in the pseudo-uridine synthase 1 (PUS1) gene (Bykhovskaya et al. 2004). Childhood-onset exercise intolerance is also a prominent early feature resulting from mutations in the mtdNA cytochrome b gene (Bruno et al. 2003). Progressive external ophthalmoplegia (PEO) is seen in the Kearns–Sayre syndrome as part of a multisystem disorder and is associated with the mtdNA point mutation mt3243A in 80% of affected individuals (Hirano and Pavlakis 1994). Multiple mtdNA deletions due to mutations in the ANTI, Twinkle and POLG genes are seen with inherited forms of PEO without other system involvement although most affected individuals present in adulthood (Agostino et al. 2003).

Chronic Progressive External Ophthalmoplegia and Kearns-Sayre Syndrome
Chronic progressive external ophthalmoplegia (CPEO) usually presents in mid-adulthood with prosis and slowly progressive weakness of the extraocular muscles however occasionally presents in childhood, with diplopia usually absent or minimal. The differential diagnosis of CPEO includes myasthenia gravis and congenital fibrosis of the extraocular muscles (Schoer and Pongratz 2006).

Kearns–Sayre syndrome (KSS) is defined by the combination of CPEO and pigmented retinopathy, often with short stature, ataxia, cardiac conduction defects, deafness, and cognitive deficits. KSS presents before age 20 years and progresses in adulthood (Yamashita et al. 2008).

Both CPEO and KSS can be caused by defects of mitochondrial or nuclear DNA and can occur sporadically or may be inherited in maternal, autosomal dominant or autosomal recessive patterns (di Mauro et al. 2013). Autosomal dominant and autosomal recessive forms of CPEO are linked to mutations in several nuclear DNA genes including POLG, C10orf2, RRM2B, SLC25A44, POLG2, DGUOK and SPG7 which cause defects in intergenicomic signalling leading to multiple secondary mitochondrial DNA deletions (Yamashita et al. 2008; Mancuso et al. 2015).

SYSTEMIC MYOPATHIES OF CHILDHOOD
A number of systemic conditions can cause myopathies in childhood. These include endocrinopathies, renal conditions, infections, connective tissue disorders and eosinophilic syndromes.

HYPERTHYROIDISM
Hyperthyroidism can cause a proximally-predominant pattern of muscle weakness in children, with respiratory and bulbar muscles usually spared. Ocular findings may include lid oedema, lid lag and proptosis with eye movements usually normal (Chan et al. 2002). The serum creatine kinase is not elevated and muscle biopsy shows non-specific abnormalities with atrophy of both type I and type II fibres. Neuroimaging shows enlarged extraocular muscles (Liu et al. 1996).

The incidence of myasthenia is increased in patients with hyperthyroidism and both hyperthyroidism as well as hypothyroidism can aggravate myasthenic weakness. Thyrotoxic
periodic paralysis can develop in adolescents and young adults usually of Asian or Latin American ethnicity and has been linked to susceptibility loci involving genes for muscle potassium channels (Ryan et al. 2010; Cheung et al. 2012). Treatment of these conditions is of the underlying thyrotoxicosis.

HYPOTHYROIDISM

More than a third of adults with hypothyroidism have muscle weakness and cramps with abnormal deep tendon reflexes (Duyff et al. 2000) but the figure for children is not clear: the degree of muscle weakness generally parallels that of the underlying hypothyroidism while the serum creatine kinase is moderately elevated. Where undertaken, muscle biopsy shows type 1 fibre predominance with selective type II atrophy.

In children with congenital hypothyroidism, muscle weakness and hypertrophy may produce a Herculean appearance which, in combination with a coarse facies, glossemegaly; hoarse cry and abdominal distention, is known as the Kocher–Debré–Sémélaigne syndrome (Agrawal and Thakur 2010): all symptoms resolve with treatment of hypothyroidism. This syndrome is exceedingly rare where neonatal thyroid screening programmes are in place. In older children and adults muscle hypertrophy very uncommonly develops with hypothyroidism, a phenomenon known as Hoffmann syndrome.

CUSHING SYNDROME

Cushing syndrome and exogenous steroid treatment give rise to a similar myopathic syndrome with progressive weakness, chiefly affecting the pelvic girdle, muscle wasting and sometimes pain. The EMG is myopathic but the serum creatine kinase, AST and ALT are normal while muscle biopsy shows selective atrophy of type II fibres. The myopathy resolves on treatment of the Cushing syndrome or on withdrawal or reduction of the steroid dose (Minetto et al. 2011).

CRITICAL ILLNESS NEUROPATHY/ MYOPATHY

A systematic study of 830 admissions to a paediatric intensive care unit for longer than 24 hours found that 1.7% developed generalised weakness (Banwell et al. 2003). Acute weakness in an ICU setting can be due to peripheral nerve, neuromuscular junction, muscle or combined aetiologies. Critical illness myopathy (CIM), sometimes known as acute quadriplegic myopathy, was initially described in patients with status asthmaticus receiving high-dose steroid therapy with or without associated nondepolarising blocking agents; other associations are with sepsis, multi-organ failure and organ transplantation (Williams et al. 2007). Serial creatine kinase monitoring may warn of an evolving myopathy (Tabarki et al. 2002) while in CIM affected muscles are electrically inexcitable (Rich et al. 1996). There is no specific treatment and recovery can be slow (Banwell et al. 2003).

MYOPATHIES ASSOCIATED WITH OTHER SYSTEMIC ILLNESSSES

Muscle weakness and hypotonia are common features of rickets and osteomalacia. In some children they may be the presenting manifestation of this condition, causing diagnostic difficulty if bone X-rays are not obtained (Torres et al. 1986; van der Heyden et al. 2004; Alyaaruhi and Rodd 2005). Phosphate depletion (Goodman et al. 1978), magnesium deficiency (Berkelhammer and Bear 1985) and hypermagnesaemia (Emser 1982) are rare causes of myopathy, as is parathyroid disease. Muscle weakness may also be seen in malnourished children (Donley and Evans 1989; Renault and Quesada 1993) although the respective roles of neural and muscular involvement are unclear.

Drug side-effects must always be considered in a child presenting with weakness or rhabdomyolysis but in practice this is a rare issue in children. Medication-related myopathies can be seen with treatment with procainamide (Lewis et al. 1985), sodium valproate (Kasturi and Sawant 2005), clofibrate, labetolol, statins and didanosine (Vladutiu 2008). Hypokalaemia can cause a myopathy after treatment with cisplatin and amphotericin B (Mohammadianpanah et al. 2004).

ARTHROGRYPOSIS MULTIPLEX CONGENITA AND AKINESIA DEFORMATION SYNDROME (MULTIPLE CONGENITAL CONTRACTURES)

Congenital contractures can be isolated or can affect multiple joints. The term arthrogryposis multiplex congenita (AMC) describes a heterogeneous group of disorders whose common feature is congenital contractures of several joints. Arthrogryposis is a clinical finding rather than a specific diagnosis and is seen in more than 300 specific conditions (Hall 1997): in many affected individuals the aetiology remains unknown. Arthrogryposis affects one in 3000 live births (Fahy and Hall 1990). Fetal movement is required for normal joint development and a common factor to all syndromes associated with multiple congenital contractures is reduced or absent fetal movements. The term fetal akinesia deformation syndrome (FADS) is now applied to the series of phenotypes resulting from reduced movement in utero. Common features of FADS, in addition to joint contractures, include craniofacial changes, micrognathia, limb pterygia, pulmonary hypoplasia and intrauterine growth retardation. FADS may result from any cause of reduced movement including exogenous factors (e.g. maternal anti-acetylcholine receptor antibodies), restricted fetal environment (e.g. oligohydramnios), and disorders of the central nervous system or peripheral neuromuscular system. The clinical presentation and outlook of these conditions is very variable, depending on the timing of
the period of immobility, the number and location of immob-
ibilised joints as well as the presence or absence of brain and
other abnormalities.

In evaluating an infant with AMC it is important to
undertake a detailed neurological examination. A normal
neurological examination suggests arthrogryposis is due to
amyoplasia, distal arthrogryposis, a generalised connective
tissue disorder or fetal crowding. In contrast, weakness and
abnormalities of the deep tendon reflexes suggest that move-
ment was decreased in utero as a result of an abnormality of
the central or peripheral nervous system, the motor end plate
or muscle.

**AMYOPLASIA CONGENITA**

Amyoplasia congenita, the most common form of FADS, is
associated with a distinctive pattern of joint contractures (Hall
et al. 2014) while amyoplasia occurs sporadically. In most but
not all individuals affected there is symmetrical involvement
of all four limbs with reduced muscle mass, internal rotation
of the arms, sloping of the shoulders, extension of elbows,
flexion of the wrists, flexed fingers, flexion of the hips and
knees, as well as usually severe equinovarus deformities of the
feet (Fig. 26.4). A minority of individuals have contractures
involving only three limbs, only the upper limbs or only the
lower extremities (Hall et al. 2014): there may also be associ-
ated gastro-intestinal anomalies, congenital absence of dig-
its and congenital fractures (Hall et al. 2014). Amyoplasia is
thought to result from vascular compromise in utero or may
be neurogenic in origin.

Fetal movements are usually reported to be reduced, breech
presentation is common and delivery is often by caesarean sec-
tion. Fractures at birth are common (Sells et al. 1996) while
the hips may be subluxed or dislocated. Joint contractures are
associated with shortening of the limbs and dimples over the
joints with loss of the deep tendon reflexes but normal sen-
sation. A flat capillary angioma – usually midline facial but
occasionally located elsewhere – is present in 80–90% of indi-
viduals affected (Sells et al. 1996). Micrognathia is common
and about one in four of affected infants have contractures
of the temporomandibular joint. Feeding difficulties are very
common in infancy and may be followed by language prob-
lems as well as poor growth. Intelligence is usually normal.

Pathologically, the anterior horns have reduced numbers
of large motor neurons with only minimal gliosis and the
smaller anterior horn neurons are present or increased
(Hageman et al. 1987), with the muscles having fibro-fatty
tissue interspersed with normal-looki ng muscle fibres. The
EMG may show mild signs of denervation, suggesting a
longstanding loss of some motor nerve fibres.

Early specialist physiotherapy intervention, early surgery,
rehabilitation and careful follow-up are essential to give opti-
mum results (Mennen et al. 2005): the outcome is relatively
good despite the extensive deformities. Of 38 children studied
by Sells et al. (1996), two thirds were fully ambulant by 5 years

![Figure 26.4 Mitochondrial myopathy (electron microscopy × 28,500).
(Top) 13-year-old patient with typical history: note classic ‘parking
lot’ inclusions within mitochondria. (Bottom) 5-year-old patient: note
proliferation of the cristae within mitochondria. ‘Parking lots’ and
paracrystalline arrays do not generally become apparent before 7–8
years of age.

of age and most were completely or relatively independent.
Most had undergone numerous orthopaedic procedures,
including castings.

**DISTAL ARTHROGRYPOSIS**

The distal arthrogryposis syndromes affect predominantly the
hands and feet, are often associated with an abnormal facies
and almost always dominantly inherited, although possibly
with reduced penetrance and variable expressivity (Bamshad
et al. 1996; Beals 2005). Nine subgroups have been identified,
of which at least five have a known genetic basis. Characteristic findings in these subgroups include:

- **Type 1** Camptodactyly, talipes equinovarus foot deformities, normal facies
- **Type 2** Freeman–Sheldon syndrome: contractures of hands and feet, characteristic (‘whistling’) facies, flexion and ulnar deviation of the fingers, scoliosis
- **Type 3** Gordon syndrome: cleft palate, finger contractures, short stature
- **Type 4** Scoliosis, finger contractures
- **Type 5** Finger contractures, ptosis, restricted eye movements, strabismus
- **Type 6** Finger contractures, sensorineural hearing loss
- **Type 7** Temporomandibular contractures, camptodactyly
- **Type 8** Finger contractures, multiple ptygeria with stunted growth
- **Type 9** Beals syndrome: finger contractures, ear deformity

Common deformities in the upper limbs include ulnar deviation, camptodactyly, hypoplastic and/or absent flexion creases and overriding fingers, while in the legs common features include talipes equinovarus, calcaneovalgus, vertical talus and metatarsus varus (Beals 2005). Most of the distal arthrogryposis syndromes spare the proximal joints.

A vast number of complex syndromes of chromosomal or genetic origin featuring multiple congenital contractures, dysmorphism and multisystem abnormalities also underlie FADS (Ravenscroft et al. 2011; Hall 2014). The most common is the Pena–Shokeir phenotype (Pena and Shokeir 1974; Hall 2009) which includes intra-uterine growth retardation, craniofacial anomalies, limb contractures and a variety of other anomalies including pulmonary hypoplasia and short gut. At least 20 familial forms are recognised but peripheral neuromuscular disorders can also underlie the Pena–Shokeir phenotype (Hall 2009).

### CENTRAL NERVOUS SYSTEM CAUSES OF ARTHROGRYPOSIS

Developmental abnormalities of the brain, either genetic, or caused by infection or vascular lesions, are sometimes associated with arthrogryposis: such conditions may be associated with increased tone and spasticity. Chromosomal anomalies are a rare cause of AMC, while arthrogryposis is sometimes seen in children with congenital forms of spinal muscular atrophy, such as those associated with mutations in UBE1 (Ramser et al. 2008).

### ARTHROGRYPOSIS DUE TO MUSCLE AND NERVE DISEASES

Arthrogryposis is relatively common in severe neuromuscular disorders associated with fetal akinesia. The molecular basis of individuals affected by this condition is extremely varied but much easier to identify with the advent of next-generation sequencing techniques allowing rapid and affordable screening for large numbers of conditions (Ravenscroft et al. 2011). Myopathies and muscular dystrophies are more commonly implicated than congenital neuropathies.

A very rare but important cause of FADS is transient neonatal myasthenia gravis caused by transplacental passage of maternal anti-acetylcholine receptor antibodies. Transient neonatal myasthenia gravis usually remits spontaneously over days to weeks after delivery but occasionally persists, leaving the child with multiple joint contractures (AMC) or a fixed myopathy, often with marked dysarthria and velopharyngeal incompetence. FADS with congenital contractures is more often seen in children with maternal antibodies directed against fetal acetylcholine receptors. Although rare this is an important cause to recognise not only because of the recurrence risk but also as it is potentially treatable (Hacohen et al. 2014).

### OTHER MUSCLE ABNORMALITIES

#### CONGENITAL AGENESIS/HYPOPLASIA

Congenital agenesis or hypoplasia of muscle is common and may involve a whole muscle or parts of various muscles including (in decreasing order of frequency) the pectoralis, trapezius, sternocleidomastoid, serratus anterior and quadriceps femori. One common condition is the Poland syndrome in which absence or hypoplasia of the pectoral muscles is variably associated with ipsilateral thoracic and upper limb anomalies (Yiyit et al. 2015): focal agenesis of muscles is usually asymptomatic while vascular abnormalities may be a cause in some patients (Lee et al. 1995). The prune belly syndrome is characterised by absence or hypoplasia of abdominal wall muscles (Hassett et al. 2012). Thenar hypoplasia (Cavanagh syndrome) may be either unilateral or bilateral and can be associated with cardiac or ocular anomalies (Sonel et al. 2002).

#### CONGENITAL MUSCULAR TORTICOLLIS

Congenital muscular torticollis is a musculoskeletal deformity usually apparent in the first month of life and characterised by persistent head tilt towards the affected side, with the chin rotated towards the opposite side. Torticollis can be purely postural, a preferred position for the infant with no restriction of movement of the sternocleidomastoid muscle, or associated with shortening of the sternocleidomastoid muscle, with or without a palpable sternocleidomastoid mass (or ‘tumour’) (Cheng et al. 2000). Aetiology is poorly understood but may
relate to malpositioning in utero; occasional instances where this is inherited are described (Engin et al. 1997; Hosalkar et al. 2001). Presence of other findings such as plagiocephaly, craniofacial asymmetry or cranial nerve abnormalities should prompt specialist assessment. Treatment consists of gentle passive stretching and avoidance of factors promoting asymmetry (such as lack of prone positioning, excessive time in car seats and persistence of single positions in bed or during feeds). Rare treatment-refractory patients require surgical release (Cheng et al. 2000).

**MUSCLE HYPERTROPHY**

Generalised or focal muscle hypertrophy may be caused by many myopathic or neurogenic disorders. While the dystrophinopathies and other muscular dystrophies are the most common causes of muscle hypertrophy, this finding can also be seen in hypothyroidism (Kocher–Debré–Sémélaigne and Hoffmann syndromes) and myotonia congenita. Extraordinary hypertrophy has been described in a child with a mutation in the myostatin gene (Schuelke et al. 2004).

**MYASTHENIA AND DISORDERS OF THE NEUROMUSCULAR JUNCTION**

Diseases of the neuromuscular junction are clinically characterised by weakness and increased muscular fatigability. This group of conditions includes autoimmune diseases, congenital myasthenic syndromes and forms of neuromuscular blockade due to drugs, toxins or other exogenous factors. Infant botulism is discussed in Chapter 11.

**Myasthenia Gravis**

Myasthenia gravis is a rare auto-immune condition caused by autoantibodies directed against protein components of the neuromuscular junction. Myasthenia gravis presenting in childhood is classified either as transient neonatal myasthenia gravis (very rare, from transplacental transfer of maternal antibodies) or juvenile myasthenia gravis (more common, resulting from autoantibodies). About 10% of individuals affected by myasthenia gravis are children.

Myasthenia gravis is usually caused by antibodies to acetylcholine receptors (AChR) on the postsynaptic membrane of skeletal muscle. These antibodies bind to the acetylcholine receptor, activating the complement cascade and causing destruction of the postsynaptic membrane and loss of functional acetylcholine receptors at the postsynaptic membrane (Andrews et al. 1993). Anti-acetylcholine receptor antibodies are sometimes not identifiable in juvenile myasthenia gravis; this is described as ‘sero-negative’ myasthenia gravis although other antibodies may be detectable. Sero-negative myasthenia gravis may be linked to antibodies to muscle-specific kinase (MuSK), a receptor tyrosine kinase which acts as an essential component of the developing neuromuscular junction (Koneczny et al. 2014). Other antibodies of uncertain significance may be also present in juvenile myasthenia gravis; these may include those directed against titin, the ryanodine receptor LRP4 and the intracellular AChR-associated protein, rapsyn (Vincent et al. 2012).

The mechanism responsible for the production of these autoantibodies is unknown. A role of the thymus is suggested by the association of AChR-myasthenia gravis with thymic lymphoid hyperplasia and tumours as well as by the effects of thymectomy. Thymic histology, if abnormal, is only minimally so in anti-MuSK myasthenia gravis (Berrhi-Aknin and Le Panse 2014). A genetic susceptibility is suggested by the relative frequency of clinical or EMG manifestations in relatives of individuals with myasthenia and by increased frequency of some HLA groups (Kerzin-Storrar et al. 1988). Other auto-immune disorders may cosegregate with myasthenia gravis, particularly thyroid disease (hyper- or hypothyroidism), rheumatoid arthritis, lupus erythematosus and diabetes (Yeh et al. 2015).

**Clinical features of myasthenia gravis**

Symptoms may occur any time after one year of age but the disease is most prevalent in adolescent girls (Andrews et al. 1994). Virtually all children with myasthenia gravis have ocular involvement (variable ptosis, diplopia and/or ophthalmoplegia) at presentation, which is variably associated with symptomatic bulbar (dysphagia, dysarthria and hypernasality) and proximal limb involvement. In a proportion of these individuals (20–50%, and up to 80% in young Chinese children) (Wong et al. 1992; Afifi and Bell 1993; Anlar et al. 2005), muscle weakness remains confined to the ocular muscles; pure ocular myasthenia is more common in children than adults and usually seen prepubertally. Involvement of muscles other than those around the eyes (‘generalised myasthenia’), usually evolves within two years of initial ocular symptoms and is more common in post-pubertal adolescents.

A characteristic finding in myasthenia gravis is fatigability; variability in muscle function with good strength after rest and deterioration following exercise or towards the end of the day. This history of fatigue is occasionally either absent or difficult to obtain.

Ocular signs in myasthenia gravis may be symmetrical, asymmetrical or unilateral (Afifi and Bell 1993) and more easily seen on sustained upgaze. There is often weakness of the facial muscles, particularly the orbicularis oculi and neck flexors, while proximal limb muscle weakness may be present at the outset or develop later. Fatigability may be brought out by repeated testing of muscle groups, that is, by repeated shoulder abduction or squats. The deep tendon reflexes are normal and there are no sensory deficits.

Anti-MuSK-myasthenia gravis is rare in children but has been reported as early as 14 months of age (Yilmaz et al. 2014) and may be more common in females. In adults the clinical picture of anti-MuSK myasthenia gravis is dominated by
cranial and bulbar muscle weakness as well as frequent episodes of respiratory crises (Evoli et al. 2003) but it is not clear whether anti-MuSK-Myasthenia gravis and anti-AChR-Myasthenia gravis differ significantly in childhood.

The natural course of JMG is variable: in the absence of treatment it tends to be slowly progressive with fluctuations on a baseline of reduced function. ‘Myasthenic crises’ with increased weakness and involvement of the respiratory muscles may occur spontaneously or following febrile illnesses and may require emergent management as well as assisted ventilation.

The differential diagnosis of juvenile myasthenia includes other neuromuscular disorders in which fatigability can sometimes be marked, such as myopathies and congenital myasthenic syndromes as well as mitochondrial disorders and botulism. Rare myasthenic syndromes result from the use of agents such as penicillamine, carnitine and aminoglycosides. Structural lesions of the midbrain, such as tumours, may cause fatigable ptosis, ophthalmoplegia and oropharyngeal weakness, mimicking myasthenia. Imaging studies should be performed if the diagnosis of myasthenia gravis is not definitive, particularly if signs are confined to the cranial nerve territories.

### Diagnosis of Myasthenia Gravis

The diagnosis of juvenile myasthenia gravis (JMG) is primarily a clinical one but a number of tests provide useful supportive data. These tests have variable sensitivity, especially in children with ocular myasthenia gravis.

Antibody testing for anti-AChR antibodies or in their absence anti-MuSK antibodies is relatively inexpensive and straightforward. A positive acetylcholine antibody test is essentially diagnostic in the appropriate clinical setting with false positives very rare. Anti-AChR antibodies are more likely to be present in children with generalised myasthenia gravis than in pure ocular myasthenia gravis. Anti-AChR antibodies can be found in only 50% of prepubertal children, but are seen in 60–80% of postpubertal children with myasthenia gravis. Anti-AChR antibodies are more likely to be present in children with generalised myasthenia gravis than in pure ocular myasthenia gravis. Anti-AChR antibodies can be found in only 50% of prepubertal children, but are seen in 60–80% of postpubertal children with myasthenia gravis (Afifi and Bell 1993; Andrews et al. 1993). Of those seronegative for AChR antibodies about 40–50% are seropositive for anti-MuSK antibodies (MuSK-myasthenia gravis) (Evoli et al. 2003; Vincent and Leite 2005). The antibody titre does not vary with disease severity or after thymectomy in anti-AChR myasthenia gravis (Seybold et al. 1978; Snead et al. 1980) but may vary with disease activity in anti-MuSK myasthenia gravis (Anlar et al. 2009; Yilmaz et al. 2015).
Administration of a short-acting anticholinesterase agent to demonstrate reversibility of ptosis, ophthalmoplegia or dysarthria is a useful adjunct investigation supporting the diagnosis of a myasthenic process. Edrophonium chloride given intravenously has a rapid onset of effect (30 seconds) with a short duration (5 minutes). The effect may be immediate and obvious but can be difficult to gauge in small children: assessing the response, particularly in young children, can be aided by taking photographs or (preferably) videotaping the procedure. Muscarinic side-effects of edrophonium and the related agent, neostigmine, include hyper-salivation, bradycardia and asystole; these can be avoided by pre-treatment with intravenous atropine. The maximum dose of edrophonium chloride varies with age (1–10mg): a small test dose is usually given first, the rest being injected after 30–60 seconds if there is no response after the test dose. This test should always be performed with resuscitation equipment available. A negative anticholinesterase test does not exclude JMG and a positive result is sometimes only obtained on repeat testing. Conversely, a positive test is not pathognomonic and should not be the only basis for diagnosis (Drachman 1994).

Repetitive nerve stimulation (RNS) is a variant of motor nerve conduction testing. Serial compound muscle action potentials are recorded from surface electrodes placed over a weak muscle, with the nerve being stimulated at 2–3 Hz. A decrement in amplitude of more than 10% from the third to the fifth response is abnormal, providing evidence of a defect in neuromuscular junction transmission: this abnormality is corrected after injection of anticholinesterase. A normal RNS does not exclude JMG; in one series RNS was positive in only 33% of individuals when distal nerves were stimulated and in 66% when both proximal and distal nerves were tested (Afifi and Bell 1993). The test can be technically challenging and may be uncomfortable for children; it should only be undertaken by experienced neurophysiologists. Negative testing may prompt additional investigations such as high-frequency (20–50Hz) repetitive nerve stimulation, on which an increment in the size of the responses recorded may suggest a presynaptic neuromuscular junction transmission defect such as infant botulism or the Lambert-Eaton syndrome. Single-fibre EMG, which demonstrates increased ‘jitter’ in the latencies of two fibres of a single motor unit, is more sensitive than classic RNS in diagnosis of myasthenia gravis but difficult to perform in children (Pitt 2008).

Hyperthyroidism occurs in 3–8% of patients with JMG and either hyperthyroidism or hypothyroidism may aggravate myasthenic weakness. Thyroid function should be tested in all patients with suspected myasthenia gravis (Drachman 1994) and evidence for other autoimmune disorders should be sought by careful history, clinical examination as well as laboratory tests where indicated: JMG is rarely associated with thymoma (Ware et al. 2012; Castro et al. 2013). All children with generalised myasthenia gravis should undergo either chest CT or MRI to exclude a concomitant thymoma; imaging should also be considered in children with ocular myasthenia gravis, although their risk of thymoma is extremely low.

**Treatment of Myasthenia Gravis**

The aims of treatment of myasthenia gravis include enhancement of neuromuscular transmission with anticholinesterase agents and modulation of the abnormal immune activation causing this condition. Potential immunotherapeutic options include relatively short-acting treatments such as plasma exchange and intravenous immunoglobulin, longer-term agents such as prednisolone, cyclosporine and azathioprine as well as surgical thymectomy (Drachman 1994).

Rodriguez et al. (1983) observed spontaneous remissions in 30% of patients after a 15-year follow-up but in those with generalised weakness the remission rate was significantly lower. Younger patients are much more likely to grow into spontaneous remission than older children and adults. Prepubertal Caucasian children demonstrate a higher rate of spontaneous remission than African-American children, who also have a lower rate of response to thymectomy (Andrews et al. 1994).

Pre-adolescent children in whom the spontaneous remission rate is high and older children with purely ocular myasthenia can often be successfully managed with anticholinesterase agents alone: older children and adolescents require additional therapy directed against the immune system abnormality. The relative efficacy of these therapies in paediatric subgroups is difficult to determine given that this is a rare and clinically heterogeneous condition (Ware et al. 2012; Castro et al. 2013). The agents used are generally determined on an individual basis, based upon institutional experience and with the long-term cost–benefit ratio in mind (Richman and Agius 2003).

The aims of immunotherapy for myasthenia is to induce and then maintain immunological remission. Corticosteroids, sometimes used in combination with intravenous immunoglobulin or plasmapheresis, are effective for induction of remission. Maintenance of the remission with a slow reduction of the maintenance corticosteroid dose may be accomplished with other drugs such as azathioprine or by thymectomy (Richman and Agius 2003).

**Anticholinesterase agents**

Anticholinesterase agents are the first line of treatment of myasthenia but are symptomatic rather than curative. These drugs increase the half-life of acetylcholine released into the synaptic cleft by inhibiting hydrolysis by acetylcholinesterase, thus increasing the probability of acetylcholine molecules reaching the reduced number of receptors on the postsynaptic membrane (Drachman 1994); while an initial good response is usually seen, effectiveness may wane over time. Pyridostigmine is the most commonly used oral agent; neostigmine may be useful parenterally during crises or when oral intake is otherwise not possible. The clinical effect of pyridostigmine commences after about 30 minutes and peaks about 2 hours post-dose.
The initial dose of pyridostigmine is 0.5–1mg/kg every 4–6 hours, with a maximal dose of 7mg/kg/day. The dosage should be slowly increased with timing tailored to the individual needs of the child. In adolescents, doses greater than 120 mg given five times per day rarely give extra benefit and increase the risk of cholinergic crisis. The sustained-release preparation of pyridostigmine should be used only for troublesome symptoms overnight or on waking, as there is evidence from animal studies that sustained exposure to anticholinesterase agents may damage the endplate region of the neuromuscular junction (Hudson et al. 1978). Parents should be counselled as to potential adverse effects of pyridostigmine, which include abdominal cramping and diarrhoea. Diaphoresis, nausea, vomiting, bradycardia and miosis are seen with significant over-treatment and may be complicated by increased muscle weakness, a ‘cholinergic crisis’. Treatment of cholinergic crisis is a reduction or cessation of pyridostigmine followed by a slow reintroduction once all symptoms have resolved.

Children with anti-MuSK myasthenia often respond relatively poorly to anticholinesterase therapy and may be at increased risk of cholinergic crisis (Ionita and Acsadi 2013).

**Corticosteroids**

Corticosteroids induce remission in most children with JMG but their long-term use should be based only on a considered decision taking into account the long-term side effects of corticosteroid therapy, including weight gain, growth suppression, osteoporosis, hypertension and susceptibility to infection (Ionita and Acsadi 2013). Initiation of high-dose corticosteroid therapy may cause increased weakness in children with myasthenia; a low starting dose (0.5mg/kg/day) is therefore required for outpatients, with a gradual increase over the following weeks. In children with severe weakness or those in myasthenic crisis higher doses may be given but inpatient monitoring of respiratory function is essential and additional treatment with intravenous immunoglobulin or plasmapheresis should be considered (Richman and Agius 2003). Once children are in remission, a prednisolone dose of 1–2mg/kg/day is given as maintenance until good disease control is sustained for some time, when a very slow steroid wean should be initiated. Switching to an alternate-day schedule may maintain remission while minimising side-effects.

**Intravenous immunoglobulin**

Pooled immunoglobulin from blood donors can be given intravenously and is a safe and effective treatment of paediatric myasthenia gravis. (Selcen et al. 2000; Ionita and Acsadi 2013). Intravenous immunoglobulin (IVIG) is probably superior to plasma exchange in terms of ease of use and side-effect profile in children. IVIG may have a role for acute intervention in myasthenic crises or the acutely unwell, or as a chronic maintenance therapy when all other treatment modalities have failed (Ionita and Acsadi 2013). Benefit may be seen in 3 or 4 days but lasts less than 3 months. Possible side-effects include headaches, back pain and aseptic meningitis.

**Plasma exchange**

Plasma exchange can produce rapid but short-lived improvement in myasthenia gravis and has been used for the treatment of myasthenic crises as well as for pre- and post-operative support. Plasmapheresis is rarely used as maintenance therapy for myasthenia as it requires two large-bore intravenous lines and benefits are only transient (Ionita and Acsadi 2013).

**Other long-term immunotherapeutics**

Other long-term immunotherapies may be required as an alternative to corticosteroids or as a steroid-sparing strategy. Azathioprine may be used in conjunction with steroids or in isolation (Ware et al. 2012). A randomised, double-blinded trial in adults showed that azathioprine, used as an adjunct to alternate-day prednisolone in antibody-positive generalised myasthenia gravis, reduced the maintenance dose of prednisolone and was associated with fewer treatment failures, longer remissions and fewer side effects (Palace et al. 1998). Testing of thiopurine methyltransferase activity and/or genetic variants in the TPMT gene is important prior to initiation of azathioprine therapy to enable accurate dosing calibration (Relling et al. 2011).

Cyclosporine, tacrolimus and mycophenolate mofetil can all be considered if azathioprine is not tolerated, while cyclophosphamide has been used for very severe disease (Richman and Agius 2003). High-dose pulse methylprednisolone has been used successfully in children with refractory disease (Sakano et al. 1989).

**Thymectomy**

Thymectomy is always indicated in children with thymomas. Thymoma is much less common in children than adults with myasthenia gravis. In those without thymoma thymectomy improves the chances of inducing a long-term remission in JMG, particularly in those who appear to have relatively treatment-refractory disease (Ware et al. 2012). It is usually indicated for moderate or severe disease, particularly if there are oropharyngeal or respiratory symptoms. Intervention with short-term agents such as IVIG, plasma exchange or corticosteroids may be required for stabilisation before or after surgery. Thymectomy frequently results in significant and lasting improvement, although other long-term therapy remains necessary for some time as the full benefit of thymectomy may not be evident for a year or more. Children are more likely to be improved or go into remission if thymectomy is performed early, particularly within the first year following the onset of symptoms (Andrews et al. 1994; Richman and Agius 2003; Heng et al. 2014). Endoscopic thymectomy may yield excellent results but care must be taken that all thymic remnants are removed intrao-operatively (Ware et al. 2012; Christison-Lagay et al. 2013; Goldstein et al. 2015).

Adults with anti-MuSK myasthenia gravis, in which there is little or no thymic abnormality, do not respond to thymectomy (Evoli et al. 2003).
Wittbrodt (1997) reviewed drugs prescribed for coexisting conditions that may impair neuromuscular transmission. Commonly prescribed agents which may exacerbate symptoms in myasthenia gravis include aminoglycoside antibiotics, ciprofloxacin, lithium, penicillamine, magnesium and botulinum toxin.

TRANSPORT NEONATAL MYASTHENIA

Approximately 5–10% of infants born to mothers with myasthenia are affected by transient neonatal myasthenia gravis (NMG), after antibodies directed against acetylcholine receptors are transferred from the maternal to the fetal circulation (Hoff et al. 2003). In one study 13 of 30 newborn infants of myasthenic mothers were anti-AChR antibody positive: all five newborn infants clinically affected were in the AChR antibody-positive group and no AChR antibody-negative mothers had an affected infant (Batocchi et al. 1999).

Importantly, many patients with myasthenia gravis have antibodies directed not only against the main adult immunogenic region of the AChR but also against the fetal isoform (Polizzi et al. 2000). The adult: fetal antibody ratio has been found to predict, either before or during pregnancy, the occurrence of NMG for the first child at least (Gardnerova et al. 1997). There is no relation between the severity of maternal disease and involvement of the infant.

The clinical features of transient neonatal myasthenia are usually distinctive (Papazian 1992). The onset is delayed to a few hours after birth, sometimes as long as 2–3 days and is marked by hypotonia, feeding difficulties due to poor sucking and/or swallowing, poor crying and facial diplegia. Prossis is present in only a minority of individuals while respiratory distress requiring mechanical ventilation may occur. These features permit an easy diagnosis when myasthenia is known in the mother but she may be undiagnosed or asymptomatic. The diagnosis may be suspected if there is a positive response to administration of anticholinesterases. Repetitive nerve stimulation can also be used to assist diagnosis but is painful and can be technically difficult in infants.

Treatment is with maintenance anticholinesterase therapy. In severe forms with respiratory distress and/or profound hypotonia exchange transfusion has been used (Pasternak et al. 1981). The role of IVIG is not clear (Bassan et al. 1998): symptoms usually resolve by 4–6 weeks but occasionally can take up to several months (Morel et al. 1988).

More severe, less common variants of neonatal myasthenia gravis include the fetal akinesia deformation sequence (FADS) and the fetal acetylcholine inactivation syndrome. FADS in infants of myasthenic mothers is characterised by a combination of fixed joint contractures and craniofacial anomalies (hypertelorism, micrognathia, low-set ears), limb anomalies as well as pulmonary hypoplasia (Polizzi et al. 2000). The fetal acetylcholine receptor inactivation syndrome presents in the neonatal period with facial diplegia, a high arched palate, velopharyngeal incompetence, conductive hearing loss and cryptorchidism (Oskoui et al. 2008; Hacohen et al. 2014). Antibodies against the AChR are markedly elevated, although not always specific for the fetal AChR subunit (Hacohen et al. 2014). Muscle weakness may be significant and permanent but may respond to some degree to treatment with salbutamol (Allen et al. 2016).

CONGENITAL MYASTHENIC SYNDROMES

The congenital myasthenic syndromes (CMS) are a heterogeneous group of genetic disorders of neuromuscular transmission. Anatomically, CMS generally arise from molecular defects of neuromuscular junction proteins at the presynaptic, synaptic or postsynaptic levels. With the advent of whole exome sequencing, more than 20 individual CMS are now recognised (Table 26.6) (Engel et al. 2015).

Most individuals display symptoms in the newborn period or the first year or two of life however these can occasionally present in later childhood or even adulthood and may be misdiagnosed as congenital myopathies or seronegative autoimmune myasthenia gravis (Burke et al. 2004). Autosomal recessive inheritance is seen in all but the slow channel syndrome and synaptotagmin 2 deficiency (Herrmann et al. 2014).

The clinical picture is variable. There is often an obstetric history of reduced fetal movement, polyhydramnios and preterm delivery, or congenital joint contractures may be present. Feeding difficulties with poor suck and cry, prossis and ophthalmoplegia, as well as facial and generalised weakness often dominate the neonatal period: mild facial dysmorphism and a high-arched palate are also reported (Goldhammer et al. 1990; Burke et al. 2004). Later, delay in motor milestones, fluctuating prossis and ophthalmoplegia, oropharyngeal dysfunction as well as weakness and fatigability are common (Engel et al. 2015). Life-threatening episodes of respiratory insufficiency with sudden apnoea and cyanosis can be seen from birth or later in infancy. These episodes are often precipitated by minor infections or other intercurrent illnesses and can point to the myasthenic syndromes caused by choline acetyltransferase deficiency, rapsyn mutations and sodium channel mutations (Engel et al. 2015).

Diagnosis is based on the nerve conduction studies, which generally show a decremental response to repetitive nerve stimulation or increased jitter on single-fibre EMG. Empiric trials of treatment with anticholinesterases and 3–4 diamino pyridine (which increases acetylcholine quantal release) may give a guide to the underlying diagnosis but can lead to an increase in weakness in some rare forms (such as, e.g. COLQ deficiency) and are only recommended in hospital settings with access to emergency care. Ephedrine and salbutamol help in other individuals (Beeson et al. 2005). Genetic testing for the known various CMS is now commercially available.
**LAMBERT–EATON MYASTHENIA SYNDROME**

Lambert–Eaton myasthenia syndrome (LEMS) is a very rare immune-mediated disorder of presynaptic neuromuscular junction transmission. LEMS is clinically characterised by fatigable muscle weakness, hyporeflexia and autonomic disturbance: it is much more common in adults in whom it is associated with antibodies to presynaptic voltage-gated calcium channels. About half of the adults with this condition have an associated small-cell lung carcinoma (SCLC) which also expresses these calcium channels (Tittu et al. 2011). Neoplasms associated with paediatric LEMS include leukaemia, neuroblastoma, Burkitt lymphoma and Wilms’ tumour (reviewed by Hajjar et al. 2014).

The diagnosis is suggested by neurophysiological studies which show low-amplitude CMAPs with marked facilitation on high-frequency repetitive nerve stimulation (Hajjar et al. 2014). Treatment is of the underlying malignancy where present and by immunosuppression, pyridostimine and 3, 4 DAP.

**Other Neuromuscular Blocking Agents**

Drugs potentially interfering with neuromuscular transmission are discussed above in the section on Juvenile Myasthenia Gravis. This topic has been reviewed by Wittbrodt (1997). The toxins of several venomous animals have been instrumental in understanding the structure and function of the neuromuscular junction (Vincent et al. 2000). Agents impairing neuromuscular transmission at a presynaptic level include arthropod venoms and some insect bites, while several snake venoms are active at the postsynaptic level (Kularatne and Sananayake 2014). Electrophysiological abnormalities are also an indication of acetylcholinesterase inhibition secondary to organophosphate poisoning (Besser et al. 1989).

CHAPTER 27

Electrolyte and Acid-Base Metabolism Disturbances, Nutritional Disorders and Other Systemic Diseases

Peter Baxter

A degree of neurological involvement is common in many systemic diseases, some of which have already been discussed or alluded to elsewhere in this book. Such involvement represents a significant part of the work of neurologists and serves to remind us that the nervous system is critically dependent on the rest of the organism. A complete coverage of this vast field is not the aim of this chapter, which is limited to the most important disorders that can produce major neurological disturbances and which have not been previously dealt with. These include neurological syndromes due to disturbances of the electrolyte and acid-base metabolism to which the nervous system is extremely sensitive, nutritional diseases involving the central nervous system (CNS), which represent a major cause of neurological disease in developing countries, and CNS involvement in endocrine and visceral diseases. Both the peripheral and the CNS can be affected in several of these conditions (Aicardi 2009a).

DISORDERS OF WATER AND ELECTROLYTE METABOLISM

COMPLICATIONS OF ACUTE DEHYDRATION

Globally, acute dehydration is one of the commonest preventable causes of death and morbidity in childhood. Younger children, especially infants, and those with pre-existing problems such as undernutrition, are at particular risk. Gastroenteritis is well recognised as the most common cause, but dehydration can also follow insufficient intake, or water loss due to other gastrointestinal disorders, excess diuresis or excess sweating. Evidence-based guidelines are widely available for the assessment and management of acute gastroenteritis and of dehydration, but compliance by health professionals may still vary (Kosek et al. 2003; NICE 2009; Niescierenko and Bachur 2013; Freedman et al. 2015).

As well as systemic features, early neurological symptoms of hypovolaemia include headache and pre-syncopal features such as orthostatic dizziness, which are difficult to assess in young children. Later ones include irritability, fatigue, lethargy and muscle cramps, while a reduced conscious level is a near terminal sign of severe shock (NICE 2009).

Hypovolaemia from any cause is a significant risk factor for acute venous stroke, especially when exacerbated by sepsis or haematological risk factors. The latter include anaemia, polycythaemia, thrombocytosis, haemoglobinopathies and prothrombotic conditions. Hypovolaemia and haemoconcentration secondary to nephrosis are also recognised predisposing factors. As well as focal deficits, presenting features of venous stroke can include seizures and encephalopathy. Complications include hydrocephalus and subdural, subarachnoid or intracerebral haemorrhage. The diagnosis is confirmed by neuroimaging. The presenting features and management of acute venous stroke are discussed in Chapter 15.

The role of hypovolaemia in the aetiology of acute arterial ischaemic stroke is less marked, but correction of fluid and electrolyte imbalances is also part of standard acute management.

Hypovolaemia and vascular collapse following acute blood loss, vasodilatation, or capillary leak, including septic shock and post-traumatic states, carry similar neurological risks. If complicated by disseminated intravascular coagulation there is additional risk of haemorrhage. In a large African study of children with infection and shock, in the acute phase 15% were in coma and 37% had seizures; 2% of survivors had neurological sequelae.

Hypovolaemia and electrolyte disturbance are also recognised complications of therapeutic hypothermia, but their contribution to any long-term sequelae is difficult to disentangle from those caused by the primary pathology (Roach et al. 2008; Polderman 2009; Maitland et al. 2011).
Neurological Complications of Acute Gastroenteritis Without Dehydration

Children with gastroenteritis can develop encephalopathy or seizures from causes other than dehydration or electrolyte disturbances. As well as excluding meningitis presenting with vomiting, possible causes to consider include febrile convulsions, heat stroke, hypoglycaemia, acute demyelinating encephalomyelitis, and direct effects from the infecting organisms. The latter includes benign convulsions associated with gastroenteritis, in which children aged 6 months to 3 years with gastroenteritis develop recurrent clusters of focal or secondarily generalised seizures without any associated encephalopathy, typically in the first 3 days of the illness. The interictal EEG is usually normal, but can show focal sharp waves. Magnetic resonance imaging (MRI) is usually normal but can show transient focal lesions. The seizures are often resistant to standard first-line acute treatment, especially with benzodiazepines, but the long-term prognosis is generally good with a low risk of later epilepsy. When associated with rotavirus infection most children do not have cerebrospinal fluid (CSF) pleocytosis or elevated protein level, but polymerase chain reaction (PCR) may detect rotavirus RNA in CSF.

Other direct effects include enteroviral encephalitis and encephalopathy. In one Japanese survey encephalopathy associated with rotavirus infection carried a 12% risk of death and a 25% risk of neurological sequelae, including central motor impairments, intellectual disability and epilepsy. Bacterial enteritides due to organisms such as Salmonella or Shigella species can also present with seizures in younger children, although again dehydration, electrolyte disturbance and hypoglycaemia may all be contributory factors. Rarely, a more severe encephalopathy, known as Ekiri syndrome in Japan, develops in association with cerebral oedema, which can have a poor outcome. The mechanism is unknown. Steroid treatment has been suggested, with little evidence of efficacy (Fig. 27.1).

Heat Stroke and Haemorrhagic Shock Encephalopathy Syndrome

Although heat stroke often coincides with dehydration, it is due to a direct effect of a raised body temperature on the brain and body, and is the most extreme form of heat-related or heat stress illness. Infants, children and adolescents are at risk in several circumstances: when they are unable to escape from unmonitored enclosed overheated environments such as cots with excess bedding, transport incubators or motor vehicles; when sweating is reduced due to congenital anhidrotic conditions or drugs such as topiramate or MDMA (Ecstasy); or when exercising during hot weather. Immobility, due for example to cerebral palsy (CP), is also a risk factor. In athletes muscle cramps can be an early warning symptom. Presenting features are fever over 40–41°C, nausea and vomiting, dry flushed skin (except in exertional cases when sweating can be profuse), seizures, encephalopathy and multi-organ dysfunction. However, by the time a child reaches medical care cooling may have occurred leaving the other effects as presenting features, which can lead to misdiagnosis as complicated shock due to dehydration or sepsis. MRI shows signal changes in the cerebellum, basal ganglia, hippocampus, and cortex. Treatment relies on immediate cooling to below 40°C and general supportive care. The condition has a significant mortality and morbidity.
The haemorrhagic shock encephalopathy syndrome can be a manifestation of heat stroke in infants and young children, although not all cases appear to be caused by this mechanism. Presenting features are diarrhoea, fever, encephalopathy, seizures, and multi-organ failure including disseminated intravascular coagulation. Neuroimaging shows a range of findings including ischaemia, oedema, and intraventricular and/or parenchymal haemorrhage. The mortality can be as high as 50%, with half of survivors left with neurological sequelae (Bacon 1983; Thébaud et al. 1999; Bytomski and Squire 2003; Jardine 2007; Rogers et al. 2009; Baugnon et al. 2010; Kuki et al. 2015).

HYPERNATRAEMIA

Hypernatraemia, variably defined as a plasma sodium concentration above 145 or 150mmol/L, most frequently occurs in association with dehydration. In developed countries the highest incidence is in exclusively breastfed infants in the first two weeks of life, due to failure to establish adequate feeding. With treatment, most of this group recover without sequelae (Bacon 1983; Thébaud et al. 1999; Byromski and Squire 2003; Jardine 2007; Rogers et al. 2009; Baugnon et al. 2010; Kuki et al. 2015).

<td>Excessive salt loss: gastroenteritis, renal (diabetes insipidus, diuretics, pseudo-hypoaldosteronism, obstructive nephropathy), or through perspiration (cystic fibrosis, heat exhaustion)</td>
</tr>
</tbody>
</table>

The haemorrhagic shock encephalopathy syndrome can be a manifestation of heat stroke in infants and young children, although not all cases appear to be caused by this mechanism. Presenting features are diarrhoea, fever, encephalopathy, seizures, and multi-organ failure including disseminated intravascular coagulation. Neuroimaging shows a range of findings including ischaemia, oedema, and intraventricular and/or parenchymal haemorrhage. The mortality can be as high as 50%, with half of survivors left with neurological sequelae (Bacon 1983; Thébaud et al. 1999; Byromski and Squire 2003; Jardine 2007; Rogers et al. 2009; Baugnon et al. 2010; Kuki et al. 2015).

OTHER POSSIBLE CAUSES OF HYPERNATRAEMIA

Other possible causes of hypernatraemia include salt overload, either iatrogenic such as after cardiopulmonary bypass or due to Munchhausen-by-proxy, and endocrine disorders (Table 27.1). These can be distinguished by paired studies of plasma and urine electrolyte urea and creatinine levels (Forman et al. 2012).
chronic hypernatraemia, with other signs of hypothalamic dysfunction, in the absence of persisting diuresis due to diabetes. ROHHAD (rapid onset obesity, hypothalamic dysfunction, hyperventilation and autonomic dysregulation) syndrome is a presumed autoimmune disorder that can be associated with neuroblastoma, and may account for some cases previously considered to be idiopathic. Cyclophosphamide might improve symptoms in some cases. (Wang et al. 1994; Di Iorgi et al. 2012; Armangue et al. 2012; Jacobson et al. 2016).

**HYPONATRAEMIA**

Hyponatraemia, variably defined as a plasma sodium level below 130 or 135 mmol/L, can be due to water overload, excess sodium loss, or both (see Table 27.1). Dilutional hyponatraemia most frequently occurs in hospitalised children, with hypotonic infusion fluids a major risk factor. Children at particular risk are those with impaired renal diuresis; for example, due to syndrome of inappropriate antidiuretic hormone secretion (SIADH), treatment with desmopressin, or renal impairment. It is also seen with polydipsia, both psychogenic and in people taking 3,4-methylenedioxymethamphetamine (MDMA, [Ecstasy]). Excess sodium loss is usually associated with dehydration, and can be caused by gastrointestinal or renal losses, cerebral salt wasting syndromes or medication such as diuretics. There can be multiple contributory factors in very sick children receiving intensive care, especially when this is for respiratory illness or follows brain injury of various causes including trauma, neurosurgery, subarachnoid haemorrhage and hypoxaemia (Rogers et al. 2009; Hardesty et al. 2012; Foster et al. 2014; Moritz and Ayus 2014).

When associated with hypertension and proteinuria (the hyponatraemia hypertension syndrome), presenting symptoms can be renal, with polyuria and polydipsia, or neurological: the latter can include headache, vomiting, encephalopathy and papilloedema. Renovascular causes are the most frequent (Kovalski et al. 2012).

Hyponatraemia can occur in children treated with carbamazepine or its derivatives and does not require treatment if asymptomatic.

The main neurological symptoms of hyponatraemia are encephalopathy, with headache, vomiting, ataxia and/or a reduced conscious level, and seizures, which can be focal or generalised. Febrile seizures can co-exist and if so may be more frequent and prolonged. In dilutional hyponatraemia cerebral oedema, hiccups, raised creatine kinase levels and/or rhabdomyolysis have also been reported. Additional neurological features may reflect the underlying pathology; for example, following surgery for brain tumours (George et al. 1996; Hardesty et al. 2012; Lee and Chung 2013; Khow et al. 2014).

Identifying and correcting the underlying fluid balance problem is the most important aspect of treatment, with or without sodium supplementation, if appropriate. A gradual correction of the sodium level is thought to reduce the risk of osmotic demyelination syndrome, but if a child is encephalopathic, hypertonic saline infusion is recommended. Vaptans (vasopressin antagonists) are recommended for non-acute treatment of SIADH (Moritz and Ayus 2014).

**OSMOTIC OR CEREBRAL DEMYELINATION**

Osmotic or cerebral demyelination syndrome is the umbrella term for both central pontine and extrapontine myelinolysis. Originally recognised at post-mortem, and now mostly by neuroimaging, this can be associated with hyper- and hyponatraemia and hyper- and hypo-glycaemia (Fig. 27.2). Over-rapid correction of hyponatraemia is a classic predisposing factor. Additional factors probably influencing its development include severe liver disease, hypokalaemia and hypophosphataemia. In the central pontine form, a child develops cranial nerve signs, pseudobulbar palsy, quadriplegia and/or ‘locked-in’ syndrome. In the extrapontine form, involving thalamus, basal ganglia, and hippocampus, symptoms are of a more general encephalopathy. The severity varies and does not correlate closely to the imaging appearances. There is no specific treatment. Recovery is usually prolonged, over weeks or months, but the outcome is better in children than adults (Brown and Caruso 1999; Ranger et al. 2012; Moritz and Ayus 2014).

**OTHER ELECTROLYTE DISTURBANCES**

Some of the possible causes and neurological effects of other electrolyte disturbances are given in Table 27.2. The main
Chapter 27 Electrolyte and Acid-Base Metabolism Disturbances, Nutritional Disorders and Other Systemic Diseases

Clinical features are neurological in hypocalcaemia, either primary or secondary to hypomagnesaemia, hyperphosphataemia, hypochloraemic alkalosis, and in hypermanganesaemia. Some genetic conditions, usually affecting channel or transport mechanisms, cause neurological disturbances through either direct or associated effects: examples include the hyper- and hypo-kalaemic paralyses (e.g. due to calcium or sodium channelopathies: OMIM 114208, OMIM 603967); hypokalaemic alkalosis and occasionally hypomagnesaemia in Bartter syndrome (OMIM 214700); the association of dystonia, polycythaemia and liver disease with hypermanganesaemia due to SLC30A10 mutations (OMIM 613280); and hyper- or hypo-calcaemia due to CASR mutations (OMIM 601199). In hypophosphatasia, pyridoxine responsive seizures can occur due to intracellular pyridoxal phosphate deficiency (Clayton 2006).

### NUTRITIONAL DISORDERS AND THE NERVOUS SYSTEM

#### PROTEIN ENERGY UNDERNUTRITION

The term malnutrition comprises both protein energy undernutrition and obesity. Childhood protein energy undernutrition is recognised in all parts of the world, with the highest prevalences in Africa and Southeast Asia. Together with associated problems of infection, infestation, micronutrient deficiencies, toxins from foods and other sources, and social deprivation, protein calorie undernutrition is estimated to contribute to 50% or more of global deaths in children aged 5 years or less. It probably has equally significant neurocognitive consequences, although these are less easy to quantify and the relative contributions of undernutrition itself and its associated factors are difficult to distinguish, as discussed below.

Intrauterine growth retardation is an important consequence of maternal malnutrition, when it is often also associated with later child undernutrition. In more affluent parts of the world Intrauterine growth retardation is more commonly caused by placental insufficiency. The incidence varies according to the definition used, but globally it is probably the most frequent type of undernutrition.

As well as an inadequate food supply or famine, other causes of undernutrition include conditions affecting feeding, especially central and peripheral motor disorders, such as some forms of CP and some neuromuscular disorders, or anorexia nervosa; intestinal malabsorption syndromes; cancer, chronic haemodialysis, and chronic liver disease. In more developed countries a significant percentage of hospitalised children are estimated to be undernourished. The highest risk groups include those with chronic neurological problems, although this may be changing with the more widespread use of gastrostomy feeds, and preterm infants or young children especially those receiving intensive care (Cooke et al. 2004; Muller and Krawinkel 2005; Hulst et al. 2006; Pawellek et al. 2008; Grover and Ee 2009; Ahmed et al. 2012; Bhutta and Salam 2012; Duggan 2012; Black et al. 2013; Arthur et al. 2015).

#### Clinical Features

In children and infants with protein energy undernutrition the weight velocity falls first, followed by length and lastly the occipito-frontal circumference. This is reflected by
generalised wasting with loss of body fat and muscle, and is thought to reflect relative preservation of brain growth relative to other body parts, so the child looks thin with a relatively large head. In more chronic forms stunting is more marked. Micronutrient and vitamin deficiencies can add specific signs such as anaemia, rickets or goitre. Classically, the most extreme forms have been divided into marasmus, mainly affecting infants, or kwashiorkor, mainly affecting young children, with the latter distinguished by the presence of oedema, loss of hair colour, skin changes and biochemical disturbances. Kwashiorkor was ascribed to protein deficiency, especially after the cessation of breastfeeding, but it is now recognised that the two overlap and that infestation and infection, especially diarrhoea and HIV, influence the clinical picture (Muller and Krawinkel 2005; Grover and Ec 2009; Duggan 2012).

In neurological terms children are lethargic, miserable and anorexic, with impaired development. Proximal weakness, hyporeflexia, muscle wasting and soft signs may be present in 50% or more, but more classic syndromes such as subacute combined degeneration of the cord are infrequent. Brain MRI shows a reversible diffuse shrinkage without other features. There can be non-specific EEG and evoked potential changes. Nerve conduction studies show slower motor and sensory velocities and reduced sensory amplitudes compared to controls. Nerve biopsies show delayed myelination and segmental demyelination, while muscle biopsies show reduced sarcomere size and grouped fibre atrophy with ultrastructural changes such as myofibril depletion and mitochondrial swelling (Chopra et al. 1986; Agarwal et al. 1989; Chopra and Sharma 1992; Gunston et al. 1992; Odabaş et al. 2005a, 2005b).

Neurological Complications of the Treatment of Protein Calorie Undernutrition

Treatment of established protein calorie undernutrition due to starvation involves more than just feeding and can require a staged approach in severely affected children (Grover and Ec 2009). Very early complications such as hypoglycaemia, hypocalcaemia, hypothermia and infection can cause neurological symptoms on or soon after presentation.

If feeds are re-introduced too rapidly the ‘refeeding syndrome’ can develop, with the hallmark feature of hypophosphatemia, with or without additional electrolyte disturbances (hypokalaemia, hypomagnesaemia, sodium retention with oedema), thiamine deficiency and hyperglycaemia. It typically appears 24–72 hours after feeding is started and if untreated continues for a week or more. Neurological symptoms are due to the electrolyte and other effects and can include encephalopathy, ranging from mild to severe, and peripheral signs, as described in other sections of this chapter. The cardiovascular effects can be fatal. It can follow the introduction of parenteral feeds (the hypophosphatemic-hyperalimentation syndrome). Worldwide this syndrome is probably under-recognised, especially for example, when enteral feeding is introduced in children with CP, or in any child after periods of subacute weight loss or calorie deprivation lasting several weeks.

Management of the electrolyte and glucose disorders and a more graduated calorie intake prevents the syndrome (Fuentabilla and Kern 2009; Crook 2014).

There are also rare reports, mainly in the older literature, of later onset extrapyramidal symptoms with tremors, dystonia and parkinsonian features, developing during the second to fifth week after the reintroduction of feeds. The cause is unknown. The outcome is generally good (Kahn and Falc 1956; Thame et al. 1994). One adult receiving parenteral feeding showed signal change in the globi pallidi which resolved when manganese was withdrawn (Mirowitz and Westrich 1992).

Long-Term Neurodevelopmental Effects of Protein Calorie Undernutrition

Several large studies in different countries have demonstrated adverse effects persisting into adulthood following childhood undernutrition due to starvation, even if the episode is relatively acute. In 40-year-old Barbadian adults who were undernourished in the first year of life, neurocognitive compromise, neuroticism and other specific personality traits were more frequent than in the general population. Smaller studies also associate early malnutrition with reduced head circumference and lower subsequent scholastic achievement. However, there is also an unexplained association between poor head growth due to presumed generic factors and poor weight gain, that may not be nutritional. The neurocognitive outcome may only partly be due to nutritional factors: associated understimulation may be equally or more important, and interventions incorporating enhanced psychosocial stimulation have considerably more benefit than pure nutritional rescue (Stoch et al. 1982; Ivanovic et al. 2000; Baxter et al. 2009b; Galler et al. 2012; Waber et al. 2014; Grantham-McGregor et al. 2014; Prado and Dewey 2014).

Follow-up studies of neurocognitive outcomes in infants from affluent countries born with Intrauterine growth retardation, or small for gestational age, give conflicting results. A Dutch study of adults affected by intrauterine undernutrition during a hunger famine in the Netherlands in 1945 has found smaller head circumferences and attentional deficits in older adults, but in early adulthood no neurocognitive ill-effects could be identified. The effects on the developing brain could be compounded by chronic prenatal hypoxaemia, polycythemia, the increased risk of birth asphyxia, and by hypothermia and hypoglycaemia after delivery. It is also a risk factor for CP. However, in this group environmental stimulation and enhancement still have important influences on outcome (de Rooij et al. 2010; Edmonds et al. 2010; Arcangeli et al. 2012; Streimish et al. 2012; Løhaugen et al. 2013; McIntyre et al. 2013; Christensen et al. 2014).

In children with undernutrition due to feeding and swallowing difficulties, gastrostomy feeding is now widely used, with an associated improvement in survival. There is also concern that body weight increases can reflect inappropriate fat
distribution rather than improved muscle mass. The effect on intellectual function is unclear (Vernon-Roberts et al. 2010; Brooks et al. 2014).

Following acute or more prolonged intensive care admissions, preterm infants receiving a greater energy intake than used to be recommended show better general and head growth and an improvement in ultimate brain function and IQ (Lucas et al. 1998; Brandt et al. 2003; Dabydeen et al. 2008).

NON-ORGANIC FAILURE TO THRIVE

Understimulation without undernutrition has also been recognised to be associated with ‘non-organic’ failure to thrive, poor developmental progress, and longer term cognitive, socialisation and motor dysfunctions. Initially recognised in studies of children from orphanages, who either continued in institutional care or were adopted, often internationally, the concept is also applied to children from dysfunctional families. In the latter emotional deprivation is not the only factor, and there is a high risk of continuing growth failure and of physical abuse. Affected children may have behaviour problems, bizarre eating habits, self-mutilation and poor response to pain. The outcome is affected by the duration of the deprivation, and possibly by critical periods as well, so adoption into well resourced and supportive environments may fail to completely reverse the developmental disadvantages. Nonetheless, good post adoption care still has a major positive influence. Iron deficiency may be an independent factor. Non-organic failure to thrive is also used to describe undernutrition due to non-organic feeding disorders, whose features overlap with those above (Skuse 1985; Mouridsen and Nielsen 1990; Garvin et al. 2012; Roeber 2012; Rushton et al. 2013; Doom et al. 2014; Romano et al. 2015).

MICRONUTRIENT DISTURBANCES

Undernutrition is often associated with deficiencies of specific vitamins and trace elements, including minerals, although these micronutrient deficiencies can also occur in isolation (Ahmed et al. 2012). In the latter situation causes can include inadequate dietary intake, transport defects, metabolic errors, inactivation and excess losses.

Iron Deficiency with or without Anaemia

Worldwide, iron deficiency is the most common micronutrient disturbance, affecting both high and low income countries. When associated with anaemia it has well-documented associations with developmental and cognitive under-performance. Pre- and peri-natal iron deficiency is of particular concern as postnatal supplementation may not reverse the effects. However, a causal effect has not been fully proved, partly because of a major confounding effect from socio-economic status and partly due to possible interactions between nutrients. The evidence supporting possible adverse associations with iron deficiency without anaemia is less robust. There have also been reported associations with stroke, both arterial and venous, cranial neuropathies, idiopathic intracranial hypertension, restless leg syndrome, and breath-holding attacks. The latter may respond to iron supplementation (de Andrade et al. 1997; Yager and Hartfield 2002; Kotagal and Silber 2004; McCann and Ames 2007; Roach et al. 2008; Zehetner et al. 2010; Anjos et al. 2013; Domellöf et al. 2013; Doom et al. 2014; Prado and Dewey 2014).

Iodine Deficiency

Iodine deficiency is the next most frequent micronutrient deficiency, leading to cretinism, hypothyroidism and/or goitre. According to the World Health Organization, it is the single most important cause of preventable learning difficulties and intellectual disability. Effects can begin prenatally, causing in its most severe form fetal loss, malformations or endemic cretinism. The latter has characteristic neurological findings of severe intellectual disability, hypertonia with mixed pyramidal and extrapyramidal features, hearing impairment particularly affecting higher frequencies, strabismus and, in a minority, basal ganglia calcification. Behaviour problems are strikingly absent. Goitre and growth failure are frequent as well as frank myxoedema. In the last few decades near-universal iodisation of salt has considerably reduced the prevalence (Goslings et al. 1975; DeLong et al. 1985; Halpern et al. 1991; Pharoah and Connolly 1995; WHO et al. 2007; Bhutta et al. 2013; Prado and Dewey 2014).

Less severe forms of hypo-iodinism during pregnancy appear to be prevalent in many countries and are strongly suspected to be associated with reduced cognitive function, although this has been hard to prove. In this group, the cognitive effects of iodine supplementation during pregnancy are uncertain and remain under investigation, but are thought to be positive. There is also some evidence that supplementation of mild to moderate deficiency in childhood may improve some cognitive indices (Bath et al. 2013; Pearce 2013; Taylor et al. 2013).

Other Micronutrients

The neurological effects of zinc, selenium and copper deficiencies and of supplementation, both pre- and postnatal, are less clear (Bentley et al. 1997; Picot et al. 2012; Prado and Dewey 2014; Skröder et al. 2015; Warthon-Medina et al. 2015).

VITAMIN DEFICIENCIES

B VITAMIN DEFICIENCIES

Vitamin B1 (Thiamine) Deficiency

Thiamine deficiency was first recognised in people with a restricted diet of polished rice. Routine food supplementation has reduced its prevalence so it now mainly occurs in children as part of the refeeding syndrome when supplementation...
is omitted, when breastfed by a mother with thiamine deficiency, or in association with renal dialysis, neoplasia or gastrointestinal problems including pancreatitis. However, subclinical deficiency may still be widespread in some countries. One outbreak occurred in Israeli infants following the introduction of a thiamine-deficient soy-based formula feed.

In subclinical deficiency, acute symptoms can develop after the administration of a carbohydrate load causing extra metabolic demands, or in association with intercurrent infection. These include signs in varying combinations and severity of high output cardiac failure (‘wet beriberi’); encephalopathy, with lethargy, irritability, and vomiting progressing to a reduced level of consciousness; seizures; hypotonia and brainstem signs such as ptosis, nystagmus, ophthalmoplegia and dysphonia progressing to aphonia (a hoarse cry becoming a soundless or reduced cry). Phrenic neuropathy, papilloedema and retinal haemorrhages can be present. Wernicke syndrome, the originally described triad of encephalopathy, oculomotor signs and ataxia, is less common than isolated manifestations or other combinations. Hyponatraemia and elevated blood and CSF lactate levels can occur. Neuroimaging and pathological findings resemble those found in Leigh syndrome, with symmetrical necrotising lesions affecting the basal ganglia, medial thalamus and brainstem. In thiamine deficiency the mammillary bodies may be involved as well. More chronic manifestations begin with polyneuropathy, which can be painful, with or without ataxia, or in infants with lethargy, vomiting, diarrhoea, cardiomyopathy, dysphonia or aphonia and developmental impairment.

Follow up of asymptomatic Israeli infants who received the deficient formula have not shown consistent abnormalities in neurocognitive function. In contrast, symptomatic survivors had poor long-term outcome with a high risk of epilepsy, including West syndrome, learning difficulties, intellectual disability, pyramidal and extrapyramidal motor dysfunction and persisting brainstem signs. Korsakoff syndrome is well described in adults with thiamine deficiency associated with alcohol abuse, but is very rare in children (Vasconcelos et al. 1999; Coats et al. 2012; Ornoy et al. 2013; Mimouni-Bloch et al. 2014).

Vitamin B2 (Riboflavin) Deficiency

Riboflavin deficiency itself does not have recognised neurological associations. One trial of supplementation suggested some improvement in tremor but did not show other convincing improvements in manual dexterity. However, riboflavin supplementation may improve symptoms in Brown-Vialetto-van Laere and related neuropathy syndromes which are caused by mutations in riboflavin transporter genes, as well as in some disorders of fatty acid metabolism (Bates et al. 1994; Bosch et al. 2012; Foley et al. 2014) (see Chapter 9).

Vitamin B3 (Niacin, Nicotinic Acid) Deficiency

Vitamin B3 deficiency mainly causes mouth sores and angular stomatitis. Dietary insufficiency, especially in refugee populations, Hartnup disease, and drugs such as isoniazid are recognised causes. It classically presents as pellagra, a scaly pruritic photosensitive rash, with in addition to gastrointestinal manifestations, ataxia, behavioural abnormalities and, in severe cases, seizures and neurocognitive deficits. In some children, Hartnup disease can present with isolated ataxia or developmental impairment (Malfait et al. 1993; Cheon et al. 2010; OMIM 234500).

Vitamin B6 (Pyridoxine, Pyridoxal, Pyridoxamine) Deficiency

Pyridoxine deficiency is very rare. The largest outbreak was in the early 1950s when a milk formula feed was introduced in the United States with a low pyridoxine content. Only a small proportion of infants developed symptoms, usually between 2 and 4 months of age. These were initial hyperirritability and apparent gastrointestinal colic, with regurgitation, followed by tonic posturing and focal or generalised seizures, which could be precipitated by sound, movement and feeding and which were responsive to phenobarbital or protein restriction. Follow-up showed no persisting clinical or EEG abnormality (Courson 1955; Bessey et al. 1957).

In adults, deficiency is associated with skin and mucous membrane changes (eczema, cheilosis, angular stomatitis, glossitis), anaemia and seizures. Similar symptoms can be induced by inactivation of pyridoxal phosphate by agents such as isoniazid, and Ginko fruit. Pyridoxine is also used prophylactically to prevent isoniazid induced neuropathy and to treat seizures in acute isoniazid poisoning (Shah et al. 1995).

Pyridoxine dependency (antiquitin deficiency, ALDH7A1 deficiency) and pyridoxal phosphate-dependent conditions are covered in Chapter 9.

Vitamin B9 (Folic Acid, Folinic Acid) Deficiency

The main features of folate deficiency are non-neurological: megaloblastic anaemia, mouth ulcers, and a sore, red tongue. Mood change is often reported but intervention studies in adults have not shown definite benefits from supplementation. The main neurological risk in adults is through the secondary effects of an elevated homocysteine level with an associated thrombotic tendency.

Acquired deficiency occurs through dietary insufficiency or malabsorptive states, especially coeliac disease and small bowel bacterial overgrowth. Some anticonvulsant medications are also associated with deficiencies, although other factors may be involved as well. Infants with the rare condition congenital folate malabsorption, due to mutations in the SLC46A1 transporter, present with anaemia and failure to thrive. If untreated, developmental impairment, seizures (some occipital), ataxia or athetosis can develop, together with cerebral calcification (OMIM 229050).

Cerebral folate deficiency is diagnosed when CSF 5-methyltetrahydrofolate levels are low despite normal blood
Chapter 27 Electrolyte and Acid-Base Metabolism Disturbances, Nutritional Disorders and Other Systemic Diseases

Vitamin B12 (Cobalamins) Deficiency

Deficiency of vitamin B12 can complicate a strict vegan diet, malabsorption syndromes, surgical removal of the terminal ileum, pernicious anemia, fish tapeworm infestation, and some inborn errors of cobalamin transport or metabolism. It is also recognised in some adults with AIDS. Inactivation by agents such as nitrous oxide anaesthesia can precipitate symptoms in people at risk. In children and adults the main neurological presenting features are those of a sensory neuropathy and/or a myelopathy affecting the dorsal and lateral columns, the classic syndrome of subacute combined degeneration of the cord. Depending on the predominant pathology these comprise paraesthesia, sensory axiaxia and extensor plantar responses, while deep tendon reflexes can be exaggerated or reduced. Friedreich ataxia and vitamin E deficiency can cause similar findings. Optic atrophy also occurs. MRI shows increased signal in the posterior cord on T2-weighted imaging, which does not enhance, associated with cord swelling. Some patients also have focal areas of cerebral white matter signal change. Most cases will be associated with a megaloblastic anaemia, as well as raised plasma homocysteine levels and methylmalonic aciduria. In adults, wider effects can include cognitive and psychiatric features. Prompt treatment resolves the symptoms. As treatment with folic acid can exacerbate symptoms, it is important to fully investigate megaloblastic anaemia before starting any treatment (Healton et al. 1991; Facchini et al. 2001; Rasmussen et al. 2001).

Congenital B12 deficiency occurs in breastfed infants born to B12 deficient mothers, who may themselves be asymptomatic. Failure to thrive is the earliest feature, starting in the first 6 months of life, followed by non-specific features of apathy, hypotonia, developmental impairment, anorexia and vomiting, that in severe cases can progress to seizures, regression and microcephaly. Most have anaemia, but it is not always megaloblastic. Brain imaging can be normal or show global atrophy and delayed myelination. While treatment leads to an immediate improvement, a self-limiting movement disorder, comprising focal or generalised tremor and myoclonus especially affecting the face, can occur or worsen with treatment. It responds to clonazepam. Some children have also developed West syndrome either as a presenting feature or some weeks after treatment started. Many affected infants have a poor prognosis with persisting intellectual deficits (Ozer et al. 2001; Rasmussen et al. 2001; Dror and Allen 2008; Honzik et al. 2010; Malbora et al. 2014).

LIPOSOLUBLE VITAMIN DEFICIENCIES

Vitamin D (Colecalciferol, Ergocalciferol)

Vitamin D is not really a vitamin but a hormone precursor. Deficiency is probably much more prevalent globally than previously suspected, affecting, for example, approximately one-third of French children in one survey. However, as the definitions of normal levels have not been agreed internationally, the exact prevalence is still uncertain. At risk groups include those with dietary deficiency, malabsorption, and reduced exposure to sunlight due to climate, clothing or skin pigmentation, singly or in combination. Treatment with some drugs, including anticonvulsants such as phenytoin and phenobarbital, has been associated with deficiency, especially in institutionalised children, but additional factors may play a part. Calcium deficiency is now recognised to be an important contributory factor as well.

Rickets, the most obvious manifestation, can be one cause of a large anterior fontanelle with delayed closure (others include hydrocephalus, hypothryroidism, hypoparathyroidism or craniocleidodosostosis). Other neurological features include hypocalcaemic seizures, weakness, and pain both of bone and muscle origin. While overt childhood rickets, or osteomalacia in adolescents, is still rare in developed countries, more subtle manifestations of deficiency such as proximal muscle weakness and musculoskeletal pain without obvious bony changes appear more widespread, especially in younger children. Some more severe cases can present as possible myopathies, with loss of ambulation due to weakness.

Maternal vitamin D deficiency in pregnancy can cause symptomatic hypocalcaemia in neonates. The optimal intake of vitamin D during pregnancy is unknown.

A possible role of vitamin D in acute or chronic demyelinating conditions such as multiple sclerosis, and in clinical depression, is currently being investigated, without definitive results yet available (Cimaz et al. 2000; Al-Said et al. 2009; Munns et al. 2012; Vidalilhet et al. 2012; Prentice 2013; Thacher et al. 2013; Torun et al. 2013; Elder and Bishop 2014).

Vitamin E (Tocopherols and Tocotrienols)

The neurological manifestations of a deficiency of alphatocopherol, the active form of vitamin E in humans, resemble those seen in Friedreich ataxia, with a sensory neuropathy and spino-cerebellar degeneration. Additional features can include head titubation, dystonia, pigmented retinopathy, cardiomyopathy and cerebellar atrophy on imaging. Dietary deficiency has never been reported, so children are only affected

folate levels. Most children present in the first 2 years of life with sleep disturbance followed by regression, ataxia, cerebellar atrophy, leuko-encephalopathy, microcephaly and, later in childhood, hearing impairment and polyneuropathy. One very rare cause is a defect in the FOLR1 folate receptor gene which presents in early infancy with the above features as well as seizures. An acquired deficiency due to antibodies against the folate receptor is also proposed. More controversially, cerebro folate deficiency is also reported in some children with conditions such as Rett syndrome and mitochondrial cytopathies. It is recommended that affected children should be treated with folinic acid rather than folate (Hyland et al. 2010; Grapp et al. 2012; OMIM 613068).

The importance of peri-conceptual folate supplements in reducing the risk of neural tube defects is well established. More controversial is a suggested link to the prevention of autism.

The importance of peri-conceptual folate supplements in reducing the risk of neural tube defects is well established. More controversial is a suggested link to the prevention of autism.
if they have a genetic defect in vitamin E transport (ataxia with vitamin E deficiency), or fat malabsorptive states, such as for example abetalipoproteinaemia, or cystic fibrosis especially when complicated by liver disease. Early supplementation prevents neurological problems but delayed therapy may not fully reverse them. Newborn infants, especially born preterm, can also have low levels. The role of routine supplementation in the prevention of intraventricular haemorrhage or retinopathy of the newborn remains controversial. Excess vitamin E can cause a myalgic myopathy with raised creatine kinase (Kohlschütter 1993; Cavalier et al. 1998; OMIM 277460).

**Vitamin K (Phyloquinone, Menadionones)**

As vitamin K deficiency causes a coagulopathy, intracranial haemorrhage can occur, often with severe neurological consequences. At risk groups include breastfed neonates and children with malabsorption or liver disease. Routine administration at birth has largely prevented early (first week) vitamin K deficiency haemorrhage, previously called haemorrhagic disease of the newborn, but a later onset form is still reported in many countries. Parts of Southeast Asia have a particularly high prevalence. Many affected infants have additional problems, especially liver and biliary disorders. The most effective prophylaxis is still being assessed. In theory, infants of mother taking enzyme-inducing drugs such as some anticonvulsants could be at risk of deficiency, but there is insufficient evidence to recommend routine supplementation. Excess vitamin K3 (menadione) can contribute to bilirubin encephalopathy (Puckett and Offringa 2000; Harden et al. 2009; Busfield et al. 2013; Elalfy et al. 2014).

**Other Deficiencies**

The possible importance of long-chain polyunsaturated fatty acids in the developing brain, and routine supplementation of bottle milk, has been under investigation since studies suggesting that children who had been breastfed showed a superior performance to those who had been bottle fed. Early studies suggested improved visual and developmental performance after supplementation in young children, but more recent studies have had conflicting results (Fleith and Clandinin 2005; Leung et al. 2011; Willatts et al. 2013).

**TROPICAL PARAPLEGIAS, TROPICAL ATAXIC NEUROPATHY AND NUTRITIONAL OPTIC NEUROPATHY**

A group of conditions with overlapping features of neuropathy, myelopathy, optic neuropathy or sensorineural deafness have been reported in association with undernutrition, which may be due to ingested toxins, although the exact cause is often uncertain. Deficiencies of vitamins B1, B3, B9, B12 and E all enter the differential diagnosis.

They are divided into two main groups. In the first, tropical paraplegia, signs of spastic paraplegia predominate, sometimes of acute onset, without sensory features. Currently recognised causes include lathyrism, konzo and human T lymphotrophic virus type-1 (HTLV-1) infection. Lathyrism is now localised to Bangladesh, India and Ethiopia, and is due to ingestion of grass pea seeds cooked in clay pots. Konzo has similar clinical features, with added neurocognitive impairments, and occurs in localised epidemics, mainly in Africa, due to incorrectly processed cassava. Children infected by the retrovirus HTLV1, probably by vertical transmission from their mothers, can develop early signs of myelopathy. The manifestations in adults are wider and include cognitive effects, cerebellar disorders and facial and peripheral neuropathies as well as myelopathy (Getahun et al. 2005; Kendall et al. 2009; Souza et al. 2012; Boivin et al. 2013).

The second group, tropical ataxic neuropathy, was originally recognised in adults, where a painful neuropathy with associated sensory ataxia developed in some with undernutrition. Although now less prevalent, it is still reported in countries such as Nigeria. Some cases may be related to thiamine deficiency (Ogunlesi 2004).

Nutritional optic neuropathy presents with visual impairment due to a central scotoma, associated with disc pallor. An outbreak in Cuba in the early 1990s was linked to nutritional factors, although it responded in part to vitamin supplementation (Hedges et al. 1997). Toxic forms linked to smoking may be due to an underlying Leber’s Hereditary Optic Neuropathy.

Nodding syndrome affects school age children in parts of Tanzania, Uganda and Sudan. In it the pathognomic head nodding is associated with progressive neurodegeneration, epilepsy and growth failure. The cause is unknown, although there is an epidemiological association with onchocerciasis (river blindness), as well as poverty and undernutrition. An autoimmune aetiology has been postulated (Idro et al 2016).

**OTHER INGESTED TOXINS: HEAVY METALS**

Lead neurotoxicity is covered in Chapter 13. Severe methylmercury poisoning of the fetus leads to Minamata disease, comprising microcephaly, severe intellectual disability, and CP. Lower level exposure occurs in pregnant women with a high dietary fish intake, and may have adverse cognitive effects (Myers and Davidson 1998; Axelrad et al. 2007). There is some evidence that low level exposure to other heavy metals may also affect cognition and behaviour (Sanders et al. 2015). High level exposure to such toxins is often occupational so children are at lower risk, but mercury toxicity is associated with Pink disease, which includes a painful peripheral neuropathy, and manganese toxicity can cause parkinsonism and basal ganglia signal changes.

**OBESITY**

Primary obesity is receiving increasing priority as a public health problem in some countries. Specific neurological complications in childhood include those related to the metabolic syndrome (arterial hypertension, raised blood glucose and
Acute and Chronic Encephalopathies in Children with Diabetes Mellitus

Diabetic ketoacidosis and the rarer hyperosmolar hyperglycaemic state without ketoacidosis both have major risks of neurological complications. Ketoacidosis is more frequent in newly diagnosed than established cases, but has become less frequent in both. Ketoacidosis as an initial presentation varies six-fold between different countries, for several possible reasons. While ketoacidosis presents with features of dehydration, the level of consciousness correlates best with the degree of acidosis. Neuroimaging suggests that subclinical oedema is present in over 50% of cases, but in approximately 1% of episodes during treatment severe symptomatic cerebral oedema can develop, for reasons that are still unclear. The main symptom is a deterioration in conscious level, often several hours after an initial recovery from the ketoacidosis, but in those with a reduced conscious level at presentation a failure to improve should also suggest the possibility. Additional features can include hypertension, bradycardia, pupillary changes and decorticate or decerebrate posturing. Clinical signs such as papilloedema and signs of oedema on neuroimaging are not always reliable diagnostic criteria, especially in the early stages. Despite fluid management and intensive therapy this complication has a high risk of death and, in approximately one-third of survivors, of severe motor and cognitive sequelae. Stroke and osmotic demyelination syndrome have also been described as rarer complications of ketoacidosis (Edge et al. 2001; Edge et al. 2006; Glaser et al. 2006; Petzold et al. 2011; Usher-Smith et al. 2012).

The hyperosmolar hyperglycaemic syndrome, without keto-acidosis, is rare in childhood, although is becoming more frequent with the increasing prevalence of type 2 diabetes associated with obesity where it can be the first presentation. However, most episodes still occur in children with type 1 diabetes. Initial symptoms are those of dehydration, such as lethargy, confusion and dizziness. If untreated some then develop a reduced conscious level, at times associated with seizures, hemiparesis and/or ophthalmoplegia. Stroke and rhabdomyolysis may occur, as well as renal failure, hyperthermia and pancreatitis, but cerebral oedema is unusual (Zeitler et al. 2011; Bagdure et al. 2013).

In a child with established diabetes, the other major cause of a reduced level of consciousness is hypoglycaemia. Acutely, it presents with autonomic features of a stress response, such as pallor, sweating, hunger and anxiety, which can be reduced if a child is taking beta-blocking drugs or in deep sleep. Neurological symptoms include drowsiness, headache, dizziness, blurred vision and slowed neurocognitive performance which progress to seizures and coma if untreated. Some children also develop focal seizures and/or hemiparesis. Early symptoms are often unrecognised by adolescents with mild hypoglycaemia. This age group is also at particular risk of nocturnal hypoglycaemia, especially after exercise (Ryan et al. 2006; Tamborlane et al. 2007).

Most children develop diabetes mellitus through an autoimmune mechanism, which is associated with an increased risk of other autoimmune disorders including autoimmune encephalopathies, although this appears to be uncommon. While long-term neurological impairments can follow these acute events, children with diabetes appear to be at risk of usually small reductions in a range of neurocognitive functions including IQ, motor speed, attention, reading and visuospatial abilities. Some causes of diabetes mellitus have neurological associations, such as mitochondrial disorders or specific syndromes such as DIDMOAD (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness) or Rogers (thiamine responsive megaloblastic anaemia, diabetes and deafness) syndrome. Neonatal diabetes has a range of genetic causes, some of which also cause developmental impairment, epilepsy and muscle weakness. Mutations in potassium channel subunit genes form the largest subgroup, in whom early high-dose sulphonylurea therapy is associated with an improved neurodevelopmental outcome. Otherwise onset before 6 years of age, severe hypoglycaemia and chronic hyperglycaemia are suspected contributory factors, although their relative importance and exact relationships with specific functions are less consistent across different studies. Early onset may be linked to attentional and learning difficulties and severe hypoglycaemic episodes to poorer short-term verbal memory. Short periods of hypoglycaemia do not appear to cause neurological harm. In a wider context, the long-term neurocognitive effects of hypoglycaemia from all causes are strongly affected by aetiology, comorbidities and whether acute status epilepticus occurred, but less so by age and glucose level. Neuroimaging findings in adults with diabetes are affected by vascular and other complications. In children there may be reductions of grey matter volume in specific regions such as the cerebellum and occipital cortex, which are of uncertain significance. In adults

Secondary obesity is associated with neurological problems through the underlying aetiology, and can be either genetic, as for example in Prader-Willi syndrome, or acquired, as in endocrine disorders, or in autoimmune conditions such as ROHHAD and narcolepsy-cataplexy. Excess weight gain can also be an adverse effect of some anticonvulsant or neuroleptic drugs.
with diabetes severe hypoglycaemia is not clearly associated with damage on neuroimaging (Ryan et al. 2006; Gaudieri et al. 2008; Perantie et al. 2008; Naguib et al. 2009; Lin et al. 2010; Gataullina et al. 2012; Hannonen et al. 2012; De Franco et al. 2015; OMIM 222300; 249270 and 600937).

**Acute Hemiplegia**

When acute hemiplegia occurs during hypoglycaemia it responds promptly to glucose infusion.

Transient acute hemiparesis on waking is also a classic indicator of nocturnal hypoglycaemia in children with diabetes mellitus, and more recently it has also been recognised as a manifestation of low cerebral glucose levels due to Glut1 deficiency. However, in children with diabetes it can also occur in the absence of documented hypoglycaemia. In some but not all, a brief seizure can occur, but this does not appear to be a form of Todd paresis. In this situation a glucose infusion is less effective, but the prognosis is still good with spontaneous resolution after a few hours. Recurrences may occur and be ipsi- or contra-lateral. Persistent hemiparesis can rarely occur. The mechanism is unclear, as there is little to support suggestions of hemiplegic migraine or transient ischaemic attacks. Neuroimaging, which is usually indicated to exclude other possible causes, is normal, while EEG shows contralateral or generalised slowing. In adults, diabetes mellitus is a risk factor for stroke in but this is not reported in children except in association with hyperglycaemic episodes (Pocecco and Ronfani 1998; Shehadeh et al. 1998; Fernández-Mayoralas et al. 2004).

**Peripheral, Focal and Autonomic Neuropathy**

The well-recognised adult complication of diabetic peripheral polyneuropathy, often painful, is clinically unusual in children. However, even after a few years approximately a third of children and adolescents with diabetes show subclinical evidence of large and small fibre polyneuropathy. There is a correlation with other microvascular complications and with glycaemic control. Cranial and other mononeuropathies are also rare in children with diabetes, although cases have been reported and again subclinical involvement can be detected by specific testing. The same applies to autonomic neuropathy where subclinical features are associated with glycaemic control, duration of the condition and some genetic factors, but not with polyneuropathy. Visual impairment due to retinopathy is a late complication. Optic neuropathy of vascular origin may also occur (Aicardi et al. 2009; Blankenburg et al. 2012; Höllner et al. 2013; Tang et al. 2013).

**Neurological Consequences of Hypoglycaemia**

Outwith hypoglycaemia complicating diabetes mellitus, severe prolonged hypoglycaemia of any origin, especially in neonates and/or if symptomatic, has significant long-term cognitive and other effects, which are age related. Neonates can tolerate lower glucose levels than older children without showing symptoms such as seizures. While such ‘asymptomatic’ neonatal hypoglycaemia was thought to have a good prognosis, even this is now recognised to lead to similar adverse outcomes. Blood levels below 1mmol/L for more than 1–2 hours are considered particularly likely to cause harm. Persistent or recurrent hypoglycaemia due to various genetic syndromes causing congenital hyperinsulinaemia (previously called nesidioblastosis) is associated with adverse neurocognitive outcomes both through direct genetic mechanisms and secondary to hypoglycaemia. These include cortical visual impairment, learning difficulties, microcephaly and occipital epilepsy, but absent or mild motor signs except in very severe cases. Seizures are generally infrequent and responsive to treatment, with a low risk of status epilepticus.

MRI studies show a range of abnormalities including white matter swelling and damage, especially in the parieto-occipital region, which can be cystic; encephalomalacia and global atrophy can occur, which may be unilateral; haemorrhage and stroke; and basal ganglia changes especially in the globus pallidus and thalamus. Neonates typically develop often asymmetrical posterior parieto-occipital white matter signal change. In some, early changes may resolve on follow up, but in others later localised atrophy indicates permanent damage. In older children with hypoglycaemia associated with inborn errors of metabolism occurring between 6 and 22 months the basal ganglia are more often affected and after that age the parieto-temporal cortex (Kinnala et al. 1999; Christiaens et al. 2003; Caraballo et al. 2004; Ryan et al. 2006; Boardman et al. 2013; Gataullina et al. 2013; Marzelli et al. 2014; OMIM 256450) (Fig. 27.3).

**THYROID DISEASES**

Thyroid hormones are crucial to normal neural maturation and function. In the human fetus, thyroxine (T4) is synthesised after 10–14 weeks gestation, so before then fetal thyroid hormones derive solely from the mother, although the maternal contribution remains important throughout pregnancy. In animal studies, thyroid hormones are vital for all aspects of mid and late gestational neurological development, such as neuronal proliferation, migration, synapse formation and myelination, both in the cortex and cerebellum (Williams 2008). The effects of early hypothyroidism due to iodine deficiency are described in the Iodine Deficiency section above.

**Congenital Hypothyroidism**

Without areas of iodine deficiency, congenital hypothyroidism can be caused by a variety of structural or metabolic causes, with an incidence of approximately one in 3000–4000 births, more frequently in girls than boys. As at least half the infants are asymptomatic and as early treatment affects the
neurodevelopmental outcome, many countries now have national neonatal screening programmes. Depending on what is screened, a few children may still be missed: for example, if thyroid stimulating hormone (TSH) levels are used, cases of central origin will not be detected. Untreated infants can have hypotonia, sleepiness, macroglossia, a grunting cry, umbilical hernia, sparse hair, a wide fontanelle and separated sutures. Prolonged neonatal jaundice is an important clue. If untreated, in addition to developmental impairment, ataxia or less frequently spasticity can develop in up to one-third of children and sensineural hearing impairment in 20%.

If detected by screening and treated appropriately within two weeks, the outcome is normal in most children. However, in those with severe deficiency, even early treatment does not fully reverse the effects as follow up at 10 years shows a persisting 10 point IQ difference from those with milder deficiency and control groups. Mild deficits in visuospatial and memory functions can also occur. In view of this, high-dose early treatment has been tried but with uncertain benefits and with risks of behaviour difficulties and premature suture fusion. In those treated later, up to 2 months of age, IQ is reduced and there is a risk of motor dyspraxia and hearing problems (Smith et al. 1975; Vanderschueren-Lodeweyckx et al. 1983; Simons et al. 1994; AAP et al. 2006; Mann 2011; Bongers-Schokking et al. 2013).

Some epidemiological data suggests that maternal hypothyroxaemia during pregnancy may be associated with cognitive difficulties in children. However, replacement therapy seems to have little benefit. Maternal thyroid dysfunction is also an important risk factor for neonatal encephalopathy and CP (Badawi et al. 1998; Henrichs et al. 2010; Lazarus et al. 2012; Ghassabian et al. 2014).

Thyroid dysfunction can also be associated with learning disabilities through a common aetiology. Down syndrome is associated with an increased risk of both congenital and acquired thyroid disorders. Impaired function of the NKX2-1 (previously TITF1) gene causes ‘benign hereditary chorea’ and other movement disorders, congenital thyroid dysfunction and lung disorders. Children present with hypotonia, motor delay and chorea which improves during childhood, while myoclonus becomes more prominent. Upper limb dystonia and tics can occur. Learning difficulties are frequent. Abnormal thyroid hormone transport in the X-linked disorder SLC16A2 (previously MCT8) causes Allan-Herndon-Dudley syndrome in affected boys: severe non-progressive intellectual disability with severe speech impairment, early onset nystagmus, paroxysmal movement disorders often precipitated by nursing manoeuvres and stopped by neck flexion, ataxia, progressive hypertonia and contractures, later epilepsy, and muscular atrophy and weakness with very poor head control. Features of hypothyroidism with normal or raised thyroid hormone levels can be due to mutations in thyroid receptor genes such as TR-alpha (Schwartz and Stevenson 2007; Gras et al. 2012; King et al. 2014; Peall et al. 2014; OMIM 610978; 300523; 190120).

**Childhood Onset Hypothyroidism**

In contrast to congenital forms, the neurological associations of acquired childhood hypothyroidism have been little studied. It is associated with cognitive problems affecting attention and school performance. After treatment is started behaviour problems, headache and concentration difficulties can occur, together with, if anything, slight decreases in some cognitive tests. Rarely, papilloedema and idiopathic intracranial hypertension can occur which respond to a reduced dosage. However, the effect of milder subclinical hypothyroidism is more controversial with some studies in adolescents suggesting higher scores on certain cognitive tests than euthyroid peers. This has obvious implications for treatment if investigations reveal mild biochemical hypothyroidism. Children with Down syndrome are at particular risk of both overt and subclinical hypothyroidism, so screening is recommended, but the optimal therapy is still debated (Rovet et al. 1993; Prasher 1999; Wu et al. 2006; King et al. 2014).

Hypothyroidism is also recognised as a rare cause of entrapment neuropathy, particularly carpal tunnel syndrome, in children. The Kocher-Debre-Semelaigne syndrome is the association of limb muscle hypertrophy, with slow contraction and relaxation, and raised creatine kinase levels in children with untreated, often congenital, hypothyroidism. Myopathy with elevated creatine kinase levels and occasionally acute rhabdomyolysis is well recognised although rare. In adults a range of other myopathies have been associated (Tullu et al. 2003; Gunther et al. 2006; Monzani et al. 2012; Potulska-Chromik et al. 2014).

**Hashimoto Encephalopathy**

Hashimoto thyroiditis is an autoimmune disorder of the thyroid, while the term Hashimoto encephalopathy (or syndrome)
has been used to describe neurological problems associated with raised antithyroid peroxidase or thyroglobulin autoantibody levels (see also Chapter 12). The condition is presumed to be of autoimmune origin, especially as symptoms often respond to steroid treatment, but due to uncertainty over the precise pathogenesis, it is now suggested that it should be termed ‘steroid responsive encephalopathy associated with autoimmune thyroiditis’ (SREAT). As not all cases respond to steroids, the term ‘encephalopathy associated with autoimmune thyroid disease’ has been proposed as more accurate. Since thyroid auto-antibodies are relatively prevalent in the general population, some cases may be coincidental. Despite the association, approximately half of patients have normal thyroid function. Symptoms are very varied, acute or subacute, and can fluctuate. Singly, or in combination, they include psychological features, especially behavioural change, hallucinations and sleep problems; acute encephalopathy; seizures including status; focal motor deficits; ataxia; movement disorders, and deterioration in school performance. It used to be believed to only affect older children and adolescents but many younger onsets are now being recognised, at the age of 3 years or less. EEGs are often but not always abnormal, usually with non-specific findings such as slow activity but in some with epileptiform changes. MRI is often normal but can show hippocampal hyperintensity on T2 imaging, or non-specific white matter signal change. Symptoms respond to steroids and other immunomodulatory agents, with a relatively good prognosis if treated early. Since thyroid auto-antibodies are relatively prevalent in the general population, some cases may be coincidental. Despite the association, approximately half of patients have normal thyroid function.

Hyperthyroidism

Hyperthyroidism, often of autoimmune origin, can also be associated with Hashimoto encephalopathy. ‘Thyroid storm’, comprising altered level of consciousness, tachycardia, hypertension, fever and other symptoms, is a very rare medical emergency in children. More usually, hyperthyroidism entails the differential diagnosis of tremor and can present with cognitive or psychological symptoms such as falling school performance, emotional lability, hyperactivity or dysomnia. More florid psychiatric features and seizures are rare complications in adults but are not reported in children. Moyamoya has also been associated in adults and more recently in children too. Exophthalmos can be associated with oculomotor myopathy. In adults hyperthyroidism can also cause myopathy, periodic paralysis and myasthenia gravis, but these are not reported in children (Aslan et al. 2011; Li et al. 2011).

Adrenal Insufficiency (Addison Disease)

In younger boys particularly, adrenal leukodystrophy usually presents with adrenal insufficiency some years before the onset of neurologic symptoms. Some may never develop the leukodystrophy but require long-term follow up due to the risk of adenomyeloneuropathy later in life. Otherwise tubercular, autoimmune and mitochondrial causes of adrenal insufficiency can also be associated with neurologic involvement (Korenke et al. 1997).

Adrenal insufficiency itself causes weakness, fatigue, cramp and malaise, in association with disturbances in electrolytes and occasionally hypoglycaemia, which rapidly respond to steroid
Steroid Myopathy
Steroid myopathy is a well-characterised complication of both acute and chronic corticotherapy, or Cushing disease, associating proximal weakness, wasting and myalgia with type 2 fibre atrophy on muscle biopsy. In children, most reported cases are in children receiving treatment for juvenile chronic arthritis in which case dermatomyositis enters the differential diagnosis (Naim and Reed 2006).

Cardiac Disorders

Neurological Complications of Non-Operated Congenital Heart Disease
Cognitive and Motor Development and Heart Malformations
Most children with congenital heart disease have normal neurocognitive function. However, congenital heart defects are nonetheless associated with an increased risk of neurodevelopmental impairment, through mechanisms such as shared genetic aetiologies, a higher chance of structural brain abnormalities, and probable effects on brain growth and development beginning in utero. The neurological risk also correlates to the complexity of the underlying cardiac defect, being lower in forms such as uncomplicated ventricular septal defect and higher in conditions such as transposition of the great arteries or hypoplastic left heart syndrome. Postnatally chronic hypoxaemia and other complications of cyanotic heart disease and postoperative neurological complications also contribute. With improved survival especially in more complex conditions, earlier intervention, and changes in bypass techniques the outcome has been changing in more recent series (Wright and Nolan 1994; Stieh et al. 1999; Limperopoulos et al. 2010; Block et al. 2010; Limperopoulos et al. 2012; Marino et al. 2012; Beca et al. 2013; Bertholdt et al. 2014; von Rhein et al. 2014; Khalil et al. 2016; Marelli et al. 2016).

Down syndrome and 22q deletion are the first and second most common recognised causes of congenital heart disease, and both have significant neurodevelopmental and intellectual associations. Other recognised conditions associated with specific neurological and neurodevelopmental problems include Aarskog-Scott, Alagille, Noonan, PHACE (posterior fossa brain malformations, hemangiomas of the face, arterial anomalies, cardiac anomalies, and eye abnormalities), Turner, and Williams syndromes. Conversely coarctation of the aorta may be associated with cerebral aneurysms and may also produce cerebral haemorrhage in their absence (Freedom 1989; Marino et al. 2012).

In clinical terms children with more complex disease have a higher risk of microcephaly and of abnormal neurological behaviour in infancy. Outcome studies in children and adults with complex congenital heart disease show an increased risk of developmental disability involving motor skills, intelligence, school and employment achievement, and attentional, speech, language and social abilities.

Fetal and neonatal neuroimaging studies have shown structural abnormalities in 18–40% of fetuses with congenital heart disease including ventriculomegaly, which was the most frequent, agenesis of the corpus callosum and vermian hypoplasia. In addition there is an important prevalence of white matter abnormality, intraventricular haemorrhage and microstrokes prior to any intervention, confirmed by pathological studies, again particularly in those with more complex forms of congenital heart disease. Finally, there appears to be a specific failure of brain growth in the third trimester, especially with conditions that restrict output from the left ventricle, as well as delayed maturation and altered circulation indices. How these all correlate with cognitive outcome is still mainly to be defined, although brain volume has been shown to correlate to cognitive function in adolescents with congenital heart disease (Limperopoulos et al. 1999; Miller et al. 2007; Block et al. 2010; Limperopoulos et al. 2012; Marino et al. 2012; Beca et al. 2013; Bertholdt et al. 2014; von Rhein et al. 2014; Khalil et al. 2016; Marelli et al. 2016).

Paroxysmal Episodes in Congenital Heart Disease
Paroxysmal episodes associated with congenital heart disease include syncope, seizures, strokes (see Strokes section), and Fallot attacks.

Cardiac syncope can occur with congenital (or acquired) conditions that obstruct left sided outflow, such as hypertrophic cardiomyopathy or aortic stenosis, or that cause cardiac conduction defects, such as Ebstein anomaly. Most cardiac syncope are due to dysrhythmias, either supraventricular or ventricular, which are not associated with structural defects: these are discussed in Chapter 16. As some causes of cardiac syncope carry a risk of sudden death, especially with exertion, exertion-related syncope needs urgent cardiological assessment. Nocturnal syncope is another suggestive symptom.

Epileptic seizures can occur due to an underlying genetic aetiology or cortical malformation, such as some of those listed in the Cognitive and Motor Development and Heart Malformations section, or as discussed below in association with stroke or abscess and postoperatively.
In young children with right sided outflow obstruction and ventricular septal defects, such as Tetralogy of Fallot, hyperycyanotic spells occur as paroxysmal episodes where a child cries, becomes more deeply cyanosed and then becomes limp. Precipitants include exertion, feeds and bowel movement. When severe, convulsions and death can ensue while prolonged attacks may risk hypoxic-ischaemic damage. The mechanism is unclear. Acute management includes oxygen, the knee-chest position, morphine and beta-blockade.

Strokes
Congenital heart disease is associated with strokes though embolic, thrombotic or vasculopathic mechanisms, with embolic the commonest. While strokes are most frequent after surgical interventions (below), non-operated patients are also at risk, albeit less so. Emboli can be thrombus of cardiac origin, tissue from atrial myxoma, or valvular material. Children with untreated cyanotic heart disease and right-to-left shunts are at particular risk of stroke, both arterial and venous, but the incidence has declined since earlier intervention has become the norm. Most occurred in infants, with iron-deficiency anaemia and hypoxaemia as risk factors for large vessel arterial stroke, while polycythaemia was a contributor to venous stroke in older children. Most children present with acute motor deficit but aphasia or hemianopia can occur. Subclinical strokes are increasingly recognised (Phornphutkul et al. 1973; Block et al. 2010).

Coarctation of the aorta and aortic stenosis are particularly associated with vasculopathies such as moyamoya. In theory, hypertensive haemorrhagic stroke is a risk in untreated coarctation, but this appears unusual. The role of a patent foramen ovale in permitting paradoxical venous embolic stroke is still controversial (see Chapter 15).

Brain Abscesses
These are discussed in Chapter 11. Congenital heart disease, either directly or secondarily to endocarditis, is an important predisposing factor for cerebral abscess in many but not all series. Presenting symptoms can include fever, headache and other symptoms of raised intracranial pressure, and focal signs including seizures. Papilloedema is of little value in patients with cyanotic heart disease, because retinal vessels are frequently engorged and tortuous with blurring of the disc margins. Treatment is based on retrospective studies but there is no high level evidence. No current outcome data specific for congenital heart disease is available (Goodkin et al. 2004; Ozsürekci et al. 2012; Felsenstein et al. 2013; Lumbiganon and Chaikitpinyo 2013).

NEUROLOGICAL COMPLICATIONS OF SURGERY FOR HEART DISEASE
Catheter studies and surgical interventions, whether palliative or corrective, carry neurological risks. These are also affected by the complexity of the surgery, its duration, age at surgery and the child’s pre-operative state.

In children, the main immediate neurologic risk from cardiac surgery is a post-bypass encephalopathy which may be associated with multi-organ involvement. The mechanism is complex, with hypoxia-ischaemia, thrombosis, embolism, metabolic, inflammatory and haematological derangements all possible contributors. The multi-organ component can make postoperative management more difficult; for example, due to problems with fluid and electrolyte control. Various controlled trials of intra-operative management have sought to reduce the risk, with some success, but the outcome is still variable, probably partly influenced by the pre-existing condition of the child. As with all sick children, critical illness neuropathy and myopathy are also possible (Dominguez et al. 2007; Nelson et al. 2008).

A specific form of postoperative encephalopathy with chorea beginning in the first 2 weeks after surgery was recognised as a complication soon after bypass surgery was introduced, and appeared to be related to aspects of surgery such as deep hypothermia and circulatory arrest. The outcome varied but in older children especially persisting chorea and intellectual deficits were frequent (du Plessis et al. 2002).

Focal insults are also important in the immediate postoperative period, when the risk of arterial and venous stroke is highest. Clinically overt strokes have an incidence of less than 1% overall, but routine pre- and postoperative MRI in neonates with more complex disorders show an incidence of up to 9%. Balloon atrial septostomy for transposition of the great arteries may be a risk factor for MRI detected stroke in neonates. Prosthetic replacement valves have a persisting association with stroke. Postoperative stroke is associated with a poor prognosis: in one series only 14% had a normal outcome (McQuillen et al. 2007; Domi et al. 2008; Roach et al. 2008; Block et al. 2010) (Fig. 27.4).

In neonates with complex heart disease requiring bypass surgery, and in those receiving palliation with Blalock-Taussig shunts, MRI can demonstrate new white matter signal changes postoperatively but as these may later resolve their significance.

Figure 27.4 Acute left hemiparesis post cardiac bypass surgery.

is currently unclear. Post-mortem studies can show periven-
tricular leukomalacia or gliosis (Kinney et al. 2005; McQuillen
et al. 2007; Marino et al. 2012; Beca et al. 2013).

Spinal cord stroke can also occur, in particular with surgical
correction of coarctation, probably by an embolic process via
the artery of Adamkiewicz. Clinically, motor and sphinc-
ter signs predominate, but dorsal column function can be
relatively preserved. There can also be better recovery of
sensory than motor function.

Seizures, both clinical and electrographic, are seen in
4–21% postoperatively (‘post pump seizures’), with the lower
incidence in children with Tetralogy of Fallot and the higher
in those with hypoplastic left heart syndrome or an inter-
rupted arch. Other factors include the presence or absence
of a recognised genetic syndrome and the duration of car-
diopulmonary bypass. Treatable metabolic and toxic causes,
such as hypoglycaemia, electrolyte disturbance, and drug
toxicity, should be excluded, especially if associated with an
ecephalopathy: for example, some cardiopulmonary solutions
are associated with hyponatraemia and seizures. Stroke, both
haemorrhagic and thrombotic, is another possible cause.
Treatment follows standard guidelines for acute seizures, but
needs to allow for possible drug accumulation if hepatic or
renal insufficiency is present. The neurodevelopmental out-
come is poorer in neonates with postoperative seizures than
those without (Rappaport et al. 1998; Clancy et al. 2003;
Dominguez et al. 2007; Kim et al. 2011; Gaynor et al. 2013).

Late Sequelae of Cardiac Surgery

The neurocognitive effects of surgery itself are difficult to disen-
tangle from the pre-operative factors discussed above, includ-
ing the nature of the underlying condition. Newly acquired
motor deficits and later epilepsy are the most clear cut, but
intellectual, learning and behaviour disabilities are also very
important. The longer term outcomes of an acute postopera-
tive encephalopathy vary markedly, but in general the longer
the encephalopathy lasts the more worrying the prognosis.
As well as seizures, other proxy outcome measures are being
sought so that the effects of interventions can be assessed more
rapidly than through waiting for assessments at school age or
later (Bellinger et al. 1995; Dominguez et al. 2007; Kim et al. 2011; Gaynor et al. 2013).

NEUROLOGICAL COMPLICATIONS OF
ACQUIRED HEART DISEASE

Viral myocarditis and rheumatic carditis can also be com-
licated by embolic stroke, with case series reporting risks
of 4–12%. Many forms of congenital heart disease, valvular
disease including prosthetic replacement valves, rheumatic
carditis and indwelling catheters are risk factors for bacterial
endocarditis, which in children has a 4–20% reported risk of
stroke. In one case series, more than half of those with strokes
due to bacterial endocarditis were left with long-term deficits.

In adults bacterial endocarditis can lead to meningitis, abscess,
and myotic aneurysms, but in children the magnitude of these
risks is unclear (Ferrieri et al. 2002; Roach et al. 2008;
Yenkaesan and Wainwright 2008; Murdoch et al. 2009;

CARDIOLOGICAL COMPLICATIONS
ASSOCIATED WITH NEUROLOGICAL
DISORDERS

A number of genetic, metabolic, storage, and neuromuscular
disorders are associated with cardiomyopathy and/or conduc-
tion defects. Some of the more frequent are listed in Table 27.3.
The neurological features are discussed in the relevant
chapters. In many, the cardiac aspect is a potentially life-limiting
feature, so routine cardiac monitoring is a standard part of
long-term management. As well as causing cardiac symptoms,
dilated cardiomyopathy has a 6% risk of stroke. Finally, both
chronic respiratory failure, due for example to a neuromuscu-
lar condition, and neuromuscular scoliosis can be associated
with pulmonary hypertension and subsequent right ventric-
ular dysfunction (Hermans et al. 2010; Finsterer et al. 2012).
PULMONARY DISEASES AND OTHER VENTILATORY PROBLEMS

Pulmonary diseases and other ventilatory problems can affect the CNS through intermittent or chronic hypoxia, carbon dioxide retention, or both. A critical review of the effects of hypoxia, which included cardiac as well as respiratory causes such as sleep disordered breathing, asthma, chronic ventilatory impairment and respiratory instability, concluded that there was evidence of adverse effects on development, behaviour and academic achievement at all ages except for preterm infants. However, the first two conditions accounted for the majority of the evidence and confounding factors are present in both. Blood carbon dioxide levels also have well recognised effects on cerebral perfusion and intracranial pressure (Bass et al. 2004; Lim and Lin 2009).

In addition, chronic bronchiectasis due to conditions such as immunological dysfunction or cystic fibrosis is a recognised risk factor for brain abscess. Malabsorption in cystic fibrosis, especially in association with biliary disease, can lead to undernutrition (discussed in the Protein Energy Undernutrition section), in particular vitamin E deficiency. Mutations in the NKX2-1 gene (see Thyroid section) can cause respiratory symptoms such as surfactant-deficient term neonatal respiratory distress syndrome, and later in childhood recurrent infections and asthma.

Conversely, acute and chronic ventilatory disorders are associated with a number of central or peripheral motor disorders as well as structural or functional brainstem disorders. A weak cough can also lead to retained secretions and an increased risk of infection. In addition, recurrent or chronic aspiration with symptoms such as cough, wheeze and collapse/consolidation can occur in children with neurological disorders and an ‘unsafe’ swallow or gastro-oesophageal reflux disease (Proesmans et al. 2014).

INTERMITTENT OR CHRONIC HYPOXIA AND CARBON DIOXIDE RETENTION

From a neurological perspective several conditions need to be considered.

Sleep disordered breathing, including obstructive sleep apnoea, may affect school performance. Children with Down and Prader-Will syndromes are at an increased risk (RCPCH 2009).

Acute mountain sickness can occur in over 20% of children moving from low to high altitude. Symptoms comprise headache, fatigue, nausea, dizziness, and sleep disturbance. In most, symptoms resolve spontaneously or after treatment with hydration, analgesia and preventing further ascent. In a small number of untreated patients, cerebral oedema can develop with symptoms of confusion and ataxia progressing to coma. The mechanism is unclear but hypoxia is presumed to play a role. Treatment includes urgent descent, dexamethasone and oxygen (Imray et al. 2011; Rexhaj et al. 2011).

Carbon monoxide poisoning with acute severe tissue hypoxaemia also causes an acute encephalopathy, sometimes with motor or central and peripheral visual deficits, that may be delayed and transient. Initial symptoms include confusion, dizziness, seizures and coma. Papilloedema and retinal haemorrhages can occur. Neuroimaging typically shows basal ganglia involvement, especially affecting the globus pallidus, but additional cortical and cerebellar changes are reported including laminar and focal infarctions. Survivors can have a variety of neurocognitive and psychiatric sequelae (see Chapter 13) (Hon et al. 2006; Velioglu et al. 2013).

Idiopathic congenital central hypoventilation syndrome (Onidne’s curse) is a rare condition with severe hypoventilation during sleep associated with a range of genetic causes. These include neurocristopathies such as Hirschsprung disease (Haddad syndrome) and neuroblastoma. Autonomic and cognitive dysfunction can be associated (OMIM 209880).

Acute neuromuscular weakness due to anterior horn cell problems, classically polio, neuropathies such as Guillain–Barré syndrome, myasthenic crisis and acute myopathies with or without rhabdomyolysis are well recognised risk factors for acute respiratory insufficiency. Difficulty weaning from ventilatory support after a period of intensive care can be due to critical illness neuropathy or myopathy. Risk factors include multisystem involvement, the need for renal dialysis, and sepsis. It is an important differential if assessing for possible brain stem death. While clinically overt cases are infrequent, neuropsychological studies show a degree of neuropathic dysfunction in more cases (Williams et al. 2007).

Hyperventilation is also an important complication of chronic conditions causing severe progressive neuromuscular weakness and some specific ones such as spinal muscular atrophy with respiratory distress (SMARD). Hyperventilation is intermittent at first, mainly associated with REM sleep, so initial symptoms of headache, nausea and fatigue due to carbon dioxide retention and hypoxaemia occur on waking. As the severity worsens, anorexia, fatigue and listlessness develop. Acute on chronic respiratory failure can be triggered by aspiration or intercurrent infection. Prophylactic monitoring, assessment and management involve specialist respiratory care, as well as a number of ethical issues, and are discussed in several guidelines (Bushby et al. 2010; Hull et al. 2012; Gray et al. 2013).

Children with chronic lung disease due to preterm birth are also at risk of hypoxia and carbon dioxide retention. Adverse neurodevelopmental outcomes often have additional non-respiratory causes related to preterm birth. In addition, although the incidence of broncho-pulmonary dysplasia is unchanged, its character and pathophysiology appears to differ since the introduction of surfactant and newer ventilatory techniques. In the ‘old’ form both progressive neurological impairment and a specific self-limiting movement disorder were reported. The latter began at 3 months of age with prominent tongue, facial and distal limb dyskinesias. Chronic
lung disease is associated with progressive white matter injury in preterm infants, which may not have clinical effects, but here infection may play an important role (Ellison and Farina 1980; Glass et al. 2008; Mosca et al. 2011).

**COMPLICATIONS OF EXTRACORPOREAL MEMBRANE OXYGENATION**

In neonates and children with cardiorespiratory failure, ventilatory and intensive circulatory support may not be sufficient, in which case extracorporeal life support, mainly extracorporeal membrane oxygenation (ECMO), can be indicated. In neonates, congenital diaphragmatic hernia, meconium aspiration syndrome and sepsis are the commonest reasons, while in older age groups there is a wider range, with seasonal variations due to causes such as influenza. The children are usually extremely ill with multiple additional problems including sepsis, haematological and metabolic derangements which already place them at increased risk of neurological sequelae. Nonetheless, survival rates approximate 80%. Veno-arterial ECMO requires ligation of the right internal jugular vein and the right carotid artery, together with heparinisation. Seizures, focal ischaemia and intracerebral haemorrhage are the major acute risks, occurring in 5–20%, all as might be expected associated with a poorer outcome. During ECMO, EEG monitoring can show a range of focal or diffuse abnormalities including status epileptics. Of the survivors, 15–25% have major neurological impairments, including intellectual disability, epilepsy and quadriplegia, while up to 50% may have later learning and behaviour difficulties. In some but not all series, more lesions occur in the right hemisphere. Veno-venous ECMO without carotid artery ligation may have a lower overall risk, but direct comparison is difficult (Karimova et al. 2009; Dalton and Butt 2012; Mehta and Ibsen 2013; de Mol et al. 2013).

**APNOEIC EPISODES AND APPARENT LIFE-THREATENING EVENTS**

Apparent life-threatening events are defined as ‘an episode that is frightening to the observer and that is characterised by some combination of apnoea (central or occasionally obstructive), colour change (usually cyanotic or pallid), marked change in muscle tone, choking or gagging’. Apnoeic attacks mainly occur in neonates and young infants, with a wide differential diagnosis, mostly respiratory, cardiac or gastro-oesophageal reflux related. Recognised neurological causes are less common, but include brainstem disorders and epilepsy (Table 27.4). Epilepsy can present with pure apnoeas, typically without bradycardia, in the neonatal period, or less frequently as a manifestation of focal epilepsy in infancy. Causes can include temporal lobe tumours, KCNQ-related epilepsy, migratory partial seizures and 1p36 deletion syndrome. Apnoeas in neonatal hyperekplexia can be life threatening and can be aborted by neck flexion (Watanabe et al. 1982; Ramelli et al. 1998; RCPCH 2009; Kanabar et al. 2012; Thomas et al. 2013; Allen et al. 2014).

**HYPERVENTILATION**

Hyperventilation attacks are functional events triggered by psychological factors. Many are asymptomatic but in some symptoms of dizziness develop, while in a small number tetany develops due to a lowered ionised calcium level. Symptoms of dizziness frequently occur with hyperventilation performed during EEG recordings. Acute symptoms respond to rebreathing, which is also a diagnostic pointer, while further treatment may require psychological referral or the teaching of specific breathing exercises.

A number of conditions with neurological features are associated with intermittent hyperventilation or variable respiratory patterns, including Rett, Pitt-Hopkins and Joubert syndromes.

**HEPATIC DISEASE**

**HEPATIC ENCEPHALOPATHY**

Hepatic encephalopathy constitutes the end stage of acute or chronic liver disease and culminates in hepatic coma. In adults but not in children, the diagnosis of acute severe hepatic failure requires the presence of an acute encephalopathy. In many countries the most important cause is acute viral hepatitis, with a risk of encephalopathy of up to 72%. In some series, infants form the largest age group. Hyperammonaemia is suggested to be a pathogenetic factor, with astrocytes as particular

targets. However, the underlying aetiology or complications, including metabolic, infectious or autoimmune disorders, gastrointestinal haemorrhage and drugs, can also contribute to the neurological features.

The onset of hepatic encephalopathy is sometimes fulminant but it is more often heralded by malaise, anorexia and vomiting. Disorders of consciousness are the principal symptoms. Disorientation, anxiety, depression and slurred speech appear first. They are rapidly followed by drowsiness, lethargy and inappropriate behaviour. Asterixis or ‘flapping tremor’ may be an early feature. Extrapyramidal rigidity and choreic movements are frequent in children. Ataxia, seizures, myoclonus and hyperventilation with resulting alkalosis frequently develop in advanced stages. Decerebrate posturing may occur in the terminal phase.

In adults various scales have been devised to assess the degree of encephalopathy, most often modified forms of the West Haven criteria, which can also be applied to older children (Table 27.5). In younger children and infants, paediatric scales are available, but differ between authors. When severe a paediatric coma scale can also be used, such as the James scale. The EEG often shows diffuse bursts of high-voltage slow-wave activity and sometimes triphasic spikes, epileptiform discharges and clear electroclinical seizures. In acute failure EEG abnormalities correlate with the outcome. Neuroimaging is usually normal. The course may be rapidly lethal, associated with severe cerebral oedema, or fluctuate considerably, and symptoms may be rapidly reversible if the course of the liver disease is favourable. Urgent assessment for possible liver transplantation is the most important aspect of treatment in those with severe encephalopathy. Other supportive measures include management of raised intracranial pressure and seizures, reduction of ammonia production, treatment of sepsis, and dose adjustment of drugs metabolised by the liver. A substantial minority also develop renal failure (Lee et al. 2005; Squires et al. 2006; Arya et al. 2010; Bravo et al. 2012; Hussain et al. 2014).

In adults with chronic liver failure, varying degrees of cognitive impairment have been well recognised. While there is less data in children, cognitive dysfunction appears equally important and to correlate to duration and severity of liver disease. However, the pattern of dysfunction is complex: for example, those with an early onset may be particularly compromised in terms of perceptual synthesis and psychomotor speed (Stewart et al. 1992; Moser et al. 2013).

In some children a congenital portosystemic shunt, a rare condition characterised by hyperammonaemia, can present with intellectual disability or symptoms of attention-deficit–hyperactivity disorder without other features (Kim et al. 2012).

### ANTICONVULSANT DRUGS AND HEPATIC IMPAIRMENT

Anticonvulsant and other drug-induced hepatopathy is well recognised although rare (see also Chapter 16). While the association with valproate therapy is the best known, equally important relative risks are reported for sulthiame, ethosuximide, phenobarbital, phenytoin and carbamazepine. Jaundice is a frequent clinical feature.

Fatal valproate associated hepatic failure is linked with young age, polytherapy, developmental impairment and metabolic disorders including Alper syndrome (see Chapter 9), with a reported risk of up to 1 : 600 in children under 2 years of age, but in recent series this may be lower. Symptoms usually develop in the first months of treatment and include reduced alertness, increased seizures, anorexia, vomiting, jaundice and haemorrhage. Transaminase levels can often be raised in children on valproate treatment and do not correlate to the risk of sudden hepatic failure, so are not a useful warning. Carnitine has been proposed as prophylaxis but its efficacy is not proven. Parents of children treated with valproate should be advised to report any of the symptoms above immediately.

From a wider perspective, acute or subacute encephalopathy can occur in children and adults receiving valproate with or without hyperammonaemia and with or without hepatopathy. Finally, acute pancreatitis is another important complication of valproate therapy, presenting with abdominal pain and vomiting, and confirmed by raised blood levels of exocrine pancreatic enzymes. Most children have normal serum levels. If valproate is re-introduced symptoms are likely to recur (Bryant and Dreifuss 1996; Koenig et al. 2006; Gerstner et al. 2007; Ferrajolo et al. 2010).

### OTHER COMPLICATIONS OF HEPATIC IMPAIRMENT AND ITS TREATMENT

Hepatic impairment can be associated with malabsorption leading to the complications described in the Protein

Bajaj et al. (2011).
Energy Undernutrition section. Deficiencies of the fat soluble vitamins D, E and K can lead to neurological complications. Coagulopathy can also complicate hepatic insufficiency due to decreased synthesis of prothrombin.

A number of neurological conditions are associated with biochemical or more overt features of liver dysfunction (Table 27.6). From experience, some children with raised alanine and aspartate transaminase levels due to muscle disorders may be initially referred to a hepatologist because a muscle origin has not been not considered.

**GASTROINTESTINAL DISORDERS**

Most neurological complications of gastrointestinal disorders are secondary to infection, auto-immunity or malabsorption. Acute encephalopathies due to viral gastroenteritis and bacterial enterocolitis are discussed in the Neurological Complications of Acute Gastroenteritis Without Dehydration section. Stroke can be associated with inflammatory bowel diseases including Crohn’s disease and ulcerative colitis. Acute inflammatory polyradiculoneuropathy (Guillain–Barré syndrome), in various forms including the acute motor axonal presentation described in Asia, is strongly associated with Campylobacter jejuni infection.

Conversely, many neurological disorders, both central and peripheral, can be associated with problems along the length of the gastrointestinal tract. Co-ordination of buccal, oesophageal, gastric, intestinal and colonic motor function depends on the central, autonomic and enteric nervous systems and requires normal voluntary and smooth muscle function. The nutritional and respiratory aspects of swallowing difficulties and gastro-oesophageal reflux disease in children with central and peripheral motor disorders are outlined earlier in this chapter. Gastro-oesophageal reflux disease is more prevalent in children with neuro-disability in general and can present with non-specific features such as self-mutilation and agitation, as well as Sandifer syndrome (see Chapter 18); (Gössler et al. 2007). Gastrointestinal dysmotility has a wide range of associations. Recognised neurological ones include mitochondrial disorders (mitochondrial neurogastrointestinal encephalopathy (MNGIE) syndrome – see Chapter 9), and neuromuscular disorders such as myotonic dystrophy type 1 and Duchenne muscular dystrophy. Symptoms include nausea, vomiting, abdominal pain and constipation. In severe cases intestinal pseudo-obstruction and failure can supervene.

Less well studied are the problems in some children with severe hypertonia, where feeding can be very difficult and even if given continuously enterally can be associated with distressing dystonic spasms. Pneumatosis coli can also occur: both it and feeding intolerance may improve after defunctioning ileostomy. As parenteral nutrition has its own complications and costs, management can be very difficult and requires expert gastro-enterological advice. Detailed descriptions, investigation and management are beyond the scope of this chapter (Di Lorenzo and Youssef 2010; West et al. 2016).

**GLUTEN ENCEPHALOPATHY**

Untreated gluten enteropathy, or celiac disease, can cause neurological effects though the associated undernutrition and micronutrient deficiencies as discussed earlier in the Nutritional Disorders and the Nervous System section. In adults associations have been suggested with epilepsy, ataxia, and neuropathy, through a presumed autoimmune mechanism, but in children the supportive evidence for any of these is weak. There may be a stronger link with headache and fatigue. One child has been reported with multiple episodes of demyelinating encephalitis in whom the recognition and treatment of coeliac disease resulted in neurological cure. In adults, gluten sensitivity, that is, positive antibody titres with or without enteropathy, is also being explored as a possible cause of neurological and psychiatric problems (Hadjivassiliou et al. 2010; Lionetti et al. 2010; Jackson et al. 2012; Terrone et al. 2013; Jorge et al. 2014).

**Gluten Enteropathy Associated with Epilepsy and Cerebral Calcification**

This rare condition was first described in Italy by Gobbi, where children with intractable epilepsy and cerebral calcification, typically in the parieto-occipital region were found to have gluten enteropathy. If detected and treated early, seizures responded favourably to a gluten-free diet. Subsequent experience has shown that most patients are from Italy, Spain or Argentina and that the epilepsy can vary markedly in severity and drug responsiveness. Dietary treatment does not lead to resolution of the cerebral calcification. Congenital folate malabsorption enters the differential diagnosis (Gobbi 2005; Johnson et al. 2013).
**WHIPPLE DISEASE**

This rare condition, mostly seen in adults, is caused by *Tropheryma whipplei*, an intracellular micro-organism which causes a histiocytic response. Intrafamilial cases can occur. In order of frequency, the main symptoms are rheumatological, cardiac and neurological. The latter include a variety of cognitive, behavioural and motor manifestations such as oculomasticatory (in particular) or more generalised myoclonus, ataxia and ophthalmoplegia. These are due to multifocal inflammatory lesions throughout the neuraxis which at their most severe cause a necrotising encephalitis. Diagnosis used to depend on small intestinal biopsy but has been replaced by PCR. The condition responds to antibiotic therapy (Lagier et al. 2010; Meunier et al. 2013).

**CYCLICAL VOMITING**

The pathogenesis of cyclical vomiting is often unclear. Among other possibilities, neurological causes to consider include migraine, fourth ventricular tumours and other brainstem disorders, including a personal case with isolated Alexander disease (see Chapter 10), lymphocytic hypophysitis, and paroxysmal vertigo syndromes such as the episodic ataxias.

**INTUSSUSCEPTION**

Intussusception is a gastrointestinal emergency classically presenting in infants and young children with abdominal pain, vomiting and blood-stained stools. However, in some infants it may present initially with disturbances of consciousness (obtundation or even coma) that suggest a primary neurological disease. Similar presentations have also been described in children with bowel strangulation or volvulus. Vomiting may be incorrectly thought to have a neurological origin. There is usually a full recovery once the cause is treated. The mechanism is unexplained. These rare examples reinforce the importance of a full history and thorough general examination in all children presenting with acute encephalopathy (Goetting et al. 1990; Pumberger et al. 2004).

**RENAL DISEASES**

Cerebral symptoms and signs frequently accompany uraemia, although the mechanisms of neurological impairment are poorly understood. However, neurological manifestations of renal disease have considerably decreased in frequency with newer therapies. Some therapeutic procedures, for example dialysis, may have complications mainly due to one specific factor but in most cases the aetiology is probably multifactorial, including factors such as electrolyte disorders, hypertension or neurotoxicity.

**PERIPHERAL URAEMIC NEUROPATHY AND MYOPATHY**

In children with renal impairment weakness, falls and exercise limitation can have multiple contributing factors, including disuse, anaemia, vitamin D deficiency, neuropathy and myopathy.

In adults, chronic renal failure is associated with clinical polyneuropathy in half or more of all patients. In children, clinically apparent neuropathy is not widely reported but neurophysiologic studies have still shown a significant subclinical prevalence of up to 76%. As in other toxic or metabolic neuropathies, when symptomatic the neuropathy can be painful or uncomfortable, with symptoms of tingling, electric shocks, burning and hyperaesthesia, especially in the feet. Leg cramps are a characteristic early symptom. Typical clinical findings are mainly sensory with vibration impairment an early feature. Neurophysiological findings indicate a predominantly axonal sensorimotor form affecting large and small fibres. The facial nerve is most likely to show conduction disturbances. Autonomic involvement can also be detected by specific tests but again is usually asymptomatic. Nerve biopsy shows axonal loss.

In adults, even in severe cases, successful transplantation is curative. Dialysis may prevent worsening but does not lead to improvement. Symptoms may be helped by treatment with drugs such as gabapentin or carbamazepine. Possible contributory nutritional factors should also be addressed.

Mononeuropathies are also described in association with arteriovenous fistulae, including carpal tunnel syndrome and more rarely ischaemic or compressive neuropathies. In addition, mononeuropathies such as facial weakness can be part of a renal polyneuropathy. Facial nerve palsy can also be associated with arterial hypertension.

Uraemic myopathy is another recognised complication, with muscle biopsy reflecting a variety of myopathic as well as neuropathic features (Mendoza-Guevara et al. 1997; Morgenlander 1997; Pirzada and do Prado et al. 1998; Tory et al. 2001; El-Husseini et al. 2005; Ho et al. 2012).

**URAEMIC ENCEPHALOPATHY AND OTHER NEUROLOGICAL ASSOCIATIONS**

Children with acute or chronic renal failure can develop acute or chronic encephalopathy. This usually manifests in a chronic fashion as a variable degree of impairment of cognitive function and behaviour, but can present acutely. It is recognised prior to or during dialysis, when it is termed uraemic
or dialysis encephalopathy respectively, but both types have overlapping and probably multifactorial causes.

Prior to dialysis, a substantial minority of children with mild to moderate renal impairment show reductions in measurements of intelligence, memory, concentration, executive function and academic achievement that correlate with severity and duration of renal impairment. Restless leg syndrome, a well-recognised association in adults, is now being reported in children. The differential includes direct effects from the metabolic disturbance, cerebral effects from the underlying pathology, toxins including drugs and aluminium, nutritional deficiencies, and hypertensive encephalopathy. Direct effects are thought to be due to the accumulation of toxic metabolites that are normally removed by the kidney, although no specific candidates have been confirmed. Acute symptoms respond to dialysis, over a period of hours to days. Prior to dialysis protein restriction may also help. Infants with chronic renal failure have traditionally shown a poorer prognosis than older children in longer-term cognitive outcome studies. This was suggested to be due to other, possibly genetic, conditions affecting both the brain and kidney, but recent improvements in outcome with more immediate management imply a more direct effect (Rotundo et al. 1982; Gerson et al. 2006; Slickers et al. 2007; Hooper et al. 2011; Wong et al. 2012; Johnson and Warady 2013; Riar et al. 2013).

Some underlying pathologies, especially genetic and vascular, can involve both the kidney and the brain. Genetic conditions such as Smith-Lemli-Opitz or Lowe syndrome associate renal problems, although not usually renal failure, with microcephaly, cerebral dysgenesis, seizures, learning impairment, and behavioural concerns. Cystinosis is an important cause of renal failure but the neurological effects mostly appear in adulthood. Other condition such as Von-Hippel-Landau, polycystic renal disease, and tuberous sclerosis are not usually associated with impaired renal function. Acquired causes include haemolytic-uraemic syndrome and other vasculopathies.

In addition, a large number of genetic conditions associate renal and hearing impairment: examples include some mitochondrial cytopathies, infantile Bartters syndrome and recessive Alport syndrome. Acquired causes include drugs such as aminoglycosides.

Haemolytic-uraemic syndrome (HUS) and thrombotic thrombocytopenic purpura are both thrombotic microangiopathies most frequently due to abnormal regulation of the complement alternative pathway. They are differentiated by ADAMTS13 auto-antibodies. Thrombotic thrombocytopenic purpura (TTP) is discussed below. Most childhood cases of HUS follow gastroenteritis associated with Shiga-toxin producing Escherichia coli 0157:H7. Other possible causes (‘atypical HUS’) are age related and include genetic factors, a variety of other infective agents including Streptococcus pneumoniae, dysimmune states, certain drugs and a disorder of cobalamin metabolism. While the presenting features are usually renal, neurological complications and sequelae occur in an important minority. Acute symptoms include severe headache, seizures, reduced level of consciousness and focal signs such as cortical visual impairment, hemiparesis or extrapyramidal disorders. MRI in the acute phase shows that all parts of the brain can be involved, but there is a poor correlation to outcome unless haemorrhage occurs. In some, the MRI pattern reflects arterial hypertension (see below). Depending on the aetiology and severity, treatment with fresh frozen plasma, plasma exchange, and eculizumab, a C5 blocking monoclonal antibody, are all therapeutic options. Some children can survive with persisting motor and intellectual deficits (Steinborn et al. 2004; Yamamoto et al. 2009; Nathanson et al. 2010; Loirat and Frémeaux-Bacchi 2011; Donnerstag et al. 2012; George and Nester 2014).

Lupus erythematosus is the vasculopathy most likely to have renal and neurological effects, with a wide variety of possible manifestations including psychiatric presentations, headache, seizures, stroke, movement disorders especially chorea, neuropathies which are often focal and myositis. Other vasculitides such as Henoch-Schoenlein purpura can more rarely have a similar range of neurological manifestations. In both, systemic hypertension can cause its own neurological and imaging features (Bader-Meunier et al. 2005; Hiraki et al. 2008; Garzoni et al. 2009).

Endogenous toxins are discussed above, but exogenous ones, especially drugs normally excreted by the renal route such as penicillin, can also affect the brain if retention causes toxic levels. In neurology this particularly applies to anticonvulsants such as topiramate, gabapentin, pregabalin and vigabatrin, which are largely excreted by the renal route, while others such as levetiracetam, zonisamide, lacosamide, ethosuximide and felbamate still need dosage adjustments. In addition, administration of aluminium, especially with citrate compounds, was an important cause of encephalopathy until its neurotoxicity was recognised. In the older literature progressive symptoms were reported, typically starting with motor impairment, extensor plantar responses and ataxia or dysmetria, followed by myoclonus and seizures, dementia and bulbar dysfunction. In adults, additional symptoms include a variety of movement disorders such as tremor, asterixis and chorea, and there was often a fluctuant pattern. The myoclonus responded to benzodiazepines. Many such cases were probably due to brain aluminium accumulation. Similar aluminium neurotoxicity has been demonstrated in preterm children without overt renal impairment (Foley et al. 1981; Sedman et al. 1984; Bishop et al. 1997).

Acute hypertension can present with headache, seizures, reduced level of consciousness, subarachnoid haemorrhage and visual symptoms. On fundoscopy ateriovenous nipping, retinal haemorrhages and papilloedema may be present. While clinical stroke can occur, in contrast to adults, hypertension is not a common cause of intracerebral haemorrhage in children. Both coarctation of the aorta and polycystic renal disease can associate hypertension with intracranial aneurysms but the latter are not usually symptomatic until early adulthood. The symptoms and pathological features of hypertensive
encephalopathy in children have been known for decades but the characteristic association with posterior reversible encephalopathy (PRES) was not recognised until the advent of neuroimaging, especially MRI. This condition comprises selective white matter signal change classically involving the parieto-occipital region, which resolves once the cause is treated. While most often due to acute hypertension it can have other causes, especially anti-neoplastic agents. With experience it is now recognised that PRES is not always posterior nor always reversible: frontal white matter involvement is frequent, especially the dominant superior sulcus; there can be a holohemispheric watershed pattern and appearances may be asymmetric. Some children with oncological causes can develop focal haemorrhages or coning, and residual damage especially laminar necrosis can be seen. Most children recover completely after appropriate treatment but some can have persistent deficits (van Vught et al. 1976; Hinckey et al. 1996; Onder et al. 2007; Roach et al. 2008; Chen et al. 2013; Cordelli et al. 2014) (Fig. 27.5).

Chronic arterial hypertension, which may be associated with previously unrecognised renal impairment, is an important differential diagnosis of migraine. Once diagnosed, careful tapering of the blood pressure is vital as over-rapid reduction can lead to blindness due to optic nerve infarction (Browning et al. 2001).

**COMPLICATIONS OF TREATMENT OF CHRONIC RENAL FAILURE**

The onset of a reduced level of consciousness in a child during or soon after haemodialysis requires standard assessment for causes of an acute encephalopathy, including vascular and electrolyte disorders. One important although unusual possibility is the dialysis dysequilibrium syndrome, particularly in younger children, which appears to be related to cerebral oedema secondary to osmotic shifts between the brain and blood. Mild forms present with headache, restlessness, nausea and muscle cramps, but more severe features can include myoclonus, seizures, confusion and coma. It is more severe and frequent if the initial blood urea is very high and the risk is reduced with a slower correction of uraemia. Adding an osmotic agent such as mannitol also helps avoid the problem. Alternatively haemofiltration might be preferable as initial treatment since this also results in a slower osmotic shift. As there is no specific test it is a diagnosis of exclusion (Zepe-da-Orozco and Quigley 2012).

Another dialysis-specific cause is aluminium toxicity. In haemodialysis this is linked to the aluminium concentration of the dialysis fluid, but acute cases can follow oral administration. Symptoms included personality changes, dysarthria, apraxia of speech, myoclonus and seizures. The EEG shows slowing of background tracings and multiple paroxysms. Chronic dialysis encephalopathy due to aluminium toxicity has now largely disappeared following appropriate water treatment (Schreeder et al. 1983).

Many children with chronic renal conditions have evidence of undernutrition. Classically, Wernicke encephalopathy could occur in children on dialysis, although awareness now usually leads to prevention (Worsley et al. 1965; Castillo et al. 2012).

Haemodialysis can also be associated with chronic subdural haematoma.

The cognitive impairment associated with uraemia may not completely resolve with dialysis and further improvement can occur following successful transplantation (Moser et al. 2013).

**REJECTION ENCEPHALOPATHY**

Neurological disorders post transplantation are discussed in the Neurological Complications of Allogeneic Bone Marrow and Organ Transplantation section. Especially in the first few months after transplantation, acute rejection episodes can be complicated by an acute encephalopathy with headaches, seizures and reduced level of consciousness. The cause is uncertain. Treatment is symptomatic and the outcome is usually good. It is important to recognise that this syndrome is not due to disturbances in electrolytes, hypertension, fever or steroids, so steroid treatment may be continued.
Several bone disorders may be associated with neurological symptoms and signs, through various mechanisms that include compression of nerves at the skull base, venous compression with resulting hydrocephalus, narrowing of the foramen magnum or of the vertebral canal with resulting compression of the medulla, spinal cord or nerve roots, and craniosynostosis (Salanitro 2004). Several of these disorders such as achondroplasia and osteogenesis imperfecta are covered in Chapter 6.

Fibrous dysplasia of bone is characterised by proliferation of fibrous tissue in osseous tissue due to a post zygotic activating mutation in the GNAS1 gene. Onset is in childhood or adolescence in over half the cases. Up to 34% of cases may exhibit the association of café-au-lait skin pigmentation and endocrine disorders (McCune Albright syndrome; OMIM 174800). Craniofacial involvement can lead to pain and cranial nerve compression (Wilson and Hall 2002; Lee et al. 2012).

Osteopetrosis, due to osteoclast dysfunction, can be dominant or recessive. The latter has at least eight recognised genetic causes and is usually more severe, especially in its infantile form. Infants present with feeding difficulties secondary to choanal atresia and later develop compressive cranial neuropathies which can cause visual impairment, nystagmus and strabismus; hearing loss which affects nearly 80%; facial paralysis, anosmia and trigeminal neuropathy. Depending on the genetic cause, intellectual disability can be mild or severe. These children develop extra-medullary haematopoiesis with hepatosplenomegaly and eventual marrow failure. Bone marrow transplant has good results if the donor is well matched but not otherwise.

Carbonic anhydrase II deficiency also causes osteopetrosis with basal ganglia calcification and renal tubular acidosis. The osteopetrosis, but not the other manifestations, responds to transplantation (Sly et al. 1983; Gerritsen et al. 1994; McMahon et al. 2001; OMIM 259700).

**HAEMATOLOGICAL DISORDERS**

**HEREDITARY HAEMOGLOBINOPATHIES**

**Sickle Cell Disease**

The major neurological complication of sickle cell disease is the much increased risk of ischaemic stroke, both overt and subclinical. In overt stroke, symptoms occur in isolation or during a sickle crisis. Risk factors include anaemia, nocturnal hypoxaemia, arterial hypertension, elevated flow rate on transcranial Doppler in the anterior cerebral artery especially, and moyamoya syndrome. The risk is highest in the 2–5 year age group. Large vessel disease affecting the carotid circulation mainly leads to large middle cerebral artery territory infarcts, or moyamoya. Smaller infarcts involve the basal ganglia or deep white matter. Treatment includes hydration and exchange transfusion.

Depending on the definition used and the imaging technology, subclinical strokes occur in over a third of children by early adolescence and are associated with a significantly increased risk of clinically overt stroke. The risk of intracerebral haemorrhage is also significantly raised. This is more frequent in young adults and is associated with large vessel vasculopathy or sinus venous thrombosis. Similarly subarachnoid haemorrhage can occur, especially in adolescents, either of aneurysmal origin, or in association with sinus venous thrombosis or moyamoya. Spinal infarcts have also been reported.

Current management recommendations include regular screening by transcranial Doppler, and transfusions for secondary stroke prevention, but their effectiveness is not fully proven. Hyperventilation during EEG recording should be avoided in patients with sickle cell disease as it may result in neurological impairment precipitated by the reduction of blood flow that occurs during the test. Children with sickle cell trait (heterozygotes) have a low incidence of neurological accidents, of the order of 6%.

Academic difficulties, cognitive deficits and behavioural problems are common in children with sickle cell disease. However, at present it is difficult to disentangle the roles of biological and environmental factors present in most affected children.

In adults, leukoencephalopathy is increasingly recognised, and has been described acutely in children in association with acute chest crisis. Because of auto-splenectomy the risk of infection with encapsulated bacteria such as pneumococcus, including meningitis, is increased. Headaches and migraine are also prevalent in children with sickle cell anaemia, and may be undertreated (Lee et al. 2002; Henderson et al. 2003; Roach et al. 2008; DeBaun et al. 2012; Wang and Dwan 2013; Dowling et al. 2014).

**Thalassemias**

Untreated beta thalassaemia major is associated with cerebral sinus venous thrombosis, due to the resulting anaemia. As with sickle cell anaemia, it is also linked to subclinical or silent cerebral infarcts, as is haemoglobin SC (HbSC) disease, but the risk factors and effects have not been studied in such detail.

There are also some reports of moyamoya or silent clinical infarcts in the milder form, beta thalassaemia intermedia, particularly in adulthood. Very rarely in severe anaemia, extra-medullary haematopoiesis can cause spinal cord compression. Headache and syncopal symptoms linked to anaemia are also reported. A mild peripheral neuropathy causing sensory symptoms, cramps, myalgia and weakness has been described,
congenital talipes equino-varus (OMIM 300032 and 141750). Morphologic features, microcephaly, genital anomalies in males and variable degrees of intellectual problems with a variety of dysthalassaemia gene locus on chromosome 16 can also associate. Seizures in males have severe intellectual deficits, dysmorphic features, genital anomalies and alpha thalassaemia. Up to one-third have seizures. More rarely, a contiguous gene deletion affecting the alpha thalassaemia gene locus on chromosome 16 can also associate variable degrees of intellectual problems with a variety of dysmorphic features, microcephaly, genital anomalies in males and congenital talipes equino-varus (OMIM 300032 and 141750).

OTHER ANAEMIAS

All anaemias may be accompanied by neurological symptoms such as irritability, listlessness and fatigue. A cranial bruit can be heard in some patients. Iron deficiency is the most common cause of anaemia worldwide, and has several neurological associations, discussed in the Micronutrient Disturbances section.

Several hereditary haemolytic anaemias also have neurological associations. However, the most common, glucose-6-phosphatase deficiency and pyruvate kinase deficiency only do so as possible contributors to bilirubin encephalopathy in neonates. Similarly, hereditary spherocytosis and elliptocytosis are not usually associated with neurological issues, although spinal cord disease has been reported in hereditary spherocytosis (McCann and Jacob 1976).

Among anaemias due to deficiency of glycolytic enzymes, phosphoglycerate kinase deficiency is an X-linked condition which can cause myopathy, myoglobinuria and at times central problems such as hemiplegic migraine and seizures (OMIM 311800). Triosephosphate isomerase deficiency can have widespread neurological involvement with both central and peripheral motor abnormalities, including pyramidal and extrapyramidal features such as spasticity, tremor, dyskinesia, peripheral neuropathy and myopathy. Early respiratory failure is an important cause of death (OMIM 615512). In a single case, deficiency of glucose phosphate isomerase, which catalyses the interconversion of glucose-6-phosphate and fructose-6-phosphate, caused myopathy, sensory ataxia and intellectual disability (Schröter et al. 1985).

Disorders of the gamma-glutamyl cycle can also cause haemolytic anaemia and neurological problems. Gamma-glutamylcysteine synthetase deficiency causes spinocerebellar degeneration and peripheral neuropathy, while glutathione synthetase deficiency with 5-oxyprolinuria causes intellectual disability and central motor disorders such as spasticity and ataxia (OMIM 606857 and 266130).

Other disorders associated with anaemia and neurological problems in some cases include Fanconi and Diamond-Blackfan anaemias, with microcephaly and intellectual disability; Wilson disease with haemolytic anaemia, and vitamin E deficiency. In children requiring long-term enteral feeds, some with underlying neurological problems, chronic anaemia can be a sign of copper deficiency.

POLYCYTHEMIA

In children polycythaemia is most commonly seen in neonates, particularly those who are small for gestational age. Most neonates are asymptomatic but some can develop symptoms such as feeding difficulties and jitteriness. Seizures and rarely sinovenous thrombosis are also reported. While an association with an adverse neurodevelopmental outcome is suspected, especially in those with seizures, this has been hard to prove, as confounding factors such as hypoglycaemia may contribute. Partial exchange transfusion does not improve the cognitive outcome and is associated with an increased risk of necrotising enterocolitis (Dempsey and Barrington 2006).

In older children and adults, presenting symptoms can include fatigue, headache and dizziness. Unlike adults, in children the risk of stroke and sinovenous thrombosis does not seem markedly elevated. Some cerebellar haemangiomas such as von Hippel-Landau syndrome can cause polycythaemia due to excess secretion of erythropoietin (Roach et al. 2008; Cario et al. 2009).

ACANTHOCYTOSIS

Neuroacanthocytosis describes a group of genetic syndromes associating neurological features with red cell acanthocytosis. The latter may require specialist techniques to be revealed on a blood film. The main syndromes are chorea-acanthocytosis and McLeod syndrome, both with progressive basal ganglia and other multisystem features (see Chapter 19). Symptoms usually develop in adulthood but childhood onset is described. Some people with Huntington disease-like 2 or pantothenate kinase (PANK2) also have acanthocytes. In addition, acanthocytosis is associated with abetalipoproteinemia and hypobetalipoproteinemia, both of which can cause vitamin E deficiency (Jung et al. 2011; OMIM 200150 and 300842).

DISORDERS OF COAGULATION AND PLATELETS

Haemophilia carries a major risk of intracranial haemorrhage that may occur at any age. Haemorrhage may be extradural, subdural, subarachnoid or intraparenchymal. Haemorrhage can be spontaneous or triggered by trauma, including delivery, with the former more common in children with severe deficiency and the latter more prominent in milder forms. Presenting symptoms include headache and vomiting in

In children polycythaemia is most commonly seen in neonates, particularly those who are small for gestational age. Most neonates are asymptomatic but some can develop symptoms such as feeding difficulties and jitteriness. Seizures and rarely sinovenous thrombosis are also reported. While an association with an adverse neurodevelopmental outcome is suspected, especially in those with seizures, this has been hard to prove, as confounding factors such as hypoglycaemia may contribute. Partial exchange transfusion does not improve the cognitive outcome and is associated with an increased risk of necrotising enterocolitis (Dempsey and Barrington 2006).

In older children and adults, presenting symptoms can include fatigue, headache and dizziness. Unlike adults, in children the risk of stroke and sinovenous thrombosis does not seem markedly elevated. Some cerebellar haemangiomas such as von Hippel-Landau syndrome can cause polycythaemia due to excess secretion of erythropoietin (Roach et al. 2008; Cario et al. 2009).

ACANTHOCYTOSIS

Neuroacanthocytosis describes a group of genetic syndromes associating neurological features with red cell acanthocytosis. The latter may require special techniques to be revealed on a blood film. The main syndromes are chorea-acanthocytosis and McLeod syndrome, both with progressive basal ganglia and other multisystem features (see Chapter 19). Symptoms usually develop in adulthood but childhood onset is described. Some people with Huntington disease-like 2 or pantothenate kinase (PANK2) also have acanthocytes. In addition, acanthocytosis is associated with abetalipoproteinemia and hypobetalipoproteinemia, both of which can cause vitamin E deficiency (Jung et al. 2011; OMIM 200150 and 300842).

DISORDERS OF COAGULATION AND PLATELETS

Haemophilia carries a major risk of intracranial haemorrhage that may occur at any age. Haemorrhage may be extradural, subdural, subarachnoid or intraparenchymal. Haemorrhage can be spontaneous or triggered by trauma, including delivery, with the former more common in children with severe deficiency and the latter more prominent in milder forms. Presenting symptoms include headache and vomiting in
most cases, with or without focal features and behaviour change, although young children and neonates may only show drowsiness. Some children also develop spinal haematomata which present with back pain and which can lead to paraplegia. Neuroimaging indicates the extent and origin of the haemorrhage, which is best treated by medical means including clotting factor replacement whenever possible. Surgery, when indicated, should be deferred until the relevant clotting factor deficiency has been corrected. Deficiencies in other factors including V, VII, X and XIII, afibrinogenae mia, and Von Willebrand disease, can also cause intracranial haemorrhage. Prophylactic replacement therapy may be indicated in severe deficiencies (T ezanos Pinto et al. 1992; Quinones-Hinojosa et al. 2003; de Siboni et al. 2012; Labarque et al. 2013).

Acquired clotting factor deficiency due to vitamin K deficiency is discussed in the Liposoluble Vitamin Deficiencies section.

Severe thrombocytopenia, both genetic and acquired, and functional platelet defects such as Glanzmann thrombasthenia, can lead to intracranial haemorrhage (Fig. 27.6). Prenatal or neonatal alloimmune thrombocytopenia is due to maternal antibodies against platelet antigens, usually HPA1a. If not looked for by neonatal ultrasound, the prenatal onset form can present later in infancy with symptoms related to porencephalic cysts and an associated optic nerve hypoplasia whose mechanism is unexplained. Transfusions of compatible platelets, if necessary as an Intrauterine procedure; intravenous immunoglobulin administration to the mother prenatally and to the infant postnatally; and elective delivery by Caesarean section can all be useful protective measures. Monitoring of future pregnancies is also important as the risk persists (Davidson et al. 1989; Menell and Bussel 1994).

Thrombotic microangiopathies also cause thrombocytopenia together with other haematological features and multisystem involvement including the brain. Syndromes include thrombotic thrombocytopenic purpura (TTP), haemolytic-uraemic syndrome and some secondary forms associated with pregnancy, drugs, transplantation, malignancy and infection. TTP is caused by a deficiency of Von Willebrand factor (vWF), cleaving metalloprotease ADAMTS-13, which can be genetic or acquired. The former can manifest at any age including in neonates (Upshaw-Schulman syndrome). The acquired form, due to auto-antibodies to ADAMTS-13, is usually idiopathic but can be triggered by viral infections or drugs including beta-interferon, and is very rare in children. Neurological complications predominate, and include headache, seizures, focal deficits and varying degrees of encephalopathy (George and Nester 2014; Rosove 2014).

NEUROLOGICAL COMPLICATIONS OF ALLOGENEIC BONE MARROW AND ORGAN TRANSPLANTATION

All forms of allogeneic transplantation can be associated with neurological complications, including acute and chronic encephalopathies of varying severity, seizures, focal deficits, movement disorders and ataxia, myelopathy, ototoxicity, neuropathies and myopathy. The causes are both procedure specific and generic. The latter include direct effects such as drug toxicity or radiation, or CNS infections secondary to immunosuppression.

Acute encephalopathy can be due to drug toxicity, acute demyelinating encephalomyelitis, PRES and hypertension, intracranial haemorrhage, hypoxic-ischaemic, metabolic and infectious causes, alone or in combination. Some of these can also present with focal signs.

Many chemotherapeutic and immunosuppressive agents can cause the adverse neurological effects listed above. The risks are agent, dose, route, age and pharmacogenetic related, and rare idiosyncratic responses are reported as well. Many neurotoxic effects are reported, more frequently in adults. A standardised terminology and grading system has been introduced by the National Cancer Institute (US Department of Health and Human Services 2010). Some specific effects reported in children are listed in Table 27.7.

Intracranial haemorrhage, including haemorrhagic infarction and subdural haematoma, can follow from thrombocytopenia secondary to bone marrow suppression.

Metabolic factors include renal and hepatic decompensation, which may be pre-existing as outlined in the Renal Disease and Hepatic Disease sections, acute electrolyte derangements, and those secondary to nutritional problems.
Immunosuppression post transplant, or due to other causes, increases the risk of meningitis, encephalitis or focal infection by a variety of viral, bacterial, fungal and parasitic agents, both endemic and opportunistic. Symptoms include encephalopathy, fever, seizures, and focal features.

In the acute stage immediately post transplant, aspergillosis and toxoplasmosis are the most frequent causes of CNS infection. They are also important causes of focal lesions. Candida, which may originate from indwelling catheters, can also cause CNS infection. Bacterial infections are more often due to Gram-negative bacteria such as *Pseudomonas aeruginosa*, particularly after renal transplants, or enterococci, particularly after liver transplants, but staphylococcal infection can also occur. In solid organ transplants, acute infection can originate from the surgical procedure or the transplanted tissue. Since 2000, examples of the latter in adults have included rabies and lymphocytic choriomeningitis virus. Adenovirus infection also occurs but does not usually cause encephalitis.

In subsequent months, herpes viruses [herpes simplex, varicella, human herpesvirus-6 (HHV6), Epstein–Barr (EBV) and cytomegalovirus] predominate as causes of encephalitis. T-cell depletion may predispose to this complication. Diagnoses based on PCR of CSF cannot always distinguish active from latent infection. HHV6 can reactivate, especially if graft versus host disease (GvHD) develops, and manifests as posttransplant acute limbic encephalitis (PALE) with confusion, amnesia, seizures with focal EEG changes including paroxysmal lateraled epileptiform discharges (PLEDs), often hyponatraemia, and bilateral medial temporal lobe abnormalities on MRI. After several months, severe intractable seizures develop with regression in younger children or severe memory problems in older children. Herpes simplex virus encephalitis, which often does not have MRI changes, may have a better outcome than others. Varicella zoster virus encephalitis is rare, and occasionally can also have limbic features. More frequently VZV reactivation causes shingles followed by neuralgia and neuropathy. EBV infection, especially primary, is a major cause of posttransplant lymphoproliferative disorder, which can involve the brain. Rituximab can help in treatment. EBV can also cause a non-specific encephalitis. Progressive multifocal leukoencephalopathy due to reactivation of the JC (John Cunningham) polyomavirus is fortunately rare in children. Later bacterial infections include staphylococci and other Gram-positive or capsulated bacteria, especially pneumococcus; chronic graft versus host disease is a risk factor (Kawasaki et al. 1996; Hale et al. 1999; Koc et al. 2000; Doris et al. 2007; Schmidt-Hieber et al. 2011; Howell et al. 2012; Green and Michaels 2013; Styczynski et al. 2013; Tyler 2009a, b).

Acute or subacute encephalopathy therefore requires a detailed clinical assessment while investigations need to include neuroimaging, preferably MRI unless a child is too unwell to tolerate it, a full infection screen covering all possible agents, drug levels where appropriate, and a metabolic workup that includes electrolytes, measures of renal and hepatic function, glucose, ammonia and pH. Broad spectrum treatment is usually started before all results are available.

Seizures, as well as being a manifestation of an acute encephalopathy, can also occur in isolation due to drugs, metabolic abnormalities or focal insults. Investigations and management are similar to those above. However, it is also important to keep in mind that some anticonvulsants accelerate the catabolism of steroids, resulting in possible reduction of allograft survival. Treatment of seizures should be with non-enzyme-inducing drugs.

Strokes and stroke-like episodes can be vascular, due to causes such as emboli from intravascular catheters or haemorrhage due to thrombocytopenia, focal infections, or drugs. Asparaginase in particular inactivates anti-thrombin III and is associated with venous thrombosis. Acute demyelinating encephalomyelitis (ADEM) can present in a similar way. Neuroimaging also occasionally detects subdural collections (Coplin et al. 2001; Chen et al. 2012).

Movement disorders are not usually a major problems either in terms of frequency or severity. The main association is with tremor and rarely parkinsonian features in patients on long-term cyclosporine therapy.

Acute myelopathy is mostly frequently caused by acute cord compression from intraspinal haematoma, due to haemorrhagic diathesis. If decompressed promptly, function can be preserved but often the long-term outcome is poor. Otherwise chronic myelopathy can be a late effect of radiotherapy to the spinal cord. Management should cover motor, sensory and sphincter complications.
Neuropathies can either be focal; for example, ophthalmoplegic, otoxic or femoral post catheterisation, plexopathies, or peripheral polyneuropathies, following drug therapy (see Table 27.7). Vinca alkaloids usually cause an asymptomatic neuropathy, but if they are given to a patient with a pre-existing hereditary neuropathy, such as CMT1A, severe weakness can result, with a prolonged recovery time (Chauvenet et al. 2003).

Myopathy mostly follows steroid use, which may be long term. Myalgia can occur with some chemotherapeutic agents (see Table 27.7).

Chronic encephalopathy can manifest as non-progressive learning difficulties, either global or specific, reflected in reduced IQ levels and disorders of executive and memory functions, and behaviour problems. Both radiation and chemotherapy are well-recognised contributors. Survivors of acute encephalopathies are also at increased risk.

Late effects of focal insults can also lead to central motor disorders such as hemiparesis, epilepsy, global or specific intellectual deficits and behaviour problems.

HAEMATOPOIETIC STEM CELL TRANSPLANTATION

Haematopoietic stem cell transplants are derived from bone marrow or blood, including cord blood, and can be autologous or more usually allogeneic, from a matched donor. They can be used in the treatment of malignancies such as leukaemia and lymphoma, severe haemoglobinopathies, immune deficiencies, neurodegenerative disorders such as adrenoleukodystrophy and have been tried in some metabolic conditions. All involve high-dose chemotherapy while the treatment of malignancy may include intrathecal chemotherapy and craniospinal radiotherapy which carry their own specific risks.

Older case series reported neurological complications during and after bone marrow transplantation in children of up to 40% or more, but more recent series report approximately 16%. Associated mortality rates are up to 30%. Certain causes predominate at different stages of the transplantation process. Weber et al. (2008) divided these into two groups. The first had transient self-limiting symptoms often seizures or encephalopathy during conditioning, lasting less than 24 hours, with normal neuroimaging: some had idiopathic intracranial hypertension. The second had progressive symptoms and abnormal neuroimaging. The latter could be further divided into early, less than 100 days (CNS bleeds, aspergillosis, toxoplasmosis, or drug toxicity); middle, less than 6 months (drug toxicity); and late, over 6 months (viral infection or CNS relapse) (Faraci et al. 2002; Iguchi et al. 1999; Uckan et al. 2005).

The main condition-specific problem is graft versus host disease (GvHD) in allogeneic transplants. It can be difficult to find the balance between tolerable toxicity from the agents used, and the increased risk of GvHD if lower dose regimens are followed. As well as the general neurological complications summarised above, procedure-specific complications include intracranial haemorrhage due to bone marrow suppression and neurological complications of GvHD. In one series, 11% of patients developed neurological complications due to intracranial haemorrhage, mainly subdural and secondary to thrombocytopenia, metabolic encephalopathy or infection. Other series report important drug side effects; for example, from cyclosporine. Stroke is usually haemorrhagic, either due to thrombocytopenia or fungal infection. Polyneuropathy is reported in association with other features of GvHD syndrome (Iguchi et al. 1999; Coplin et al. 2001; Faraci et al. 2002; Uckan et al. 2005; Klein et al. 2007).

The longer term neurocognitive effects are unclear as 5-year follow-up studies give contradictory results, partly due to differing inclusion criteria, but unrelated donor transplantation, total body irradiation and GvHD appear to increase the risk of adverse outcomes. The effect of socio-economic status is also very significant (Boulad et al. 1998; Phipps et al. 2008; Shah et al. 2008; Lin et al. 2009).

HEART AND HEART LUNG TRANSPLANTATION

Complications of cardiac transplantation include those related to severe cardiac failure pre- and posttransplant, which may require ventricular support devices, cardiopulmonary bypass surgery and immunosuppressant therapy. In heart transplantation, the main procedure-specific risk is hypoxic-ischaemic encephalopathy. Some of the underlying cardiac conditions have additional background associations as discussed in the Cardiac Disorders section. Although good results are now obtained, the neurodevelopmental outcome remains a concern (Wray and Radley-Smith 2006; Chinnock et al. 2008).

LIVER TRANSPLANTATION AND INTESTINAL TRANSPLANT

Liver transplantation is a powerful treatment for acute and chronic hepatic failure and has achieved considerable success. It should be performed before there is evidence of cerebral oedema as the results are otherwise poorer. However, transplantation and the immunological abnormalities that its treatment implies may give rise to neurological complications. One series reported early (<3 months after transplant) complications in 14% and later ones in 17%. Seizures predominated in both groups, followed by encephalopathy and headache. Longer term neurocognitive outcomes are reduced compared to control groups, especially in younger age groups, although this could have several mechanisms.

Intestinal transplantation can be performed with or without multivisceral (liver etc.) transplantation. The longer term outcome in survivors remains poor, with 74–96% of those receiving multivisceral transplant before the age of 3 years showing cognitive problems in one series (Stewart...

**KIDNEY TRANSPLANTATION**

Rejection encephalopathy is discussed in the Renal Diseases section. Otherwise, the generic risks are the main causes of acute neurological problems. Longer term results show reductions in neurocognitive function and are influenced by the underlying cause, neurological complications, age at transplant and delay before transplant (Falger et al. 2008; Johnson and Warady 2013; Moser et al. 2013).

Symptomatic hypoglycaemia has been observed months to years following renal transplantation (Wells et al. 1988). It occurred in children receiving propranolol and responded to discontinuation of the drug.

Neurodevelopmental Disabilities and their Management

Bruce K Shapiro

Development is a series of processes by which mature function is achieved. At birth, humans are relatively immature and most organ systems do not function in a mature fashion. The processes that guide development are complex and incompletely understood.

Neurodevelopment is also not random. It is ordered, predictable and measurable, for example, most children roll before they sit, and sit before they crawl, and crawl before they walk. The achievement of the skills, or milestones, is the functional expression of the underlying maturational processes. Neurodevelopment reflects the integrity of the child’s nervous system. Most systems of assessment focus on the achievement of new skills or milestones, but neurodevelopment is not unidirectional. Although the most dramatic changes are in the appearance of new functions, previously achieved functions may be performed more efficiently, and some functions regress.

Perturbations of the developmental process may result from many different aetiologies. Genetic, metabolic, infectious, traumatic, hypoxic–ischaemic, immunological and toxic are some of the factors that disrupt the developmental process. These factors affect multiple areas of the brain and result in diffuse brain dysfunction. As a consequence, dysfunction in one area of development projects dysfunction into other areas of development, for example, children with motor delays frequently have disordered language development. Attention-deficit–hyperactivity disorder (ADHD) co-occurs with disorders of written expression. Furthermore, the most common reason for failure of a treatment programme is missing an important co-occurring disorder (Kube and Shapiro 1996).

Developmental dysfunction is longitudinal. The abnormality that results from the insult may cause immediate dysfunction but also affects the ongoing maturational processes, later dysfunction may be noted. For example, a child who evidences delay in achievement of walking may ultimately walk but later show abnormality in his language function or difficulties with executive function and academic learning.

PRESENTATIONS OF NEURODEVELOPMENTAL DISABILITIES

Early identification of developmental disorders has the following four important functions: (1) it enables the early provision of services, (2) it allows for long-term planning, (3) it enables families to adapt to the child’s dysfunction and (4) it enables investigation for aetiologies and consideration of the genetic implications for the family. Techniques for the early identification of neurodevelopmental disabilities are screening, risk registries and parental referral (Shapiro 2011).

Screening is the application of a technique to an asymptomatic population. Ideally, screening is done before the child becomes symptomatic; the tools used have good classification abilities and there are effective interventions for the condition. The outcome of screening is risk, not diagnosis. Positive screening tests require confirmatory assessments to establish a diagnosis.

Perhaps the most effective screening is that of newborn infants. Currently, most states in the USA screen for 29 conditions, but the capability, in part related to refinements to tandem mass spectrometry techniques (e.g. matrix-assisted laser desorption/ionisation (MALDI)–time of flight (TOF)), exists for identifying over 50 conditions (Table 28.1). The impact of this approach for children with phenylketonuria or congenital hypothyroidism has been dramatic. The impact of universal screening of newborn infants for hearing impairment has been less because of the low rate of follow-up confirmatory testing; 35.3% of US infants who failed the initial screening were lost to follow-up (Centers for Disease Control 2011). The impact of the programme is greater in countries where the rate of complete evaluations is higher (see Chapter 23). Screening for neurodevelopmental disabilities is less effective because of the psychometric properties of the tools.

Risk registries are established to target certain populations for surveillance, based on their belonging to a group. Risk registries based on historical risk are not effective because most children do not have the condition that they are at risk of having and most with the condition do not come from a risk group, for example, children who are born preterm have higher rates of cerebral palsy (CP), as much as ten times the rate in the general population. However, given the rarity of CP (approximately two in 1000), almost all children who are born preterm do not have CP (approximately 94% in infants with birthweights <1500g; Oskoui et al. 2013). Most children with CP come from the population not born preterm.
On the other hand, risk based on performance is a useful method for identifying children who may need intervention, for example, 5-year-old children with persisting language delays are at extremely high risk of evidencing academic underachievement (Snowling and Hulme 2012).

Most child neurologists with an interest in neurodevelopment are not involved with the early identification of children with neurodevelopmental disorders. More often, they are asked to evaluate children who have failed to meet age-appropriate expectations or whose development has been in question as part of an acute neurological presentation (Table 28.2). The following are the roles of the consultant: (1) establish a diagnosis, (2) delineate co-occurring disorders, (3) determine aetiology, (4) treat and (5) participate in the establishment of a management programme.

National Newborn Screening and Global Resource Center (2013).

On the other hand, risk based on performance is a useful method for identifying children who may need intervention, for example, 5-year-old children with persisting language delays are at extremely high risk of evidencing academic underachievement (Snowling and Hulme 2012).

Most child neurologists with an interest in neurodevelopment are not involved with the early identification of children with neurodevelopmental disorders. More often, they are asked to evaluate children who have failed to meet age-appropriate expectations or whose development has been in question as part of an acute neurological presentation (Table 28.2). The following are the roles of the consultant: (1) establish a diagnosis, (2) delineate co-occurring disorders, (3) determine aetiology, (4) treat and (5) participate in the establishment of a management programme.

**QUANTIFYING DEVELOPMENT**

Developmental assessment stems from the empirical observation that children follow the same developmental course and what varies is the age of achievement. As a consequence, a child's development can be described by a function versus time plot which compares the age that a child achieves a milestone with the age at which that milestone is usually achieved (Fig. 28.1). As most children start at zero, the rate can be reduced to
Chapter 28 Neurodevelopmental Disabilities and their Management

1365

a ratio or developmental quotient which compares the age of achievement of a milestone with the chronological age.

The longitudinal collection of developmental achievements enables primary care providers with a method of charting the child’s development and defining several patterns of abnormality that may lead to early diagnosis. Four longitudinal patterns of development may be defined. The most common is seen in typical children and that is a pattern of a stable rate – 1 year olds doing 1-year-old activities, 2 year olds, 2-year-old activities, and so on.

A second pattern is seen when an acute event intervenes in the developmental processes. This may be noted in children who have suffered traumatic brain injury, brain infection or toxic exposures. The third pattern is noted in children who are proceeding at a developmental rate and then accelerate their rate of development. This pattern may be seen in infants who were born preterm and show acceleration of their development after achieving physiological stability or in children who are recovering from acute events.

A fourth pattern is associated with plateau/regression. This pattern may be evidenced in one or two areas of development, as might be seen in the language regression noted in the Landau–Kleffner syndrome or autistic spectrum disorder. It may represent a slowing of developmental progress that is not associated with loss of skills, as might be seen in children who are diagnosed as having mixed receptive–expressive language disorders in preschool, but fail to progress and are considered intellectually limited by middle school. Finally, this pattern is seen in children who show generalised plateauing and regression, as might be observed in neurodegenerative disorders.

When used in a cross-sectional fashion, the relationship between function and age allows for the following three conditions to exist: delay, asynchronous development or dissociation, and non-sequential development or deviance.

Delay brings children to attention. It has different definitions – developmental quotients of 85%, 75% and 70% – have all been recommended and are used in different situations. Although there is significant variability in developmental achievements within the typical population, children whose development is significantly slowed are remarkably consistent in their developmental quotients.

Dissociation facilitates early diagnosis. In the typical child, all developmental areas progress at a similar pace. Asynchrony in development is defined as a 15% difference in developmental quotients. By comparing developmental quotients, early diagnosis is possible and is illustrated in Table 28.3.

Non-sequential development or deviance occurs when the developmental progression is violated. Such examples occur in the case of bottom shuffling, where children bypass crawling or, in the case of language development, they have many words but are not using phrases or sentences. Non-sequential development may be seen in children with autistic spectrum disorders, but also in children with mixed receptive–expressive language disorders or who are being ‘over-programmed’. Non-sequential development is not a normal variant and requires additional exploration.

NEURODEVELOPMENTAL DISORDERS

‘Neurodevelopmental disorders’ is a term used to describe a group of brain-based disorders that have their onset during childhood and result in substantial functional limitations.
These disorders may result from a large number of causes. The neurodevelopmental disorders are defined functionally and do not specify severity, other than to impair function, mechanism or prognosis (Table 28.4).

As a consequence, these diagnoses are thought to be dimensional rather than categorical. The boundaries of these disorders are often indistinct, for example, at what point does clumsiness become CP? How much social impairment is required to establish the diagnosis of autism?

Frequently, a child may have multiple co-occurring neurodevelopmental disorders. Children with language disorders often have abnormalities of tone and coordination. Approximately 50% of children with CP have intellectual disability. A third of children with autism meet criteria for ADHD. The prevalence of co-occurring disorders is determined, in part, by the depth of the evaluation. Whether this represents comorbidity or multiple expressions of a common aetiology is a subject of debate.

One reason for the high rate of co-occurring conditions is that the aetiologies of neurodevelopmental disorders result in diffuse brain injury, with consequent functional impairment in multiple areas. Trauma, infection, toxins, hypoxia–ischaemia, immunological, genetic, metabolic, malformations, endocrine, nutritional and oncological aetiologies have been associated with neurodevelopmental disorders. The clinical implications of this finding are twofold as follows: developmental dysfunction in one area of development should warrant exploration of other areas of development and re-evaluation is indicated if a treatment programme is not working.

Infancy

Gross motor development is the major developmental focus between age 6 and 18 months. Most referrals are made around a year of age, but evidence of motor dysfunction is apparent before that time and new diagnoses of CP should be made by 18 months in most cases.

The motor quotient was a tool developed to predict whether children who are motor delayed at 8–18 months will walk by age 2 years. This measure compares the age of motor achievement and chronological age. Children who have a motor quotient of <50% are at high risk for significant motor delays (Capute and Shapiro 1985). Children who have motor quotients between 50% and 75% often have other developmental dysfunction.

Further evaluation of motor function will evaluate whether the child has persistence of functions that are suppressed by brain maturation, delayed appearance of functions that are closely linked to volitional motor function and classic neurological findings. Primitive reflexes are brainstem-mediated responses that appear late in gestation.
and are no longer evident by the latter part of the first year. Persistence of obligatory or excessive primitive reflexes is associated with CP. Postural responses maintain the head perpendicular to the floor and are intimately linked to volitional motor activity. The classic neurological examination evaluates strength, tone (after modifications for gestational age) and symmetry. The algorithm (Fig. 28.2) demonstrates how the use of volitional motor activity, postural responses and primitive reflexes can be combined to come to the early diagnosis of CP (Shapiro and Gwynn 2008).

**Preschool**

Preschool is a time of major developmental change. It is associated with increasing independence and socialisation. Major foci include socialisation, play, attention and activity, behavioural regulation and mastery of pre-academic skills. Fine motor demands are reflected in dressing, colouring, cutting, pasting, and pencil-and-paper tasks. The gross motor and vocabulary skills of early epochs should be integrated. Preschoolers often change their developmental trajectory and, with maturation, grow into or out of diagnoses. The large amount of behaviour to be sampled usually requires the services of a psychologist or speech language pathologist.

The most common diagnoses made in the preschool period are related to language function and include the following: mixed receptive–expressive language disorder or autistic spectrum disorder. Severe intellectual disability is usually manifest before the preschool period. Global developmental delay, operationally defined as significant delay in two or more developmental domains (motor, speech-and-language, social or daily activities; Ashwal et al. 2003), may be used for children with milder intellectual disability to provide time for clarification of the diagnosis. Although ADHD may be manifest during this time the diagnosis may be deferred until the start of school.

**School-Aged Dysfunction**

The presentation of developmental dysfunction in school-aged children is not random (Lewis et al. 2013). Most often children are referred for not meeting age-related expectations. Table 28.5 lists typical school expectations.

School-aged children with neurodevelopmental dysfunction often have behavioural disturbance. ADHD frequently accompanies disorders that cause school underachievement, and adjustment disorders with anxiety or mood issues are common. Some children would rather be thought bad than

**Figure 28.2 Algorithm for early diagnosis of cerebral palsy.** (Modified from Shapiro and Gwynn 2008.)

![Figure 28.2 Algorithm for early diagnosis of cerebral palsy.](image-url)
unable and act out in the classroom or at home. Young children may be called oppositional defiant when they are protesting about things that they cannot do. Often practitioners confront a dilemma such as the following: if he behaved better he would learn more versus if he was in a situation that was more consonant with his educational needs he would behave better.

Early primary school (age 5–8 years) is when most referrals are made for evaluation of dyslexia or ADHD. The major objective of early primary school is the mastery of fundamental reading. Fundamental reading, or decoding, requires the attachment of sounds to symbols and derivation of meaning from the words. Interruption of these processes may result from fundamental inability to attach sounds to symbols (dyslexia), a more generalised language disorder, intellectual limitation or problems with sequencing. Behaviour, particularly activity and attention, is also an area of focus.

Later in primary school (age 8–11 years), the focus shifts from learning to read to reading to learn. Reading for comprehension, inference, expository writing (themes) and mastery of the primary mathematical processes (adding, subtracting, multiplying and dividing) are the main areas of focus. Just as reading is a complex function, mathematics builds on attention/working memory, sequencing and reading (word problems), as well as numeracy.

Middle school (age 11–14) stresses organisational skills and independent function. By middle school the basic processes have been mastered and the focus shifts to process. Children are responsible for following schedules, planning long-term assignments and turning in homework when it is due. The nature of the work also changes. Chapter reading predominates and the child has to do more than read all the words; he has to integrate the material and extract meaning. Notes must be taken. The thinking required is more than recall. Against this backdrop are the social challenges that confront adolescents.

When children present for the first time in high school they are not presenting with issues relating to the content of the curriculum. For children who have no previous history of academic difficulty, consideration should be given to other conditions such as thyroid dysfunction, psychiatric disorders (e.g. depression) or substance abuse. Some children who have a history of mild academic underachievement give up. Some are very bright and have been using their intellect to cover their inefficiencies. Others may be using extracurricular activities to provide the boost that enables them to persevere. Supportive counselling, focusing on areas of strength, and classroom accommodations are effective interventions.

**AGE AND MATURATIONAL EFFECTS**

Some children who have been diagnosed with neurodevelopmental disorders may grow out of the diagnosis whereas others grow into it, and still others change their diagnoses. Some children with global developmental delay may have evidence of typical development at an older age. Between 3% and 25% of children who have been diagnosed as being on the autism spectrum do not maintain that diagnosis (Helt et al. 2008). Hyperactivity is infrequently seen after adolescence.

This phenomenon is also seen in motor domains, for example, a child may present with motor delay and signs of CP in infancy, but lose that diagnosis by early childhood. It is common to see contractures develop or progress with age in children with CP.

Finally, maturation and ageing may affect the diagnosis of dysmorphic syndromes, for example, children with Prader–Willi syndrome may present as failure to thrive. Children with fetal alcohol syndrome are more easily diagnosed as toddlers than as adolescents.

Early dysfunction that does not result in disability may serve as a marker for later developmental dysfunction, for example, an infant who presents with motor delay may close the gap as a toddler but later have evidence of language and academic dysfunction. Early mixed receptive–expressive language disorder may be a harbinger of later intellectual disability in early adolescence.

The reasons why some children change their diagnoses as they age are not clear. Damage to the developing brain not only has immediate effects but may also confer secondary effects from the response to the initial trauma (Fathali et al. 2011). Trauma at an earlier point in development may affect subsequent function. These longer-term effects may not be evident until the demands of the situation exceed the child’s abilities. ADHD is typically not diagnosed until children are in group settings, where conforming to a set of rules is required. Dyslexia and other specific learning disabilities are not diagnosed until the child is exposed to formal academic studies, even though the neural substrate for these disorders is present. Intellectual disability may not be fully manifested until the failure to achieve formal operations can be documented. Compensatory mechanisms may ameliorate the dysfunction through alternative means, children who were born preterm and have globally normal language development show atypical functional magnetic resonance imaging (MRI) connectivity on language tasks (Mullen et al. 2011).

**AETIOLOGICAL EVALUATIONS**

Neurodevelopmental disorders may result from a wide range of disorders. Establishing the diagnosis is unique to the discipline of medicine. Knowledge of the aetiology of the neurodevelopmental disorder often relieves parental guilt by reinforcing that the disability could not be avoided by changing their behaviour. Aetiological diagnosis improves our prognostic ability, guides the search for associated dysfunctions and enables the risk for a subsequent pregnancy to yield a child with the same diagnosis. Finally, an aetiological diagnosis provides insight into the biological mechanism of the disordered function and the potential for targeted pharmacotherapy of neurodevelopmental disorders.
Embodying upon a search for the aetiology should be undertaken in a considered fashion. Among the questions to answer are the following: ‘What are the parents’ wishes?’ For some parents the aetiology is not an issue whereas for others it is the major issue. ‘Does the history or physical examination provide clues to a diagnostic pathway?’ ‘What is the type and nature of the developmental disability?’ Evaluations of children with language disabilities are usually unrevealing although evaluations of children with motor impairment, cognitive dysfunction, microcephaly and epilepsy are. Clinical practice guidelines that are based on literature reviews have been developed by professional societies to aid the diagnostic search. The American Academy of Neurology has protocols for global developmental delay (Shevell et al. 2003; Michelon et al. 2011), autism (Filipek et al. 2000) and CP (Ashwal et al. 2004). The American Academy of Pediatrics has protocols for global developmental delay (Moeschler and Shevell 2006), ADHD (Wolraich et al. 2011), autism (Johnson and Myers 2007) and a recent protocol for children with motor delay (Noritz and Murphy 2013). The American College of Genetics has clinical guidelines for global developmental delay (Curry et al. 1997). Each practice guideline was developed for a specific diagnosis and based on existing literature, but the guidelines were not established as a ‘cookbook’. They were meant to be modified, based on the clinical condition.

A review of the clinical practice guidelines reveals commonalities that span the spectrum of developmental dysfunction. A comprehensive history and physical examination are the first step in the aetiological investigation. Neuroimaging and genetic studies are also recommended. Additional consultations and studies must be guided by the initial evaluations.

The history and the physical examination are the foundation of the aetiological evaluation. There is an almost endless list of conditions that lead to neurodevelopmental disability, and the number of evaluations that can be performed is almost as large. Aimless evaluation that is not directed by the clinical state results in many unneeded tests and runs the risk of not uncovering a known aetiology. All of the clinical guidelines recognise the importance of the clinical evaluation as the guide to further evaluation.

The purpose of the history is to develop a differential diagnosis. To that end the history must answer several questions. What is the presenting complaint? Often this is confounded by a listing of professionals who have interacted previously with the child and a longer list of the diagnoses that they have applied. As noted above, multiple coexisting disorders are common. However, to develop an effective management programme, it is critical to establish what the most troublesome problem is.

The history should document the child’s current functions for the following: language, motor, social, dressing, feeding, toileting and academic. Is the presenting symptom limited to a single area of development such as language or motor systems, or is it part of a more generalised process, as might be the case in intellectual disability?

Is the course of this process one of slow progress, abrupt onset with a reset of the developmental trajectory, episodic or regressive? Most of the neurodevelopmental disorders follow a course of slow progress. Disorders with an abrupt onset may suggest psychiatric, infectious, trauma or immunological disorders. Episodic disorders suggest epilepsy or genetic/metabolic processes.

Regression is an ominous sign, and may be seen as the end-result of many progressive disorders. Neurometabolic, neurodegenerative, endocrine and immunological disorders, toxins and epilepsy have all been associated with regression in multiple developmental areas. The regression seen in autism is limited to language and concomitant social areas, and does not affect motor function. At the early stages regression may be hard to appreciate and serial evaluations are warranted. Declining performance on standardised tests may be a failure to maintain the developmental trajectory and not a true regression.

The severity of the impairment is established by a quantitative approach to development. Obtaining a history of developmental achievements provides the basis for this approach in young children (see Table 28.6 for selected milestones). Parents are excellent historians if the clinician is precise in his or her questioning. If a parent has difficulty establishing an age of achievement for a specific task, the clinician may link the questions to important life events, for example, ‘Was she walking at her first birthday?’ and ‘What was he saying last Christmas?’. Parents are reliable in the reporting, especially in the face of delay. The developmental quotient derived from a parental estimate of functional age often corresponds to the results of formal testing in young children.

The reliability of developmental history may be augmented through the use of developmental milestones, in a longitudinal fashion, to develop trajectories which decreases the importance of single milestones. Reviewing baby books, photos, video recordings, and previous evaluations, screenings and school reports provides almost concurrent evidence of developmental achievements.

Threats to the validity of a milestone approach include physiological instability, using the wrong milestones, misinterpreting responses and crediting behaviour that is emerging. Developmental assessment of children who are physiologically suboptimal may underestimate the child’s true ability and has limited prognostic ability. Evaluating a child who is physiologically unstable may be a useful measure of current function and may provide a basis for short-term interventions. For these children, serial assessments should be undertaken until physiological stability has been achieved and a valid evaluation achieved.

To be clinically useful a milestone must frequently occur in the target population, be clearly observed, occur within a narrow time frame and have prognostic significance. Using the wrong milestones is another threat to the validity of the developmental assessment. There are milestones assigned to many functions, but most have limited utility in defining developmental trajectories, for example, a milestone of when
an infant starts to hold the bottle is not particularly useful in a population where breastfeeding is the norm. Using forks and spoons is not the norm in certain cultures. Greeting a familiar person is difficult to interpret and is not clearly observed. Is simple curiosity about who is at the door credited? Does the milestone require the child to say, ‘Hi!’ or start a conversation? How does it differ from absence of stranger anxiety? A milestone that normally occurs between 24 and 36 months, as in toilet training, has limited utility if you are evaluating a preschool child. Finally, there are milestones that occur in most children within narrow age norms and are easily observed, but do not have strong prognostic value, for example, drawing a circle in a clockwise or anticlockwise fashion.

Misinterpreting responses is another source of error in developmental assessment. It may result from giving credit to emerging behaviours, which tends to overestimate the child’s ability. To truly credit a skill requires the skill to be firmly established. Another error, in the language area, is misinterpreting responses. Echolalia, single word phrases (e.g. stop that, thank you) and programmed speech (e.g. language that is learned from the television and used as filler) are examples of language behaviours that result in inflated estimates of function. To minimise these effects requires that the child use words spontaneously, appropriately and with novel constructions.

The history should also investigate symptoms of neurological dysfunction. Vision and hearing status should be queried. Previous or current alterations in consciousness, e.g. loss of consciousness from trauma or associated with seizures or staring spells, should be noted. Behaviours relating to maintenance of state, feeding, sleeping and elimination should be noted. Age-appropriate social interactions and peer acceptance are important markers of language function. Increased or decreased levels activity should be investigated. General medical symptoms should be reviewed relating to growth, exercise tolerance, and cardiopulmonary, gastrointestinal, musculoskeletal, genitourinary and integumentary systems. Neurodevelopmentally significant events should be reviewed. A prenatal history of maternal chronic disease or thyroid dysfunction, fetal wastage, exposures (toxic or infectious), fetal movement quality, maternal weight gain/fetal growth, presentation and length of gestation have been related to suboptimal developmental outcomes. Natal factors that should be reviewed relate to the conduct of labour and delivery, the need for resuscitation, birthweight, intrauterine growth retardation, newborn infant seizures, intracranial haemorrhage, infection, respiratory support, pneumothorax, feeding difficulties, necrotising enterocolitis, movement abnormalities, hyperbilirubinaemia and autonomic dysfunction. Postnatal factors include hospitalisations, trauma, surgeries, toxic exposures (e.g. lead, mercury, cigarette smoke, bisphenol A), significant infections (e.g. meningitis, encephalitis), seizures and major organ system dysfunction. Previous evaluations should be obtained.

Family history should develop a three-generation pedigree that focuses on neurodevelopmental dysfunction. A family history of intellectual disability, autism, dyslexia, mixed

</table>
receptive–expressive language disorder, hearing loss, movement disorders, ADHD and consanguinity should be recorded. Non-diagnosed delays in motor, language and academic domains should be noted. Adult-onset psychiatric and neurological disorders should be queried.

The physical examination should be comprehensive. Often it is limited by the child’s age, level of cooperation or ability to comply with tasks. Special attention should be focused on current growth parameters, and somatic and head growth trajectories, head shape and status of fontanelles, facial and other dysmorphisms, congenital anomalies, visceromegaly and neurocutaneous stigmata. The neurological examination should focus on the motor examination. Evaluation of axial and appendicular tone and strength, observation of abnormal postures or movements, focal motor findings and abnormalities of cranial nerve function should be noted. Completion of peg boards, stacking blocks or timed writing tasks is a sensitive measure of fine motor abilities. Reliable examination of cortical sensory functions may not be possible until the child is school age, but coarse estimates are possible. All children who evidence developmental dysfunction should have a formal audiological evaluation and thorough ophthalmological assessment as part of the aetiological evaluation.

The clinical practice guidelines recommend neuroimaging studies, with MRI as the preferred modality. The staging of the imaging may differ, however. In the case of CP or motor delay, MRI should be the first investigation but, in children with global developmental delay or autism, it may be prudent to perform genetic testing first. Routine neuroimaging is not recommended for the evaluation of children with autism unless there is concern about underlying structural malformations, or for children with motor delays unless there are concerns about CP.

MRI of children with CP may show periventricular leukomalacia, hydrocephalus, migrational defects, leukodystrophy, neurodegenerative disorders, or evidence of basal ganglia injury that may be associated with kernicterus or metabolic disorders (Accardo et al. 2004). Neuroimaging of children with global developmental delay may show malformations, delayed myelination, or white matter disease, atrophy or heterotopias. Despite the high yields, approximately 15% of children with CP will have unrevealing MR images (Reid et al. 2013). MRI is also recommended for children with global developmental delay. The yield is increased in children who show abnormalities of head size, focal examination or seizures.

Array comparative genetic analysis has replaced high-resolution karyotype and subtelomeric fluorescent in situ hybridisation as the first-line evaluation for children with global developmental delay, children with autism who manifest intellectual disability and children with motor delay who show evidence of other clinical indicators. Array comparative genomic hybridisation (aCGH) allows for the provision of prognosis and recurrence risks, improves access to resources, helps limit further investigations and may alter medical management in many cases (Cameron et al. 2012). It has led to the delineation of novel genetic syndromes associated with developmental delay. The application of microarray analysis to children with CP is just starting to be appreciated (McMichael et al. 2014). Although evaluation of populations of children with CP has not been revealing, individual children with severe CP and intellectual disability have been shown to have abnormal arrays (O’Callaghan et al. 2012).

Chromosomal microarray analysis detects aneuploidies, well-characterised microdeletion/microduplication syndromes, and subtelomeric or other unbalanced chromosomal rearrangements. In addition, aCGH can uncover numerous copy number variants (CNVs) of unclear significance. This method is the most sensitive method for providing an aetiological diagnosis in global developmental delay. It is abnormal in approximately 8% of those with global developmental delay/intellectual disability and about 11% of those with syndromic features (Kang and Koo 2012). Microarray testing has delineated novel genetic syndromes. As experience increases, the CNVs of unclear significance will be further characterised.

Recently, whole-exome sequencing has become clinically available and holds promise for identifying the genetic cause of an increasing number of rare mendelian disorders or highly penetrant new point mutations (Sherr et al. 2013). It has greater resolution than microarray analysis and has yields in 25–30% of patients (Yang et al. 2013). At present its use should be restricted to families who are desirous of additional testing after microarray analysis has been unrevealing, and performed by centres that are able to interpret the findings.

X-linked intellectual disability is estimated to account for 10% of intellectual disability in all patients. Panels that test for genes associated with linked intellectual disability are available and should be obtained in boys who have a strong family history suggestive of X-linked inheritance. DNA testing for Fragile X should be included in the evaluation of children with global developmental delay (Kraan et al. 2013; Monaghan et al. 2013). Finally, mutations in MECP2 are found in 1.5% of girls with moderate/severe global developmental delay/intellectual disability, but the yield in boys is <0.5%.

Sex chromosome aneuploidies (XXX, XXY, XYY) have been associated with language impairment and social difficulties (Bishop et al. 2011; Lee et al. 2012). The prevalence of these disorders in the general population (approximately three in 1000) compared with the prevalence of preschool language disorders (6%) makes the likelihood of a positive result approximately one in 20. If associated with abnormal growth, the likelihood is increased.

Evaluation for inborn errors of metabolism has a low yield without clinical indicators. Non-specific investigation has not been recommended for children with autism, global developmental delay (provided that screening results for newborn infants are normal) or CP. Most of the common metabolic disorders can be detected on a screen of newborn infants, and the neurologist should be familiar with the local screening practice. Congenital disorders of glycosylation, cholesterol metabolism (e.g. Smith–Lemli–Opitz syndrome), mitochondrial disorders and the creatine transporter defect
are not part of the screening. Screening of newborn infants for peroxisomal disorders is possible but not widely applied as yet. EEG is recommended only if there are clinical findings to suggest epilepsy or a specific epilepsy syndrome (see Chapter 16).

Each of the parameters has some additional recommendations. Testing for lead has been recommended for children with motor delays – the latter because of the possibility of delayed onset or acquired thyroid dysfunction. Evaluation for coagulation disorders should be undertaken in children with hemiplegia.

**MANAGEMENT OF DEVELOPMENTAL DELAY/NEURODEVELOPMENTAL DISABILITIES**

Physicians assume several roles in the management of developmental delay. Primary prevention, early diagnosis, confirmation of the diagnosis, aetiological evaluations, delineation of coexisting conditions, interdisciplinary management, treatment, monitoring and advocacy are some of the roles that may be assumed by physicians. Some of these are more typical for primary care providers whereas others are assumed by consultants. However, the choice of which roles to assume is very much an individual decision.

Primary prevention has been effective in decreasing the prevalence of neurodevelopmental disabilities. Preconceptual provision of folate supplements has decreased the prevalence of spina bifida. Congenital rubella and measles encephalitis have become rare disorders because of effective immunization programmes. The incidence of bacterial meningitis has also decreased where there has been effective implementation of immunisation programmes. Physicians have been instrumental in movements to decrease the lead content of gasoline, ensure proper restraint systems for transporting infants and young children, and advocate for safe practices that decrease the chances of significant injury at the playground.

Universal screening of newborn infants, universal hearing assessment of newborn infants and programmes of developmental surveillance and screens, such as that developed by the American Academy of Pediatrics, are examples of secondary prevention. These programmes allow for early identification and early diagnosis, in the hope of providing interventions that ameliorate the adverse effects of the targeted disorders.

The evaluation and diagnosis of the child who presents with developmental delay/dysfunction are a traditional role assumed by healthcare providers. Often a preliminary diagnosis is suggested and the health provider considers alternative diagnoses, then facilitates the acquisition of additional information through which the diagnosis can be confirmed. This process is applied not only to the functional/developmental diagnosis but also to the aetiological diagnosis.

Failure to recognise significant coexisting conditions is a common reason for failed management programmes. As noted above, neurodevelopmental disabilities often occur multiply. To develop a successful, comprehensive management programme, significant coexisting conditions must be identified, diagnosed and incorporated into it, for example, the management of a preschool child with ADHD would change significantly when her underlying dyslexia has been diagnosed (Kube and Shapiro 1996).

Comprehensive management programmes differ from therapy, in that therapy focuses on the disease whereas a comprehensive management programme must not only address the disorder but also take into account the strengths and challenges of the individual, the supports (e.g. financial, cultural, linguistic, mental health) that a family may require to provide the programme, and the capacity of the community to meet the needs of the individual and the family. Comprehensive management programmes are by nature multidisciplinary. Often they have several goals with multiple objectives that have been established by several decision-makers. Programmes may span multiple agencies (e.g. school, church and government) and involve numerous service providers. When done well multidisciplinary management programmes set priorities, coordinate care and are individualised. When done poorly there is confusion, frustration and suboptimal outcomes.

Health providers can help the process by guiding the prioritisation of goals, monitoring progress in the programme and supporting the family.

Comprehensive management programmes have the following three goals: to address impairments that are caused by anatomical or physiological derangements, to minimise functional limitations that arise from the impairments and to optimise the individual’s ability to participate in society. A comprehensive multilevel management plan that addresses all the abilities and challenges of a child with a neurodevelopmental disability can be difficult to construct. We have proposed a model that defines a set of domains that ensures that major important elements are not neglected. For each of the domains the practitioners should ask ‘What is the likely adult outcome in this area?’ and ‘What is needed to optimise function in this domain?’ The model consists of the following ten points:

1. **Maintenance of physiological stability**, e.g. ensuring hydration and necessary calories, control of seizures, recognising and treating sleep apnoea and gastro-oesophageal reflux, and monitoring for medication toxicity.
2. **Nursing care**: skin, bowel, bladder care; techniques for feeding; positioning, seating and bracing.
3. **Activities of daily living**: how the individual will feed, dress, bathe and toilet him- or herself.
4. **Communication**: How will the individual make his or her needs known to others? Will he or she be an oral communicator, use a pictorial system or require technology?
5. **Mobility**: Will this person walk? What environmental modifications will be required to use a wheelchair at home or in the community? Is power mobility indicated?
6. Transport: What is the method by which this person will be transported? Can this child use standard transport methods safely or will substantial modifications be required?

7. School/work: Will this person be able to function in a general setting with modifications or will a special setting be required? What adaptations will be required to prevent his or her disability from causing secondary difficulties with educational or work achievement?

8. Leisure, play and socialisation: If a child has significant motor or cognitive dysfunction what adaptations will be required to enable social interactions? If a child is not a candidate for team activities, what individual or non-age-segregated activities may be instituted.

9. Behaviour: What are the behaviours that impede the child’s participation and how should they be addressed? What is the likely impact on adult function?

10. Living: Could the complexity of children’s care prevent them from living with their family? What supports are required to keep the child in the home? Where will this person live as an adult? Will the person be independent? What accommodations will need to be planned if the person is not?

This model is most useful for children with complex needs, but for children with mild developmental delays, who are otherwise healthy, the first six domains can be addressed quickly.

Physicians continue to provide medical therapies for people with neurodevelopmental disabilities. The range of pharmacological and surgical treatments for individuals with neurodevelopmental disabilities has increased markedly. The range of approaches for epilepsy has widened to include dietary, surgical and pharmacological agents. Spasticity may be addressed with pharmacological agents administered in a variety of ways, such as nerve blocks, in addition to physical and surgical modalities. There is a continuous stream of new agents to deal with behavioural issues (Handen and Gilchrist 2006; Kaplan and Mc Krakken 2012).

Traditionally, the pharmacological approaches to neurodevelopmental disabilities have been non-specific and have helped by addressing issues that arose from the neurodevelopmental disability. The advances in genetics have led to a new understanding of the biology of neurodevelopmental disabilities, with the potential for targeted pharmacological interventions. Studies of targeted pharmacotherapy are under way to determine whether the course of selected neurodevelopmental disabilities can be altered or cured (Hampson et al. 2012).

Advocacy is a major role assumed by physicians and other health providers, and may occur at multiple levels. At the most basic level, the advocacy may be facilitating the family’s ability to obtain services through referrals, enabling the family to be educated about the child’s disorder through parent groups or websites for their specific disorder/syndrome, writing necessary letters or making phone calls. Becoming involved in the community to develop educational, recreational and leisure programmes for children with disabilities, and educating providers of other disciplines, are additional roles that physicians may assume. Finally, physicians may work with others, either through their professional organizations or together with other disciplines, to effect systemic changes that benefit all people with a developmental disability.

Monitoring is a critical aspect of management. The primary objective of monitoring is to ensure that the prescribed programme is working. Failure of a treatment programme may be due to one of the following: a wrong diagnosis, an incomplete diagnosis, the wrong therapy, (incorrect administration of therapy, insufficient therapy, conflicting therapies, therapist factors, non-compliance, inability to generalise to real-life situations, incomplete/insufficient parent education, competing family factors, changing needs of the patient, age/maturational effects and insufficient resources. The needs of children and their families change over time. As a result, children’s health, learning, and adaptive and behavioural goals must be reassessed and developmentally based. Monitoring visits also afford the health provider an opportunity to answer questions raised by the family, address issues that have arisen as a result of the child ageing (e.g. school demands), prepare caregivers about anticipated future changes that will occur as the child ages (e.g. onset of menses), deal with considerations that need to take place as parents age (e.g. estate planning or guardianship) or deliver new information about the child’s condition. A periodic review should include information about the child’s health status, as well as his or her functioning at home, at school and in other social contexts. Other information, such as formal psychoeducational testing, may be needed. Monitoring visits should take place at times when rapid change is expected, when there are transitions, if there are new symptoms or if there is insufficient progress.

CONCLUSION

Development is the functional expression of brain maturational. It is ordered, predictable and predictive. ‘Neurodevelopmental disabilities’ is a term used to describe syndromes of aberrant development, and may result from a wide range of aetiologies that cause diffuse brain dysfunction. Often, neurodevelopmental disabilities occur multiply. The dysfunction may be appreciated immediately or may not be appreciated until the demands of the situation exceed the individual’s abilities. Comprehensive management programmes for children with neurodevelopmental disabilities must be comprehensive, prioritised and coordinated to be successful.

Autism Spectrum Disorder and Autistic-Like Conditions

Anne O’Hare and Roberto Tuchman

DEFINITION

When autism was first described in 1943 by Kanner, he described 11 children with an inability to relate to other people, but a heightened ability to attend to change in the non-social environment (Kanner 1943). Autism spectrum disorders (ASDs) now refer to a behaviourally defined group of neurodevelopmental disorders that are characterised by these social–communicative deficits combined with restricted and repetitive behaviours and interests. Autism was incorporated into The Diagnostic and Statistical Manual of Mental Disorders (DSM) only by 1980. Now, the recently published DSM-5 (American Psychiatric Association 2013) has moved away from this categorical description to a developmentally based, dimensional conceptualisation of ASD (Lord and Jones 2012). In both the DSM-5 and the upcoming International Classification of Diseases, 10th (ICD 10) (WHO 2015), all children meeting diagnostic criteria are regarded as having an ASD. The earlier subtypes of autism have been replaced by these recent classifications which place language function as both part of the social–communicative domain and a modifier of autism symptomatology.

There are several important points to consider in the diagnosis of an individual with ASD. First, the diagnosis of an ASD remains behaviourally based, and there are no current neurobiological markers or specific neurological tests used to make the diagnosis. Second, ASD as a spectrum disorder includes differences in the severity and presentation of the symptoms that define it, which can range from severe disabling symptoms, such as lack of any verbal or non-verbal communication or severe repetitive self-injurious behaviours, to individuals who speak fluently but whose conversational skills are restricted to specific subjects or who are obsessive about particular subjects such as the weather or maps. Third, the concept of ‘the autisms’ has been proposed to conceptualise the diverse aetiologies that are associated with and may lead to an ASD (Geschwind and Levitt 2007). It is important to appreciate that aetiology does not define whether an individual does or does not have an ASD, so, for example, an individual may have fragile X syndrome (FXS) as an aetiology for an ASD, but many individuals with FXS do not meet all the criteria for an ASD despite their social interactional difficulties. Last, and as is discussed further below, there are multiple modifiers, of which level of intelligence is a major one, which differentiate the clinical presentation, developmental trajectory and outcome of ASDs (Lai et al. 2013; Anderson et al. 2014).

In the DSM-5 the two core domains used to diagnose ASDs are the following: (1) persistent deficits in social communication and interaction across multiple domains and (2) restricted, repetitive patterns of behaviour, interest or activities. A major change in the present DSM criteria has been to include language deficits within the broader social communication domain, as well as using level of language function as a modifier to describe level of function in ASDs. The overlap of ASDs with developmental disorders of language has historically been an important subject of interest and research (Savage 1968; DeMyer et al. 1981; Rapin 1998; Dominick et al. 2007). In the younger child first presenting with a language disorder severely affecting receptive language, who has no expressive language, the differentiation at a clinical level of a diagnosis of severe expressive–receptive language disorder versus ASD can be extremely difficult, especially in light of the fact that the child might have both diagnoses. It is now recognised that there are different types of language disorders in ASDs (Rapin et al. 2009) and that there are significant genetic overlaps between ASDs and disorders of language (Muhle et al. 2004; Abrahams and Geschwind 2008). The importance of recognising and describing speech and language subtypes in children with ASDs has previously been underappreciated (McCann et al. 2007).

A specific group of children who fall under the social communication spectrum are those with semantic–pragmatic language deficit disorders. This group of children, if they do not have repetitive and restricted patterns of behaviours, interests or activities, are referred to as having a social communication disorder, under language disorders, in the new DSM classification system. They were initially described in the 1980s as having difficulties with the semantic and pragmatic use of language without meeting the full criteria for ASDs, but having social–communicative deficits that overlap with those of ASDs (Bishop 1989). Deficient pragmatics, meaning the communicative use of language, especially non-verbal...
The domains that define ASDs are therefore dimensional and the degree of severity is an important part of the characterisation. It may range from requiring minimal support, through requiring substantial support to requiring very substantial support. In addition, symptoms of ASDs must be present in the early developmental period, although they may not become fully apparent or manifest until social demands exceed that individual’s capacities. This latter point is especially relevant in those with ASDs and good intellectual skills, in whom the intellectual skills allow them to learn strategies that mask their social skills deficits. In some highly intelligent individuals with ASDs there is controversy as to whether ‘autistic spectrum condition’ may be a more appropriate term because the social skills deficits in these individuals may not cause significant clinical impairment in current functioning, which is a requirement in making the diagnosis of ASD. Intellectual disability or, in those aged <5 years, global developmental delay (GDD) commonly overlap and coexist with ASDs; to make the diagnosis of both disorders the behavioural symptoms of ASDs cannot be better explained by intellectual disability or GDD and the social communication skills should be below those expected for the general developmental level (Riou et al. 2009).

In summary, the conceptualisation of ASDs in the new DSM and the forthcoming ICD-11 classification systems addresses the heterogeneity and dimensional nature of this
group of disorders through the use of specifiers or modifiers. The move away from subgroups, which had appeared in previous iterations of DSM/ICD, is now replaced by specific descriptions of cognitive level, degree of language impairment, or other neurodevelopmental or behavioural disorder such as ASD with attention-deficit-hyperactivity disorder (ADHD), association with known medical conditions, e.g. epilepsy, genetic such as Rett or FXS or environmental contributors such as social deprivation, perinatal factors or exposure to teratogens (Lai et al. 2013) (Table 29.2).

Last, the DSM now includes catatonia as one of the specific conditions associated with ASDs. Conceptualisation of ASDs, as a consequence of variation in levels of dysfunction in social communication and restricted repetitive behaviours and interests, impacted by environmental, medical, genetic and other behavioural disorders, and often without a singular genetic, neural or cognitive explanation (Happe and Ronald 2008), goes a long way towards clarifying and defining the ill-defined boundaries and limitations of previous classification systems for ASDs.

### PREVALENCE

ASDs are common (Elsabbagh et al. 2012) and affect just over 1% of the UK population, established by active ascertainment studies of 9-year-old children (Baird et al. 2006) and adults (Brugha et al. 2011). Estimates of prevalence in the United States (Bertrand et al. 2001; Centers for Disease Control and Prevention, Autism and Developmental Disabilities Monitoring Network 2014) have recently been reported as high as one in 68. However, it has been argued that this may be an over-estimate.

based on clinical and educational records (Mandell and Lecavalier 2014). Cross-sectional, active ascertainment studies identify many children and adults who were previously unrecognised as having ASDs. This similarity in prevalence between children and adults is in keeping with the hypothesis that increases in prevalence rates observed follow changes in diagnostic practice. In the general population, social skills plot out as a continuous distribution of abilities and deficits (Constantino and Todd 2000; Constantino et al. 2000, 2003a, b) and there is a continuum of the genetics of reciprocal social interaction, which is the core and distinguishing feature of ASDs (Walters et al. 1990). The continuum of social skills in the general population is consistent with what has been termed the ‘broader autism phenotype’ (BAP) (Bolton et al. 1994). Studies suggest that there are ‘autistic traits’ in families of individuals with ASDs that are subclinical, and index the BAP (Piven et al. 1997; Bailey et al. 1998; Constantino et al. 2000; Scheeren and Stauder 2008). The prevalence of this extended phenotype is four to five times greater than ASDs.

SEX

There is a strong male preponderance in ASDs and it is unclear whether this arises secondary to a true biological vulnerability for males, or is a referral or diagnostic artefact (Jeste and Geschwind 2014; Ribet and Matson 2011; Rutherford et al. 2016). Historically, the male: female ratio was reported as 3/4:1 (Fombonne 2005a), but more recent population studies have reported a smaller ratio of 2.6:1 (Idring et al. 2012; Centers for Disease Control and Prevention, Autism and Developmental Disabilities Monitoring Network 2012). The large sample from the Autism and Developmental Disabilities Monitoring (ADDM) network for ASD surveillance, conducted in 13 different sites across the United States, has been particularly informative in the debate over sex balance in diagnosis. Giarelli et al. (2010) showed, in their population, that there was no difference by sex in the average age of the first evaluation or time of diagnosis, but that girls were less likely than boys to receive a documented diagnosis of ASD. However, the study identified that these girls had features in keeping with ASDs but they had been assigned diagnoses such as intellectual disability instead.

ASD AND INTELLECTUAL DISABILITY

Intellectual disability accounts for the most salient group differences in individuals with ASDs which are noted when the groups are categorised on IQ (Witwer and Lecavalier 2008). The initial descriptions of ASDs found a high correlation of prevalence with the severity of intellectual disability, with the vast majority of children with severe intellectual disability manifesting the autistic triad (Wing and Gould 1979; Wing 1981). Recent epidemiological studies suggest that approximately 40–60% of children with ASDs have some degree of intellectual disability (Chakrabarti and Fombonne 2005; Fombonne 2005b; Charman et al. 2011). In addition, the more you look for autistic traits among populations of children with low IQ, the more likely you are to recognise them. Children with chromosomal and single-gene disorders with low IQ will show approximately a third affected by an ASD (Skuse 2007; Moss et al. 2013).

Intellectual ability not only accounts for the differences among individuals and groups of children within the autism spectrum, but is also an important factor in moderating the expression of ASDs (Matson et al. 2008a, b; Wilkins and Matson 2009), conferring risk for their coexistence with other neurological disorders such as epilepsy (Tuchman et al. 2009), as well as predicting outcome (Billstedt et al. 2007; Eaves and Ho 2008; Helt et al. 2008; Woolfenden et al. 2012a; Anderson et al. 2014). An ASD with associated intellectual disability is more likely to be associated with a specific genetic disorder and many have termed this ‘syndromic’ ASD, but it is best to define ASD if the behavioural criteria are met, and then specify the genetic or medical condition associated with it. This approach is consistent with the notion that ASD is a behavioural clinical construct and, for some children, an underlying aetiology can be increasingly identified. There are at least over 100 underlying genetic aetiologies of ASDs presently recognised and this is rapidly expanding [National Institute for Health and Care Excellence (NICE) 2011; Dawson 2010]. This avoids the misconception for families that, if no underlying cause is established, then the diagnosis of ASD itself may be called into question.

CLINICAL FEATURES OF ASDs

ASDs in the Early Years

General developmental warnings of possible ASDs in preschool children (Landa 2008) have been summarised in best practice protocols. Warreyn et al. (2014) stresses the importance of social–communicative abilities, both as early and important features seen in preschool children with ASDs and as areas for intervention because of their importance as treatment goals. She emphasises that there are three critical abilities for infants, toddlers and preschool children, as follows: imitation, joint attention and play. Problems with imitation deviate from the typical picture at 18 months in children who go on later to have an ASD diagnosis. Joint attention is a very important early deficit for children with ASDs. They may be able to show passive joint attention, whereby they follow gaze or even imperative joint attention, which is when the child is making a request, but it is the declarative joint attention, that is, the social function of sharing an interest in something with someone else, that is particularly disrupted. This is related in longitudinal studies to reduced development of later language and ‘theory of mind’, that is, the ability to impute the thoughts of others. Play is also impoverished in infants and preschoolers with ASDs. Relational and combinational play, that is, placing one object with another, emerges in typical development when a
child is aged around 14 months. This is followed 3–6 months later by symbolic play, which is the ability to create imaginary events. Symbolic play takes a number of different forms, so the child may substitute one object for another imagined object or person, or attribute a property to an object or person, such as animating miniatures, or make reference to an object person or substance that is not actually present at the time. By the age of 20 months, the child can put this symbolic play into a meaningful sequence. Children with ASDs have deficits in basic forms of play. An early lack of symbolic play, when combined with a deficit in joint attention, is highly predictive for a later diagnosis of an ASD.

A number of interventions target imitation, joint attention and play, such as the Early Start Denver model (Dawson et al. 2010). Multicentre international studies of infants at high risk of ASDs, because of an affected sibling, have identified that the trajectory of development towards the symptomatology of ASDs is after age 1 year. Early features include reduced babbling and subtle anomalies of social responsiveness, such as difficulty in emerging gesture, joint attention, imitation and response to name. This area remains a very active research endeavour and some of the subtle infant features that will be predictive of later ASD remain to be fully delineated (Jones et al. 2014).

Infants who are later diagnosed with ASDs may still have symptoms when aged <1 year that are due to their accompanying GDD. The most common presentation of lack of speech development and absence of developmental milestones is as important as positive symptomatology, especially in younger children. Significant restricted repetitive behaviours may be difficult to distinguish in the toddler years from those that are developmentally appropriate, or they may be less salient. Recent evidence-based guidelines examined the accuracy of signs and symptoms to predict ASD and reported that, across all children’s age groups, insistence on certain routines and rituals is only 50% [95% confidence interval (CI) 35, 56] sensitive. In contrast, failure in preschool children to perform ‘protodeclarative’ pointing, that is, the child trying to share interest, along with reduced gaze monitoring and pretend play, was 100% sensitive and specific (NICE 2011).

A number of recent evidence-based guidelines have also delineated screening instruments for ASDs [New York State Department of Health, Bureau of Early Intervention 1999; Le Couteur 2003; Scottish Intercollegiate Guidelines Network (SIGN) 2007; Ministries of Health and Education 2008; Academy of Medicine Singapore 2010; NICE 2011, 2012; Hathorn et al. 2014] (Tables 29.3 and 29.4). In general, even with high-risk populations of children, these instruments are primarily useful as surveillance instruments because their properties of sensitivity and specificity are not sufficient for them to be used to rule an ASD in or out. They can be useful to structure the concerns, symptoms and signs and the Modified Checklist for Autism in Toddlers (M-CHAT; Robins et al. 2009) shown in Table 29.5 is freely available in the public domain and does not require specialist ASD expertise.

**Autistic Regression**

The clinical feature of regression of skills in paediatric neurology is usually an indication for investigation of an acquired disease such as a neurometabolic disorder or paroxysmal condition such as Landau–Kleffner syndrome dysphasia. However, regression in ASDs is usually an exception. In autistic regression, there is no confirmed aetiology, no increased incidence of epileptic seizures and no indications to investigate with EEG imaging or neurometabolic screening. Therefore, it is very important to recognise this dramatic symptom of ASDs, which has been termed a ‘red flag’ for these disorders (Filipek et al. 2000; Goldberg et al. 2003; Lord et al. 2004; Luyster et al. 2005; Walters et al. 2005; Werner et al. 2005; Baird et al. 2008; Meilleur and Fombonne 2009).

Regression in ASDs usually involves loss of social communicative behaviours and, if other aspects are lost, such as motor skills, further neurological investigation should be considered. The regression can take the form of a very abrupt change in a child’s development and behaviour; in other cases it is a more gradual change, more in the nature of a stasis (Fountain et al. 2012). It is generally described as happening before age 2 years (Barger et al. 2013), although the mean age for retrospective capture of the regression in a large cross-sectional study was 25 months (Baird et al. 2008). It is often defined as the loss of language after the first three to five-word stage of acquisition, and there is also usually a loss of non-verbal communication such as gestures, along with decreased use of eye contact to regulate social interaction; there is also some social withdrawal and lack of social interest, and sometimes a loss of play skills. If the child has not reached the three- to five-word stage of language development, there may also be regression of babble and protowords, along with regression in...

social interest and variable rates of regaining of skills. There should be very careful clinical evaluation to consider whether this could be a presentation of Rett syndrome in girls (Baird et al. 2008). Therefore, in the absence of an acute neurological event, or neurological signs including epilepsy, regression in a child aged 1–3 years should be a ‘red alert’ for assessment of ASDs and signals an altered trajectory of development (Filipek et al. 2000).

Autistic regression is very rare before the age of 1 year and so, if clinicians are faced with this timing, they need to think of other precipitants such as the autism-like regression, which can accompany infantile spasms with tuberous sclerosis and usually come on between age 4 and 10 months (Desguerre et al. 2008). Also treatable conditions such as biotinidase deficiency (Weber et al. 2004) should be considered, as well as noting important features in the clinical examination, such as the trajectory of reducing occipital frontal diameter and

---

Table 29.5 Modified Checklist for Autism in Toddlers, Revised (M-CHAT-R)

Please answer these questions about your child. Keep in mind how your child usually behaves. If you have seen your child do the behaviour a few times, but he or she does not usually do it, then please answer no. Please circle yes or no for every question. Thank you very much.

1. If you point at something across the room, does your child look at it? (For example, if you point at a toy or an animal, does your child look at the toy or animal?) Yes No
2. Have you ever wondered if your child might be deaf? Yes No
3. Does your child play pretend or make-believe? (For example, pretend to drink from an empty cup, pretend to talk on a phone, or pretend to feed a doll or stuffed animal?) Yes No
4. Does your child like climbing on things? (For example, furniture, playground equipment or stairs) Yes No
5. Does your child make unusual finger movements near his or her eyes? (For example, does your child wiggle his or her fingers close to his or her eyes?) Yes No
6. Does your child point with one finger to ask for something or to get help? (For example, pointing to a snack or toy that is out of reach) Yes No
7. Does your child point with one finger to show you something interesting? (For example, pointing to an airplane in the sky or a big truck in the road) Yes No
8. Is your child interested in other children? (For example, does your child watch other children, smile at them or go to them?) Yes No
9. Does your child show you things by bringing them to you or holding them up for you to see – not to get help, but just to share? (For example, showing you a flower, a stuffed animal or a toy truck) Yes No
10. Does your child respond when you call his or her name? (For example, does he or she look up, talk or babble, or stop what he or she is doing when you call his or her name?) Yes No
11. When you smile at your child, does he or she smile back at you? Yes No
12. Does your child get upset by everyday noises? (For example, does your child scream or cry to noise such as a vacuum cleaner or loud music?) Yes No
13. Does your child walk? Yes No
14. Does your child look you in the eye when you are talking to him or her, playing with him or her or dressing him or her? Yes No
15. Does your child try to copy what you do? (For example, wave bye-bye, clap or make a funny noise when you do) Yes No
16. If you turn your head to look at something, does your child look around to see what you are looking at? Yes No
17. Does your child try to get you to watch him or her? (For example, does your child look at you for praise, or say ‘look’ or ‘watch me’?) Yes No
18. Does your child understand when you tell him or her to do something? (For example, if you don’t point, can your child understand ‘put the book on the chair’ or ‘bring me the blanket’?) Yes No
19. If something new happens, does your child look at your face to see how you feel about it? (For example, if he or she hears a strange or funny noise, or sees a new toy, will he or she look at your face?) Yes No
20. Does your child like movement activities? (For example, being swung or bounced on your knee) Yes No

© 2009 Diana Robins, Deborah Fein and Marianne Barton.
onset of the midline hand stereotypies that can characterize Rett syndrome (Lam et al. 2000). In addition, there can be developmental ‘setbacks’ emerging as early as age 16 months for children dealing with a profound visual impairment (Dale and Salt 2008).

If there is loss of well-established verbal language skills after age 30–36 months, an epileptic encephalopathy, such as continuous spike waves during slow-wave sleep epileptic aphasia or Landau–Kleffner syndrome should be considered (Tuchman 2009; Deonna and Roulet-Perez 2016). These conditions may have very subtle outward signs of seizures, so the possibility that this is a paroxysmal disorder may be overlooked; in the case of Landau–Kleffner syndrome dysphasia, no seizures may be evident at all. Some of the features of Landau–Kleffner syndrome dysphasia in the expressive language, such as naming difficulties, verbal paraphrasias, telegraphic speech and neologisms, have a different quality to the stereotyped echolalic speech of children with ASDs, but there is some degree of overlap and mutism can occur in both regressions.

ASDs in School-Aged Children and Young People

Children who have normal intellect may not be diagnosed with their ASD until they start school (Williams et al. 2008), when the pressures to conform to the teacher’s agenda, work in groups and establish friendships with peers are noted to be impaired. Children who present in this age group seldom have impaired acquisition of language milestones, but they do have pragmatic impairments. Such children were often previously diagnosed as having Asperger syndrome, but this is a term that has now been discontinued under DSM-5 (Rapin and Dunn 2003). In this school-age group, such pragmatic impairment may manifest itself through either difficulties in conversing, such as failing to take account of the listener's needs, or problems understanding non-verbal language such as idioms and metaphors (Hutchins et al. 2012). In addition, the child's speech may be unusual due to abnormal prosody (McCann et al. 2007). Prosody is the suprasegmental aspect of speech that results in variations in pitch, fundamental frequency, loudness, pauses, intonation, stress and rhythm, and thus affects the meaning of what you say. It has an important function of conveying emotion, and even in able young people with ASDs it can be strikingly unusual, such that their speech sounds robotic, and can present a significant social barrier.

These pragmatic language impairments may be voiced by the referent but, alternatively, a school-aged child’s presentation can appear entirely behavioural. Comorbid conditions, such as oppositional behaviour, aggression and depression, ADHD and Gilles de la Tourette syndrome, are common (de Bruin et al. 2007a; Tuchman 2013a). These may be impair function more than the underlying ASD (Simonoff et al. 2008).

There may be poor coordination and children have often received prior diagnoses such as developmental coordination disorder (DCD), dyspraxia, benign hypotonia, hypermobility syndrome, congenital ataxia, and deficits in attention, motor control and perceptual abilities. Both ASD and DCD can present with emotional difficulties and poor social skills and children with DCD have similar difficulties recognising emotional states from facial expressions (Cummins et al. 2005). Frequently there are difficulties experienced in school as a result of poor handwriting, which can be compounded by dyslexia and difficulties with imaginary thought that affect composition. Alerting signs and symptoms of possible ASD in school-aged children and young people are shown in Table 29.6. The diagnosis of an ASD in adolescence can present particularly difficult diagnostic challenges, so it is critical to gather information from settings outside the clinic. Additional alerting signs are shown in Table 29.7. There are a number of structured questionnaires that can be completed by parents and teachers which can be very useful in this regard (Constantino 2002).

COEXISTENCE OF ASDs WITH GENETIC AND NEUROLOGICAL DISORDERS

Genetic Disorders

There is significant coexistence of the ASD phenotype with multiple genetic disorders (Zafeiriou et al. 2007; Garg et al. 2013), metabolic disorders (Zecavati and Spence 2009), neurological disorders such as Duchenne and Becker muscular dystrophy (Komoto et al. 1984; Wu et al. 2005; Hendriksen and Vles 2008, Young et al. 2008a), tuberous sclerosis (Gillberg et al. 1994; Tuchman 1994; Curatolo et al. 2004; de Vries 2008; Jeste et al. 2008), sleep disorders (Richdale 1999; Schreck et al. 2004; Oyane and Bjorvatn 2005; Allik et al. 2006; Malow et al. 2006; Goodlin-Jones et al. 2008) and epilepsy (Tuchman and Rapin 2002; Roulet-Perez and Deonna 2006; Garcia-Penas 2008; Munoz-Yunta et al. 2008) (Table 29.8).

The reported prevalence of ASDs in boys with FXS has a wide range and ASDs have been described in as many as 67%, with 90% of boys displaying at least one behaviour that is characteristic of ASDs. There also appears to be a drift towards meeting ASD criteria as children affected with FXS get older. There seems to be some evidence that social behaviours, such as avoiding group activities, not responding to joint attention and lacking empathy, along with repetitive behaviours, distinguish boys with FXS ASD from boys with just FXS. Repetitive behaviours related to stereotyped object play may be the best single predictor of ASD in boys with FXS (Brock and Hatton 2010).

Rates of ASDs in tuberous sclerosis complex vary (Jeste et al. 2014). Numis et al. (2011) described it in 40% of individuals with TSC1 gene, more commonly with an earlier age of seizure onset and more frequent seizures. The affected individuals had EEGs with a greater amount of interictal epileptiform features in the left temporal lobe, but no difference in the regional distribution of tuber burden.

Reproduced with permission from the National Institute for Health and Care Excellence (2011).

Numerous disorders with intellectual disability, an ASD and known genetic deficits have been described, and the genes of several of these syndromes have been linked to aberrant synaptic protein synthesis, suggesting a possible common pathway leading to the autism phenotype and cognitive impairment (Kelleher and Bear 2008; Jeste and Geschwind 2014). Recent evidence-based guidelines in the UK (NICE 2011) listed the frequency of coexisting medical conditions in ASD.

Cerebral Palsy

There is considerable overlap of diagnoses between cerebral palsy and ASDs (Surén et al. 2012). ASDs have been reported in 6.9% of children with cerebral palsy overall, with 18.4% in non-spastic subtypes, particularly the hypotonic subtype. There is no increased incidence of epilepsy for children with cerebral palsy who have a comorbid ASD (Christensen et al. 2014).

Visual Impairment

Children with a visual impairment are considered to be at greater risk of ASDs, but there is complexity to the clinical features because of the overlap in symptomatology that is common to children who are congenitally blind and those affected by an ASD. Williams et al. (2014) advise that symptoms suggestive of ASD in sighted children can be less clinically significant in children who are congenitally blind, and this includes repetitive or stereotyped finger or hand movements, repetitive interests or stereotyped behaviours, absence of pointing, limited range of facial expressions, undue sensitivity to noise, difficulty with imaginative play by parent report and difficulty establishing age-appropriate friendships. However, blind children who are congenitally visually impaired and do not have an ASD are more appropriately responsive to social situations and make appropriate social overtures. They also display shared enjoyment, as well as being able to offer comfort and direct others’ attention. Problematic maladaptive behaviours such as aggression towards family and non-family members, as well as self-injury, are often more problematic behaviours reported in blind children with an ASD than in those with uncomplicated congenital visual impairment. There have also been reports that some blind children experience a lessening of autistic symptoms after age 5, even to the extent that they no longer meet criteria for an ASD (Hobson and Lee 2010).

Hearing Impairment

Children with ASDs have unusual listening behaviour and are inattentive to voice and language. Jure et al. (1991) demonstrated that the increase in ASDs for children with a hearing impairment can usually be explained by both conditions having a common aetiology. It has been described for individuals with congenital rubella and cytomegalovirus (CMV) (Ivarsson et al. 1990, Yamashita et al. 2003, Sweeten et al. 2004).

PERINATAL AND NEONATAL RISK FACTORS FOR ASDs

The aetiology of ASDs is often unknown, although there is a high concordance rate in monozygotic twins of 60–92% compared with 0–10% in dizygotic twins, so genetic influences are clearly very important (Jeste and Geschwind 2014). The lack of complete concordance in monozygotic twins indicates that there is likely to be a role for environmental factors. ASD aetiology is likely to be polygenic and potentially epistatic if these environmental factors interfere with genetic factors, resulting in increased risk (Larsson et al. 2005).

The relationship between perinatal and neonatal factors and the expression of ASDs appears complex (Calderon et al. 2010, 2014). In a meta-analysis Gardner et al. (2011) reported inconsistent results, but the strongest evidence for association with ASD risk includes abnormal fetal presentations, umbilical cord complications, fetal distress, birth injury or trauma, multiple birth, maternal haemorrhage, summer birth, low birthweight, small for gestational age, congenital malformation, low 5-minute Apgar score, feeding difficulties, meconium aspiration, neonatal anaemia, ABO or rhesus (Rh) incompatibility and hyperbilirubinaemia. An increased risk of an ASD and associated social communication difficulties has been reported in preterm infants (Johnson et al. 2011).

CMV has been linked with a teratogenic influence affecting the migration of neural cells from the ventricular zones to the cortex during gestation. Resulting neurological disability can include ASD (Engman et al. 2010).

Maternal intake of periconceptional folic acid has been associated with a reduced ASD risk in a large population-based case–control study, with almost a 40% reduction in ASD risk. Although it is not known whether the association with an ASD is causal, there is consistency across a range of studies (Surén et al. 2013; Schmidt 2013).

A parental history of some forms of psychiatric illness confer an increased risk of ASDs in offspring. The NICE (2012) described these in parental schizophrenia, affective disorder, and other mental and behavioural disorders. Rai et al. (2013)
described an increased risk of ASDs for cases of ASDs without intellectual disability, where there was a prenatal history of maternal depression with some additional risk from antidepressant use. Rates of parental psychiatric conditions at the time of the affected infant’s birth have been described in 18.6%, incorporating schizophrenia-like psychosis, affective disorder or substance abuse (Larsson et al. 2005).

**DIAGNOSTIC TESTS FOR ASDs**

There are a variety of specialist diagnostic tools that can be used in the assessment of ASDs which are regarded as criterion standards for research. They require specialist training and can be lengthy in their administration, e.g. the Diagnostic Interview for Social and Communication Disorders (Wing et al. 2002) takes 3 hours to administer and the Autism Diagnostic Interview Revised (Lord et al. 1994), which is appropriate for children with a mental age of ≥18 months can take 1–2 hours to administer. It is generally accepted that multidisciplinary approaches to assessment and diagnosis are the criterion standard in clinical practice, with use of a number of different professionals who can employ formal assessment mechanisms and where clinical judgement remains critical, because there are no criterion standard assessments with optimum sensitivity and specificity across all age groups and complexity of development for children with a potential ASD (Samtani et al. 2011).

**INDIVIDUAL PROFILING**

**Neuropsychology**

Neuropsychological correlates include impairments in executive functioning, weak central coherence and deficits in theory of mind tasks, which look at whether the person can take on the perspective of another person (Korkmaz 2013). Weak central coherence is integrating information into meaningful wholes and executive functioning explores the ability to simultaneously engage in multiple tasks.

Executive functioning skills are goal-directed behaviours which include planning, working memory, multi-tasking and flexibility, and deficits can be seen in ASDs; some consider them to be related to social and non-social difficulties. Neuropsychiatric conditions are associated with executive functioning difficulties; Clark et al. (2002) have suggested that executive dysfunction can outweigh verbal intelligence as a predictor of adaptive functioning and achievement.

Children with sensory modulation disorders show intense and prolonged negative responses towards everyday sounds, sights, tastes, smells, movements and touch, leading to labile emotionality and mood, with heightened stress and behaviours to avoid the input; this can be combined with maladaptive behaviour of aggression. Rates can be very high, affecting over half of children with ASD and Ben-Sasson et al. (2013) showed that high rates of sensory over-responsivity were associated with high levels of family life impairment and parenting stress, and persisted. Parents may have to compromise participation in community activities and social interactions, as well as taking avoidance procedures in activities of daily living; this was reported in the toddlers whom Ben-Sasson et al. were profiling. It has also been shown to be the case for older children with Asperger syndrome (Epstein et al. 2008). In addition, this parental stress is related to levels of executive dysfunction.

**Epileptic Seizures**

The prevalence of epileptic seizures in individuals with ASDs and intellectual disability is 21.5%, compared with 8% in those of normal intellect (Amiet et al. 2008). In the largest sample studied to date, 5815 children first diagnosed with ASDs, drawn from three genetic database populations and one epidemiological population, the two major risk factors for associated epilepsy in ASDs were IQ and age (Viscidi et al. 2013). The two major findings of this study were that the average prevalence of epilepsy in ASDs was 12%, reaching 26% by adolescence, and that one standard deviation (SD) increase in IQ decreased the odds of epilepsy by 47%. In addition, this study found that developmental regression was not a risk factor for developing epilepsy in that sample of children with a first diagnosis of ASD.

Multiple studies on regression and epilepsy have demonstrated that there is no increase in epileptic seizures associated with the preschool regression seen in ASDs (Shinnar et al. 2001, Valicenti-McDermott et al. 2008). The timing of the regression and the features of the language impairment are important considerations to orient the clinician to the possibility of ASDs as opposed to other conditions associated with loss of speech (Korkman et al. 1998; Tagawa et al. 1999; Wheless et al. 2002; McVicar et al. 2005; Trevathan 2005; Gallagher et al. 2006).

ASDs and epilepsy share genetic variants and pathophysiological mechanisms such as dysregulation of excitation/inhibition imbalance, caused by defects in either GABAergic fibres or γ-aminobutyric acid (GABA)-receptor function (Jeste and Tuchman 2015). Children with epilepsy are at high risk for developing ASDs and social cognitive impairments (Tuchman 2013b). In a large community-based cohort of childhood onset epilepsy (n=555) followed prospectively, 30% of children with infantile spasms and intellectual disability had a diagnosis of ASD (Berg et al. 2011). The bidirectionality of the ASD–epilepsy relationship suggests that there should be a high degree of vigilance for epilepsy in children with ASDs, and for ASDs and social cognitive impairments in children with epilepsy.

The complex relationship between epilepsy and ASD has recently been extensively reviewed (Tuchman et al. 2010a, b).

**Clinical Features (Physical)**

There are certain physical features to pay attention to over and above the behavioural features that may assist in establishing
Chapter 29 Autism Spectrum Disorder and Autistic-Like Conditions

Table 29.9 Differential diagnosis for autism spectrum disorders (ASDs)

| Consider the following differential diagnoses for ASDs (see corresponding chapters) and whether specific assessments are needed to help interpret the ASD history and observations: |
| Neurodevelopmental disorders |
| - Specific language delay or disorder |
| - Intellectual disability or global developmental delay |
| - Developmental coordination disorder (DCD) |
| Mental and behavioural disorders |
| - Attention-deficit–hyperactivity disorder (ADHD) |
| - Mood disorder |
| - Anxiety disorder |
| - Attachment disorders |
| - Oppositional defiant disorder (ODD) |
| - Conduct disorder |
| - Obsessive–compulsive disorder (OCD) |
| - Psychosis |
| Conditions in which there is developmental regression |
| - Rett syndrome |
| - Epileptic encephalopathy |
| Other conditions |
| - Severe hearing impairment |
| - Severe visual impairment |
| - Malnutrition |
| - Selective mutism |

The range of investigations for establishing an underlying aetiology for ASD is extremely wide; it must be informed by the presenting history and physical examination, with a particular note of any dysmorphic features. The heterogeneous aetiologies of non-genetic ASDs require tailored investigations, for example, exploration of an intrauterine CMV infection (see Chapter 2). A hearing test must always be performed, but potentially the most helpful investigations are genetic.

INVESTIGATIONS

The underlying aetiology. The differential diagnosis of the aetiology is very wide (Table 29.9) (see Chapter 5) and it is important to pay attention to any evidence of dysmorphism (Timonen-Soivio et al. 2015), suggesting genetic or teratogenic aetiologies with assessment of growth parameters and body habitus, particular attention to the size of the occipitofrontal circumference, and clear observations and descriptions of any stereotypies or unusual movements observed. The ‘fetal teratogen face’ is considered to arise from exposure to substances that affect the central nervous system; it is seen in children exposed to anticonvulsants and has similarities to that seen in children exposed to alcohol, both of which have been implicated in ASDs (Christensen et al. 2013). The facial ‘gestalt’ includes a short palpebral fissure, smooth philtrum and thin upper lip. There may be evidence of epicanthic folds, macrocephaly and hypoplastic nasal alae (Moore et al. 2000) (see Chapter 5).

Girls with ASDs should be carefully monitored for signs indicative of Rett syndrome, particularly head growth deceleration (Young et al. 2008b).

The environmentally modulated movement disorders of stereotypies are highly suggestive of ASDs, particularly abnormalities of gait and hand-and-finger stereotypies, especially atypical gazing at fingers and objects. In ASDs, stereotypies do correlate with the severity and intellectual impairment (Goldman et al. 2009). Persistent toe walking is common and associated with hypotonia. It is often benign and only evident intermittently, for example, when the child walks in bare feet, although, for some children, it can contribute to the development of secondary motor deformity (Barrow et al. 2011; Shetreat-Klein 2014).

There is some controversy over the significance of an enlarged orbitofrontal cortex in children with autism. There are some studies that show a decreased head circumference at birth compared with control groups, but then one that increases in age more than in the control group up to adolescence. Some studies have shown that this correlates with an enlarged brain volume (Sparks et al. 2002; Redcay and Courchesne 2005; Stanfield et al. 2008). Marked macrocephaly is associated with the PTEN genotype (Table 29.10).

INVESTIGATIONS

The range of investigations for establishing an underlying aetiology for ASD is extremely wide; it must be informed by the presenting history and physical examination, with a particular note of any dysmorphic features. The heterogeneous aetiologies of non-genetic ASDs require tailored investigations, for example, exploration of an intrauterine CMV infection (see Chapter 2). A hearing test must always be performed, but potentially the most helpful investigations are genetic.

Genetic Testing

Advances in genetic technology can now result in a diagnostic yield of aetiology in ASDs of 30–40%. Table 29.10 summarises the ASD genotypes with their phenotypes.

This yield is likely to increase even more with next-generation sequencing (Jeste and Geschwind 2014). An empirical recurrence risk in individuals without an identifiable aetiology is 3–10%. There is some modification for sex so risk is 7% if the child is a girl and 4% if the child is a boy, but if there are multiple children already affected with ASDs then there is a 30% recurrence risk (Schaefer et al. 2013). Rosti et al. (2014) argue that a good starting point to consider genetics is to distinguish between the ASD without an identifiable aetiology, for which the phrase ‘essential’ ASD is coined; such cases make up about 75%. These are children who lack dysmorphic features, have a high male:female ratio, a higher sibling recurrence rate and a positive family history. The sibling recurrence rate is up to 35% and a positive family history of up to 20%. Rosti et al. (2014) propose that a ‘syndromic’ ASD, that is, one that is characterised by accompanying recognisable patterns of dysmorphology, a reduced male:female ratio (3.5:1), a lower recurrence risk (4–6%) and a family history, occurs to a lesser extent (up to 9%). They propose that single gene disorders are mainly metabolic conditions that have accompanying ASD features (Table 29.11).

Schaefer et al. (2013) suggest a first- and second-tier investigation approach for the genetic investigations for individuals with ASDs (Table 29.12).

Rett syndrome and examination of mutations in the MECP2 gene need to be considered for girls who present with
ASDs. When individuals with Rett syndrome with an earlier diagnosis of an ASD are compared with those with a first diagnosis of Rett syndrome, the differences tend to reflect the fact that there is better preservation of speech in the former, with less involvement of hand use and more persistence of ambulation. Most MECP2 mutations will be identified on whole-exome/whole-genome sequencing, and 17.6% of patients with MECP2-positive Rett syndrome have an earlier diagnosis of ASDs (Young et al. 2008b). MECP2 mutations have been linked to a range of clinical phenotypes beyond ASDs. A novel A140V MECP2 mutation was identified in a 12-year-old girl who had experienced some earlier difficulty socialising with her peer group, showed a preference from early school age for routine and had severe non-verbal learning disability. She became increasingly withdrawn and then disinhibited with obsessive–compulsive behaviour, and received a diagnosis at

From Rosti et al. (2014). CHA, congenital heart abnormalities.
Role of Cranial Imaging

Cranial imaging may be indicated as part of the assessment of an accompanying learning disability, but is not indicated as such in the investigation of the aetiology of the ASD. There is a lack of definitive data with respect to the role of imaging in elucidating the neurobiology of ASDs (Volkmar et al. 2014). However, the limbic system appears to be involved from some postmortem studies and functional magnetic resonance imaging (MRI) has identified difficulties during tasks of social and affective judgement, and processing of facial and non-facial stimuli. Structural MRI shows that the brain size is increased in ASDs and diffusion tensor imaging suggests that aberrations in development of the white matter track occur. However, this information remains at the research level and does not support cranial imaging in everyday aetiological investigation for ASDs.

Additional Investigations

Investigation for iron deficiency anaemia, nutritional deficiencies and lead levels needs to be judged on an individual basis. Children with ASDs can have complex restrictive diets and amino acid deficiencies; lower bone density has been described against age-matched control groups (Arnold et al. 2003; Hediger et al. 2008; Keen 2008) and there are differences in nutritional intakes (Hyman et al. 2012). However, reports differ. Emond et al. (2010) reported no difference in energy intake or growth for children with ASDs.

INTERVENTIONS

Most interventions in ASDs are evaluated against outcomes such as cognition, language or amelioration of maladaptive behaviours, rather than by quality of life. There are particular challenges to assessing quality of life in ASDs because the children may not have the language skills to express their views, or they may have difficulty identifying, discriminating and describing their emotional state. However, several possible indicators of quality of life in ASD, such as social support, academic functioning or satisfactory employment, family life and self-determination, are all important to keep in mind when advising parents (Burgess and Gutstein 2007).

This is particularly the case if the clinician is considering pharmacological treatments because these can be effective, but they have only a limited role in addressing particular symptoms and should be considered only after careful deliberation of the risks and benefits (Volkmar et al. 2014). They are generally considered for the treatment of comorbid psychiatric or neurodevelopmental conditions in ASDs, and are usually a short- to medium-term intervention. Pharmacological treatments by or in collaboration with clinicians who have appropriate training and experience include risperidone for the short-term treatment of significant aggression, methylphenidate for the treatment of attention difficulties and hyperactivity, and melatonin for the treatment of intractable sleep problems (Braam et al. 2009). A summary of the evidence for efficacy and significant side effects is shown in Table 29.13.

Children with ASDs have less total sleep duration, which includes more frequent waking at night time; this is evident from 30 months of age and persists until adolescence. This decrease in sleep duration does not appear to be entirely accounted for by the increased sleep disturbance seen for children with a learning disability. It is possible that it has a relationship to reduced behaviour and family distress in the day time. There is increasing evidence that the fundamental differences in circadian melatonin production for some children with ASDs can reduce sleep latency, so melatonin can increase the sleep duration for children with ASDs (Humphreys et al. 2014).

There is a substantive literature on the neuropsychological underpinnings of symptoms, signs and surface behaviours in ASDs, and these have made a substantial contribution to informing interventions. There is a whole range of examples that incorporate a wide range of psychosocial interventions, most of which are based on behavioural theory or communication-focused therapies (Seida et al. 2009). Many of the studies had methodological weaknesses, but the overall picture was of a positive outcome, with an impression that some form of treatment was more favourable than no treatment at all. Neuropsychological insights might allow for treatment to be adapted for children with ASDs such as cognitive–behavioural therapy for anxiety, where the impairments of social skills, self-care, organisational skills, and circumscribed interests and stereotypies can be accommodated in the way that the therapy is applied (Wood et al. 2009; Ung et al. 2015).

Similarly, neuropsychological insights have informed interventions for very young children, such as targeting joint attention behaviour for infants (Whalen and Schreibman 2003; Warreyn et al. 2014), and have provided the impetus to identify the condition as early as possible in high-risk populations. Sometimes well-established neuropsychological understanding, such as that of ‘mentalising’, that is, the ability to impute the thoughts of others (Fisher and Happe 2005; O’Hare et al. 2009), may still be under development in terms of an evidence base for efficacy, but they do inform how a child’s environment might be potentially modified to support his or her difficulties (Thuermann and Goldstein 2001; Wellman et al. 2002). Information about the early impairments in ASDs also informs approaches in parent-mediated programmes (Green et al. 2010).

It is of course critical to pursue evidence bases for interventions for very young children, such as targeting joint attention behaviour for infants (Whalen and Schreibman 2003; Warreyn et al. 2014), and have provided the impetus to identify the condition as early as possible in high-risk populations. Sometimes well-established neuropsychological understanding, such as that of ‘mentalising’, that is, the ability to impute the thoughts of others (Fisher and Happe 2005; O’Hare et al. 2009), may still be under development in terms of an evidence base for efficacy, but they do inform how a child’s environment might be potentially modified to support his or her difficulties (Thuermann and Goldstein 2001; Wellman et al. 2002). Information about the early impairments in ASDs also informs approaches in parent-mediated programmes (Green et al. 2010).

Communication is a major focus of intervention, and alternative communication modalities such as sign language, visual supports and picture exchange may be indicated. Programmes to enhance social reciprocity and pragmatic language skills may be appropriate. Structured educational models can show some efficacy such as the Early Start Denver Model (Dawson et al. 2010) and the Treatment and Education of Autism and Related Communication Handicapped Children’s Programme (Schopler 1994). These are reviewed in in the 2014 review ‘Practice parameters for assessment and treatment of children and adolescents with autism spectrum disorder’ (Volkmar et al. 2014).

Although there are a number of other techniques working on sensory modulation difficulties and trying to help through social pragmatic models of intervention, a clear evidence base for their efficacy can be outstanding (Volkmar et al. 2014).

Sensory modulation difficulties are prevalent in ASDs. In addition to addressing areas of need in activities of daily living, executive function, handwriting and other motor skills, occupational therapy is often considered in order to promote the ability of the child with an ASD to manage sensory processing. There are two main approaches including sensory integration therapy, which is child centred and usually clinic based, and sensory-based intervention, which employs environmental modification. The evidence base for both approaches is presently insufficient to advocate one over the other (Lang et al. 2012; Case-Smith et al. 2014).

**PROGNOSIS**

There are a number of broad indicators to prognosis; children may do better than these historical groups if their condition is

<table>
<thead>
<tr>
<th>Table 29.12</th>
<th>First- and second-tier genetic investigations in autism spectrum disorders (ASDs)</th>
</tr>
</thead>
</table>
| **First tier** | Three-generation family history with pedigree analysis  
Initial evaluation to identify known syndromes or associated conditions:  
Examination with special attention to dysmorphic features  
If specific syndromic diagnosis is suspected, proceed with targeted testing  
If appropriate clinical indicators present, perform metabolic and/or mitochondrial testing (alternatively, consider a referral to a metabolic specialist)  
Chromosomal microarray: oligonucleotide array–comparative genomic hybridisation or single nucleotide polymorphism array  
DNA testing for fragile X syndrome (to be performed routinely for boys only)\(^1\) |
| **Second tier** | MECP2 sequencing to be performed for all girls with ASDs  
MECP2 duplication testing in boys, if phenotype is suggestive  
PTEN testing only if the head circumference >2.5 standard deviations above the mean  
Brain MRI only in the presence of specific indicators (e.g. microcephaly, regression, seizures and history of stupor/coma) |

\(^1\)DNA testing for fragile X syndrome in girls if indicators present (e.g. family history and phenotype).

MECP2, methyl-CpG-binding protein 2; PTEN, phosphatase and tensin homologue.

*A positive response in this study was defined as a >25% reduction in the ABC subscale and a Much Improved or Very Much Improved rating on the Clinical Global Impression–Global Improvement (CGH).

'Study identified as funded by pharmaceutical industry.'
recognised early and they have early intervention (Pickles et al. 2016). Prognosis can also be affected by the underlying syndromic explanation for an ASD, if one exists. Thus, discussion of prognosis is complex and one may not be in a position to predict too far ahead at the time of early diagnosis, although it is important to remember that parents value good quality information and also an opportunity to ask questions during the disclosure of their child’s diagnosis.

Anderson et al. (2014) reported a longitudinal study of individuals diagnosed with ASDs at age 2 years, who were followed up until age 19. They reported that 9% of these adolescents, who had had an intellectual assessment in the normal range at age 2, no longer met criteria for a clinical diagnosis of an ASD. In addition, there were 28% without intellectual disabilities who, although still having some degree of social impairment, were performing at an age-appropriate level in their cognitive and academic functioning. They found that this pattern of progress was quite slow to evolve in the sense that, even at the age of 9, the children still met criteria for an ASD, and they suggested that one needs to follow individuals into adult life to identify those who were going to have this very positive outcome conclusively. The converse of this research is that individuals with an identified intellectual disability at age 2 years had a much poorer prognosis and continued to meet criteria for ASDs in young adult life. Infant and toddler oral and motor manual skills in ASDs also correlate with later speech fluency (Gernsbacher et al. 2008).

Individual profiling for cognitive functioning in young children with ASDs may be valuable in terms of informing prognosis (Howlin et al. 2014). Severe language delay in childhood with no speech by age 5 years is associated with a poor outcome, as is the addition of epilepsy. Individuals with an IQ in the average range tend to maintain this when reassessed in middle adult life. The outlook for an individual living independently in adult life is much reduced if they had an IQ <70 in childhood and poor language development (Howlin et al. 2004).

Language outcome in adolescence may be similar for those with and those without language loss, but nevertheless it is poorer than the outcome that might otherwise have been expected for children who had earlier language acquisition before the onset of their regression (Pickles et al. 2009). Quality of social engagement with peers is important for prognosis, and a better functioning and ultimately improved quality of life for individuals affected by ASDs is predicted by their skills in this area, rather than their cognitive functioning and academic achievements (McGovern and Sigman 2005).

Prognosis is not more adversely affected in children who have presented with an earlier history of regression and, generally speaking, this dramatic regression in infancy is not repeated in later life, although a more insidious form of regression has been described in adolescence (Billstedt et al. 2005), and there has been the very rare but dramatic presentation described of onset catatonia in adult life (Wing and Shah 2000).

Close et al. (2012) reported that specific co-occurring conditions could lead to a change in an ASD diagnosis, so that, on follow-up some years later, it was no longer current. The stability of the ASD diagnosis was much increased by the presence of intellectual disability and epilepsy, whereas it was decreased by the presence of a past hearing problem, and affected similarly by the presence of depression and behavioural and conduct problems. Delayed speech and speech problems in an intellectual disability, along with anxiety, were more likely to lead to persistence of the diagnosis. ADHD caused some change in diagnosis away from an ASD for some individuals.

Rates of epilepsy range from 1.8% to 23.7% and are generally similar to those reported in general populations of individuals with intellectual disability (Woolfenden et al. 2012a). The standard mortality rates for individuals with ASDs is two to three times higher than peers, but similar to populations with an intellectual disability alone, and epilepsy was responsible for 7–30% of these deaths (Woolfenden et al. 2012a).

**SIGNPOSTING INDIVIDUALS AND FAMILIES TO INFORMATION ON ASDs**

Affected individuals, where appropriate, and their families may also benefit from interventions to inform them about ASDs and to help them build up their own skills, such as in parenting their affected child. Children, young people and their families can be encouraged to continue to learn about ASDs through interventions and support and there is a range of sources of further information appended in recent guidelines (SIGN 2016).

The literature from the charity Research Autism (www.researchautism.net) urges the professional to ‘recognise the value of people with ASD and the contribution they can make to society, without minimising the difficulties they and their families face’. Young people have voiced that they want to be told the truth about their ASD condition and that they found the diagnosis supportive; they expressed a preference that their peers know about the kinds of difficulties that they experienced and what might help them (SIGN 2007).

Attention-deficit–hyperactivity disorder (ADHD) is a neuro-logical disorder that is manifest through behavioural symp-tomatology and defined by developmentally inappropriate levels of inattention and/or hyperactivity/impulsivity. It be-came a diagnosis in the revised edition of the third DSM-III-R (APA 1987) and built upon the previous diagnoses of attention deficit disorder (ADD), minimal brain dysfunction (MBD) and hyperkinetic reaction disorder of childhood. ADHD remains a construct that is still evolving as evidenced by the recent changes in DSM-5 (APA 2013).

Perhaps the most significant change in DSM-5 is the decision to classify ADHD as a neurodevelopmental disor-der and not include it with the Disruptive, Impulse Control and Conduct Disorders. This change separates ADHD from oppositional defiant disorder and conduct disorder and expands the focus to functional impairments. Classifying ADHD as a neurodevelopmental disorder will emphasise the possibility of co-existing disorders and may lead to more comprehensive assessment across multiple domains of function. The end result being faster access to the full complement of therapeutic interventions for the full array of impairments associated with ADHD (Tannock 2013).

The symptoms listed for ADHD were originally designed for school-aged children. Since DSM-IV it has become clear that ADHD precedes school and extends into adulthood. The DSM-V has made changes that attempt to address older adolescents and adults. The number of symptoms of inatten-tion and/or hyperactivity/impulsivity required for diagnosis in older adolescents and adults have been decreased from six or more, to at least five symptoms. While the questions have not changed, explanatory examples that are appropriate to older adolescents and adults are included. This may lead to increased recognition of ADHD in older populations and a resultant increase in prevalence. DSM-5 did not include changes that would modify the diagnosis in preschool children and infants.

Another substantial change is the removal of subtypes of ADHD and replacing them with specifiers of current function. This was done because the DSM-IV classification did not identify discrete subgroups with long-term stability (Tannock 2013). Other changes include removing pervasive developmental disorder and autism as exclusionary conditions, increasing the age at onset to 12 years from 7, and explicitly requiring information from at least two different informants.

The other major classification system, ICD-10 (WHO 1992) uses symptoms that mirror the DSM. The ICD lists nine symptoms of inattention, five symptoms of hyperactivity and four symptoms of impulsivity. To make the diagnosis of hyperkinetic disorder requires at least six symptoms of inatte-nition, at least three symptoms of hyperactivity and at least one symptom of impulsivity. Inattention, hyperactivity, and impulsivity must all be present for a diagnosis to be made. When comparing the systems only the ‘ADHD, combined type’ would be considered a hyperkinetic disorder. It is likely that girls, older adolescents, and adults would be less likely to be diagnosed as hyperkinetic disorder than ADHD.

The current criteria are listed in Table 30.1.

LIMITS OF THE DIAGNOSIS OF ADHD

The boundaries of ADHD are difficult to define. ADHD shares symptoms with many disorders and with typical development. At its core, ADHD is a dimensional disorder. The overlap with typical development and the lack of biomarkers has caused people to doubt the existence of ADHD as a biological entity and attribute the rising prevalence of the disorder to working parents, technology, television and environmental factors.

Other issues that limit the diagnosis relate to technical aspects. Disorders that are behaviourally defined have three issues that limit the reliability of the diagnosis. First, the same behaviour may have different names. For example, one observer may call a behaviour ‘impulsivity’, but a second observer may call the same behaviour ‘spontaneity’. In the case of ADHD this is commonly seen in the child who is described by his parents as ‘all boy’. Second, different behaviours may have the same name. Hyperactivity often is confounded by reckless behaviour. Some children with executive function difficulties have problems with planning their day while others have difficulty starting tasks. Third, different mechanisms may result in the same behaviour. Some children may not conform to classroom rules because of lack of experience while others may have significant hyperactivity.
### Table 30.1 DSM-5 criteria for ADHD

People with ADHD show a persistent pattern of inattention and/or hyperactivity-impulsivity that interferes with functioning or development:

1. **Inattention:** Six or more symptoms of inattention for children up to age 16, or five or more for adolescents 17 and older and adults; symptoms of inattention have been present for at least 6 months, and they are inconsistent with developmental level:
   - Often fails to give close attention to details or makes careless mistakes in schoolwork, at work, or with other activities (e.g. overlooks or misses details, work is inaccurate)
   - Often has trouble holding attention on tasks or play activities (has difficulty remaining focused during lectures, conversations, or lengthy reading)
   - Often does not seem to listen when spoken to directly (mind seems elsewhere, even in the absence of any obvious distraction)
   - Often does not follow through on instructions and fails to finish schoolwork, chores, or duties in the workplace (not due to oppositional behaviour or failure to understand instructions) (e.g. starts tasks but quickly loses focus and is easily side-tracked)
   - Often has difficulty organising tasks and activities (e.g. difficulty managing sequential tasks; difficulty keeping materials and belongings in order; messy, disorganised work; has poor time management; fails to meet deadlines)
   - Often avoids, dislikes, or is reluctant to do tasks that require sustained mental effort over a long period of time (such as schoolwork or homework, preparing reports, completing forms, reviewing lengthy papers)
   - Often loses things necessary for tasks and activities (e.g. school materials, pencils, books, tools, wallets, keys, paperwork, eyeglasses, mobile telephones)
   - Is often easily distracted by extraneous stimuli (for adults and older adolescents, may include unrelated thoughts)
   - Is often forgetful in daily activities (doing chores, running errands, returning calls, paying bills, keeping appointments)

2. **Hyperactivity and impulsivity:** Six or more symptoms of hyperactivity-impulsivity for children up to age 16, or five or more for adolescents 17 and older and adults; symptoms of hyperactivity-impulsivity have been present for at least 6 months to an extent that is disruptive and inappropriate inconsistent with the person's developmental level:
   - Often fidgets with or taps hands or feet, or squirms in seat
   - Often leaves seat in situations when remaining seated is expected (e.g. leaves place in the classroom, in the office or other workplace, or in situations that require remaining in place)
   - Often runs about or climbs in situations where it is not appropriate (in adolescents or adults may be limited to subjective feelings of restlessness)
   - Often unable to play has difficulty playing or engage in leisure activities quietly
   - Is often "on the go" acting as if “driven by a motor” (e.g. unable to be or being uncomfortable being still for an extended time, may be perceived as restless by others)
   - Often talks excessively
   - Often blurs out an answer before a question has been completed (e.g. completes other people’s sentences, cannot wait for turn in conversation)
   - Often has trouble waiting his/her turn (e.g. while waiting in line)
   - Often interrupts or intrudes on others (e.g. butts into conversations or games, may start using other people's things without asking or receiving permission, may take over what others are doing)

**In addition, the following conditions must be met:**

Several inattentive or hyperactive-impulsive symptoms were present before age 12 years

Several symptoms are present in two or more setting (e.g. at home, school or work; with friends or relatives; in other activities)

There is clear evidence that the symptoms interfere with, or reduce the quality of, social, school, or work functioning

The symptoms do not happen only during the course of schizophrenia or another psychotic disorder. The symptoms are not better explained by another mental disorder (e.g. mood disorder, anxiety disorder, dissociative disorder or a personality disorder)

Other technical issues include: How much redundancy in the symptoms is present (Mota and Schachar 2000)? How to reliably quantify the responses—How often is often? How to make the criteria more specific? How to address the special issues of preschool children? How to distinguish ADHD from other disorders?

Intellectual ability may affect the diagnosis of ADHD. Children who are intellectually advanced may achieve academically despite their inefficiencies. Some may not present for evaluation of ADHD until they attend college and lose the supports that have been provided by their families.

**ADHD ACROSS THE LIFESPAN**

ADHD is a life-long disorder. The manifestations of the disorder change with maturation. Parents may time the onset of hyperactivity to fetal life with increased fetal movements. Infants may show inability to regulate their states with resultant difficulty in establishing sleep–wake cycles. Impairment in self-organising may be seen in colic that is much more severe in degree or extends well beyond the typical age. Toddlers may be noted to run as soon as they walk.

Preschool is a time marked by high activity, fine motor control and play. Children with ADHD may show difficulty in circle time or playing games. Children may not learn from their experiences and be seen as oppositional. Temper tantrums may be more severe and more frequent. Some children show inability to effectively modulate sensory responses and overreact to tags, rumpled socks, loud noises or certain foods.

School-aged children must follow rules, listen to directions, complete tasks, and keep track of their belongings. Early school-aged children have difficulty with attention and academic achievement. Problems following classroom routines and fidgetiness may be noted. Early reading and mathematics difficulties are common. Maintaining friendships may be a challenge because of bossiness, inconsistent responses or behavioural modulation difficulties (humour as well as anger). Team sports may not be successful and accidents are not uncommon because of poor motor coordination, impulsivity and inattention. Minor trauma is common and multiple shin bruises due to play are the norm. Some children may drift and get lost while the parent is shopping.

Older children express their ADHD with impulsive acts and difficulty with higher types of learning. They face organisational challenges on an ongoing basis; completing and turning in homework, chapter reading, long-term assignments are some of the expressions of disorganisation. They push beyond the limits. Deficits in the social use of language and longer than typical time for responses may be seen.

Older adolescents may not have hyperactivity but experience low boredom tolerance and subjective restlessness. Executive dysfunction predominates in adulthood with organisation, time management and planning issues. Inattention and impulsivity adversely affect driving ability.

**PREVALENCE**

The prevalence of ADHD continues to increase. In the USA, the National Survey of Children’s Health reported that, of US children aged 4–17, 7.8% and 9.5% were reported by their parents to have ever been diagnosed with ADHD by a healthcare provider in 2003 and 2007, respectively. The third National Survey of Children’s Health (2011–12) found that 11% of US children (6.4 million) were said to have been diagnosed with ADHD by a healthcare provider. This represents a 42% increase between 2003 and 2011 (Visser et al. 2014). International data suggest a worldwide prevalence of 5.3–5.9% and a European prevalence of 4.6% (Le et al. 2014). A careful population-based study conducted in Rochester, Minnesota noted that the highest estimate (definite and probable) of cumulative incidence of ADHD at age 19 years was 16.0%, while the lowest estimate was 7.4% (Barbaresi et al. 2002).

ADHD is the most common neuropsychiatric condition seen by child psychiatrists, child neurologists and paediatricians. Despite the prevalence of ADHD, many children with ADHD are under diagnosed and do not receive treatment. The overall prevalence of ADHD makes it a public health focus but the increasing prevalence, increased health costs and adverse outcomes in academic, occupational and social spheres should make it a major community focus.

Why the prevalence of ADHD is increasing is unclear. The differences between European and US reports have been attributed to the differences in diagnostic criteria between the ICD and the DSM. When DSM-IV was implemented, the prevalence numbers increased because of greater recognition of inattentive ADHD, identification of ADHD in adults and adolescents, and discovery that presentations of ADHD in girls may have been more subtle. Case finding and differing diagnostic criteria do not explain the entire difference of the past 4 years. A large number of studies have sought, unsuccessfully, to identify environmental factors that are related to ADHD.

The incremental costs of caring for people with ADHD are high. The overall US annual incremental costs (in 2010 dollars) of ADHD for children/adolescents ranged from $32–72 billion, with the majority of costs attributed to health care ($21–44 billion) and education ($15–25 billion) (Doshi et al. 2012). In the Netherlands the average total cost ranged from €9860–14 483 per patient (in 2012 euros) and annual national costs were between €1.04–1.53 billion (Le et al. 2014). The majority of costs were attributed to education, followed by health care and social services. Loss of family productivity was also substantial.

As a group, people with ADHD have lower academic achievement and higher rates of retention (i.e. repeating a school year) and school non-completion (Polderman et al. 2002). The incremental cost of non-completion ranged from $13 000–16 100 (Doshi et al. 2012).
Inattentiveness was strongly related to academic outcomes. Many children, however, have sufficient academic performance and this serves to delay identification and diagnosis. Occupational health is also adversely affected by ADHD (Küpper et al. 2012). Low frustration tolerance, irritability and impulsivity and executive dysfunction have been related to reduced productivity and workplace impairment. Adults with ADHD are at increased risk of accidents, trauma, workplace injuries and traffic accidents.

Adults with ADHD are at risk for social dysfunction. In the UK, studies of offenders indicated around 45% of young people and 24% of male adult offenders have a childhood history of ADHD and are more likely to be disruptive when incarcerated (Young and Thome 2011). In the US, ADHD is associated with more cigarette smoking and substance use disorder (SUD) (Wilens and Morrison 2011). The cigarette smoking is less likely to remit and the SUD is more likely to be more severe and chronic in duration. ADHD treatment does not appear to predispose to SUD.

**DIFFERENTIAL DIAGNOSIS, COMORBIDITY AND CO-EXISTING DISORDERS**

ADHD is defined by developmentally inappropriate levels of inattention and/or hyperactivity/impulsivity. As a diagnosis it is too narrow for clinical use. While it describes one aspect of a child’s difficulties, it is incomplete. Children with ADHD usually have additional impairments. Many of these impairments are closely tied to ADHD; either in prevalence or in manifestations. These impairments may span academic, social, emotional, behavioural, language, cognitive and motor domains. Often they require therapeutic interventions that extend beyond the attention and hyperactivity impulsivity domains.

Every professional who sees a child with ADHD will identify an area of concern related to their discipline. Parents may be overwhelmed by the long list of descriptive diagnoses that may be assigned to their child with ADHD. Other terms suggested to broaden the description of children who fall into the ADHD classification include: DAMP (deficits in attention, motor control and perception; Gillberg 2003), ESSENCE (early symptomatic syndromes eliciting neurodevelopmental clinical examinations; Gillberg 2010), encephalopathy, developmental brain dysfunction (Moreno-De-Luca et al. 2013) and a resurrection of MBD.

Some have suggested that these impairments are not independent disorders but are manifestations of the same processes that give rise to ADHD. Consequently, these impairments may not be comorbid but co-occurring (Kaplan et al. 2006). Clinicians must decide whether the child’s dysfunction represents ADHD, a disorder that mimics ADHD (differential diagnosis), ADHD and an impairment that is a co-existing disorder, or ADHD and an independent impairment (comorbid disorder). Thus a listing of the differential diagnosis of ADHD (Table 30.2) will also contain comorbid/co-occurring disorders.

In developing a differential diagnosis, practitioners must consider the mechanism of the observed behaviour in addition to documenting the behaviour. For example, children with intellectual disability, specific learning disabilities, autism spectrum disorders, or mixed receptive language disorders may seem inattentive or excessively active because they cannot perform at the expected level. Children with anxiety, adjustment or affective disorders may be otherwise occupied and seem inattentive. Physiological derangement as in hearing loss, or thyroid, sleep or neurodegenerative disorders may mimic ADHD.

The interaction of multiple factors may need to be considered. Most often clinicians have to weigh the relative contributions of attention, anxiety and language in the diagnostic process. Sometimes this does not clarify until a course of therapy is undertaken.

**Specific Learning Disabilities**

Specific learning disabilities (SLD) are characterised by difficulty in acquiring and using academic skills at an age-appropriate level. The difficulty is not due to intellectual limitations or lack of instruction. SLD are complex constructs that may affect reading, mathematics and written expression. They may occur singly or in combination. ADHD is often seen in combination with SLD. Learning disorders and ADHD were noted in 3.7% of a national sample (Pastor and Reuben 2008). Children with isolated SLD may exhibit behaviours consistent with ADHD.

Specific reading disability may assume a number of different forms in children with ADHD. Younger children have
difficulty with basic reading (decoding). Often their deficit is in blending the sounds into words. Older children may have difficulty extracting meaning from text. While they can read every word on the page they do not derive meaning from what they have read. Clinically, students may report, ‘I spent two hours reviewing that chapter and still failed the test’.

Specific reading disability is linked closely to language abilities (McArthur et al. 2000, Snowling and Hulme 2012) and is also common in ADHD (Sexton et al. 2012). Clinical samples suggest that the prevalence of ADHD in children with specific reading disability approximates 40% (Hart et al. 2010). Rates of ADHD in children with specific reading disability range from 9% to 60%. Population studies suggest rates of 9–42.5% (Yoshimasu et al. 2010).

SLD affecting written language is also common in ADHD. Approximately 60% of children with ADHD have disorders of written expression (Yoshimasu et al. 2011). These disorders may be due to difficulty with fine motor, language or organizational dysfunction that is seen often in ADHD.

Children with ADHD also are at higher risk for mathematics difficulty (odds ratio = 2.55) (Czamara et al. 2013). Children with ADHD symptoms may misread addition and subtraction signs, misalign columns and not recall multiplication tables. They have difficulties with mental mathematics due to working memory deficits and timed quizzes.

Language Disorders

Language disorders show (see Chapter 31) persistent difficulty in the acquisition or use of language. Symptoms of ADHD show considerable overlap with disorders of communication. This overlap is further complicated by the independent relationship between SLD and language. It is extremely difficult to extricate the contributions of attention, language, working memory and anxiety to a child’s performance on an assessment instrument.

The relationship between language disorders and ADHD is bidirectional (Sundheim and Voeller 2004). Half of children with ADHD have language disorders and half of children with language disorders have ADHD. Difficulty in processing language shows similar symptoms to inattention. Excessive talking and interrupting others is seen in both ADHD and Social Communication (pragmatic) language disorders.

Autism Spectrum Disorder

Autism spectrum disorder (ASD) and ADHD overlap the social border. ASD is characterised by deficits in social communication and interaction, and restricted, repetitive behaviour, interests or activities (APA 2013) (see Chapter 29). Children with ADHD may evidence some of the characteristics that define ASD. For example, it is not uncommon for children with ADHD to exhibit variable responses to social interactions because of inattention or impulsivity, poor eye contact, misreading social cues and difficulty maintaining friendships. Difficulties modulating responses to sensory stimuli are not specific to ASD and may be seen in ADHD.

In the past, the presence of autism spectrum disorder excluded the diagnosis of ADHD. More current research shows a bidirectional relationship between ADHD and autism spectrum disorder. Studies suggest that from 20% to 30% to up to 78% of children with autism meet criteria for ADHD (Murray 2010; Taurines et al. 2012). A study of children with ADHD showed that 20% exhibited autistic traits (Kotte et al. 2013). The overlap of ASD with ADHD is in part due to cognitive, language and anxiety issues but children who ‘outgrow’ the ASD diagnosis evidence executive dysfunction and increased levels of impulsivity (Troyb et al. 2014) and some meet criteria for ADHD.

Tourette Syndrome

Tourette syndrome is a triad of multifocal tics. ADHD and obsessive compulsive features (see Chapter 20). The presenting symptom may be the tics, the ADHD or the obsessive compulsive features. The other features may develop or diminish as the child matures. While tics may develop in association with stimulant medication, children with ADHD should be monitored for the appearance of tics and obsessive compulsive features.

Intellectual Disability

Children with intellectual disability may exhibit behaviours that can be interpreted as being consistent with ADHD. While most intellectual disability is identified in the preschool period, some children with milder or borderline degrees of cognitive limitation are not diagnosed until primary school. These children may have difficulty following complex instructions and classroom routines, organising tasks, exhibit reluctance to engage in tasks that require sustained mental effort, and seem distractible or forgetful because they do not fully understand the tasks.

Intellectual disability does not exclude ADHD. Many children with intellectual disability meet criteria for ADHD. Using ICD-10 criteria, the prevalence of hyperkinesis in children with intellectual disability was 8.7%, almost tenfold more than for children without intellectual disability (Emerson 2003).

The DSM qualifies the inattentive and hyperactive domains by requiring function that is not appropriate to developmental level. It does not provide guidance as to how to determine this. Consequently, determining whether children with mild intellectual disability also meet criteria for ADHD may be difficult. For those children it may be prudent to deemphasise the diagnostic process and undertake a therapeutic trial under close monitoring (Simonoff et al. 2013).

Anxiety, Affective and Adjustment Disorders

ADHD commonly coexists with childhood psychiatric disorders. Anxiety, affective and adjustment disorders share symptoms with ADHD. They all may manifest academic underachievement but have different underlying mechanisms.
The inattention that is seen in anxiety disorders is attributed to worry and rumination while that of ADHD is due to attraction to external stimuli or preoccupation with enjoyable activities (APA 2013). Children with depressive disorders have difficulty concentrating when they are experiencing a depressive episode. Increased activity may be seen with bipolar disorder. ADHD is a frequent co-existing condition of disruptive mood regulation disorder but pervasive irritability is not a predominant feature of ADHD.

Anxiety, affective and adjustment disorders also coexist with ADHD. Approximately 25% of children with ADHD have anxiety disorders (Schatz and Rostain 2006), while depressive disorder may be present in 20% (Green et al. 1999). Adjustment disorders may be seen in children who are defeated, experience substantial negative expressed emotion, or chaotic social situations.

Oppositional Defiant Disorder

Oppositional defiant disorder (ODD) is often diagnosed in conjunction with ADHD. Approximately one-third of children with ADHD have co-existing ODD (Green et al. 1999). Young children who are in situations where they are chronically unable to perform or who are usually unable to complete tasks may exhibit the angry mood/irritable features and argumentative behaviour that defines ODD, but are more correctly considered adjustment disorders. Non-conformance with requests must be interpreted in relation to the child’s abilities and recognise the variable performance of children with ADHD. Children with the diagnosis of ODD should be evaluated for ADHD.

Substance Use Disorder

Substance use disorder may be associated with disorganisation, poor time management and inattention. Impulsivity and hyperactivity may be present with certain substances. While people with ADHD are at risk for substance use disorders, the sudden onset or worsening of pre-existing symptoms should lead the clinician to the correct diagnosis.

Sleep Disorders

The association between sleep disorders (see Chapter 18) and ADHD is unclear (Yoon et al. 2012). ADHD symptoms, particularly inattention, are seen in primary sleep disorders – excessive daytime sleepiness, restless legs syndrome, periodic limb movement in sleep, sleep disordered breathing and obstructive sleep apnoea. Twenty-five to fifty per cent of children with ADHD have sleep problems. Sleep deprivation can mimic or exacerbate ADHD symptoms but it is not clear that it causes ADHD.

Staring Spells/Epilepsy

Inattention is often manifested by staring spells. Staring spells may be seen in ADHD but are also noted in daydreaming, migraine (see Chapter 17), or absence seizures (see Chapter 16). Most staring episodes are not epileptic; however, epilepsy must be excluded as a cause of inattention. Absence seizures are associated with short (<20 seconds) staring spells, no aura or postictal drowsiness. Electroencephalographic studies with hyperventilation will help distinguish typical absence from atypical absence seizures. Staring spells that last longer than a minute and are associated with aura and postictal drowsiness may be focal seizures with impaired awareness. Absence seizures may be further separated into typical absence or atypical and absences with special features. While epilepsy is not common in children with ADHD, ADHD is seen in approximately one-quarter to one-third of children with epilepsy (Cohen et al. 2013; Masur et al. 2013).

Developmental Coordination Disorder

Disordered motor coordination and ADHD overlap about 50% of the time (Martin et al. 2006). Motor coordination issues were part of minimal brain dysfunction and included in DAMP (deficits in attention, motor control and perception) (Gillberg 2003). Falling, bumping into things and knocking things over may be due to deficiencies in motor control, impulsivity or hyperactivity. Postural instability may be misperceived as fidgetiness. Developmental coordination disorder may underlie the written language disorders and the dysarthria seen in children with ADHD.

Sensory Processing (Integration) Disorder

Sensory integration disorder is characterised by inappropriate or deficient sensory processing. Clinically, it manifests as under or over responsiveness to sensory stimuli. Children may be overwhelmed by loud noises, irritated by tags or rumpled socks, or display aversion to certain foods or smells. They may seek out certain clothing textures, crave roughhousing/wrestling, need to touch everything and be excessively affectionate. Motor dysfunction that is similar to DCD forms a subtype of sensory processing disorder. Whether sensory processing disorder is an independent disorder is still being debated. In addition to ADHD, sensory integration issues are seen in autism spectrum disorder, developmental coordination disorder and anxiety disorder (AAP et al. 2012).

Hearing Loss

Conductive hearing losses (see Chapter 23), such as those associated with otitis media are not usually associated with disorders of attention or learning. Sensorineural hearing loss, on the other hand, may be progressive in nature and may impair communication. The child with a hearing loss may have difficulty sustaining attention in tasks, does not listen when spoken to, does not follow through on instructions, may seem distracted, and may exhibit behaviour that is deemed forgetful or not giving attention to details. Special care should be taken to ensure adequate hearing in children who present with primarily inattentive symptoms.
Neurodegenerative Disorders
Symptoms of inattention, poor organisation and hyperactivity/impulsivity may be present early in the course of neurodegenerative disorders. Some children with adrenoleukodystrophy have been diagnosed as having ADHD before the full scope of the disorder became apparent. A history of worsening symptoms should raise a consideration of a progressive neurological process.

Elimination Disorders
Encopresis and enuresis are more common in ADHD than in the general population. Enuresis may be confined to nighttime wetting. In younger children, however, it is not uncommon to see the child rushing to the bathroom because the child was not reading his or her bodily signals properly and was preoccupied. Daytime urinary incontinence is associated with ADHD, while night-time enuresis does not put a child at increased risk of ADHD (von Gontard et al. 2011). Daytime enuresis is most often treated behaviourally while night-time enuresis may require pharmacological intervention.

Children with ADHD have increased rates of constipation and faecal incontinence when compared to children without ADHD. Faecal incontinence was uncommon in children with ADHD (0.9%) but was approximately six times more common than in children without ADHD. Children with ADHD had more visits than those without ADHD for both constipation and faecal incontinence.

EVALUATION
The diagnosis of ADHD rests on its behavioural characteristics. The diagnostic process is much more than an enumeration of symptoms. The clinician must elicit the symptoms from at least two sources and then interpret them. The age at onset, duration and the functional limitations caused by the symptoms must be established. Other conditions that have similar symptoms must be considered and incorporated into the diagnostic formulation. Exclusionary disorders must be appropriately diagnosed.

Behavioural checklists may assist the diagnostic process but they do not replace it. The limitations of behavioural checklists have been enumerated (Shapiro 2001). Checklists that are wide-ranging do not focus on ADHD. Those that focus on ADHD may miss important co-existing conditions.

ADHD checklists do not provide context. Parents do not have a point of reference upon which to base their responses. A very active child may have a negative checklist because his brother is much worse. The checklists do not quantify behaviour. How many fidgets equal a ‘very much’?

Reporter bias is a problem for behavioural checklists. While most checklists are supposed to represent a sample of behaviour for an extended period before the list is completed, most reporters focus on the day or two before the visit. Yesterday’s behavioural flare may obscure 3 months of good progress. The variability exhibited by children with ADHD make it difficult to capture behaviour with a single descriptor. Another bias arises because most of the symptoms are listed as negatives. Parents have difficulty reporting that many negative attributes of their child and blunt the extreme responses.

Inter-rater reliability of behaviour checklists is poor. Parents and teachers often do not agree on the child’s behaviour. The results on checklists may vary widely when a child has multiple teachers and individually completed checklists are obtained. This may reflect the bias of the reporter, the variability of the child, the demands of the class, or characteristics of the interaction of the child and teacher.

The lack of the homogeneity of the ADHD syndrome and the large number of related disorders mandate that symptoms must be obtained through skilful history taking and then interpreted by knowledgeable professionals to establish the proper diagnosis. Direct verbal interaction is the best way to establish the diagnosis of ADHD but it is time consuming and inefficient. Behavioural checklists may be adjunctive methods for obtaining information but they do not establish the diagnosis of ADHD.

AETIOLOGY
ADHD is a final common pathway of multiple pathologies. Most cases have a hereditary component but ADHD is also seen in association with many different brain insults and disorders. Prenatal exposures to alcohol, tobacco and illicit drugs have been associated with ADHD. Preterm birth, iron deficiency, lead exposure, mercury toxicity and thyroid disorders are associated with ADHD and academic dysfunction. Epilepsy, cerebral palsy, spina bifida, migraine, traumatic brain injury and brain infections are strongly related to difficulties with attention and executive function.

Searching for the aetiology of a person’s ADHD has a low likelihood of establishing a cause and a lower likelihood of altering the treatment approach. Investigations that seek to determine the cause of ADHD have been unsuccessful. There is no consistent biomarker that will make the diagnosis of ADHD. There is a strong hereditary component to ADHD, but whole exome sequencing studies have failed to yield consistent findings. Candidate gene analyses have revealed statistically significant results, but only account for a small percentage of the variance. Neuroimaging studies, while illuminating brain behaviour interactions, have not yielded consistent results. Electrophysiological approaches have held promise but are not clinically applicable. Metabolic studies have not been useful. Despite this, the medical and psychological evaluations of ADHD may prove useful in identifying important co-existing conditions that will affect the management plan.

Medical Evaluation
The majority of the medical evaluation follows the schema outlined in Chapter 28. It should include family history,
significant past events, complete review of systems, developmental and school history and behavioural history with a specific focus on ADHD. Early infancy manifestations of ADHD relative to state and activity should be noted. Inquiries relative to attention should not only focus on the primary symptoms of ADHD but also develop a picture of a child who has difficulties with the processes upon which ADHD is built. Questions about attention should extend beyond short attention and encompass over-focusing, perseveration, difficulties with transitions and variability of performance (‘Some days he hits on all eight cylinders and some days he hits on three’). Factors that modify the attentional problems should be noted.

Distractibility may include questions relating to unfinished activities that are started, multitasking, minding other people’s business more than his own, participating in conversations that are taking place in the next room. Asking how many times the child has been misplaced while the parents are shopping is a question that often yields a positive response and serves as an entry point to talking about distractibility. Another dimension of distractibility relates to environmental distractions such as the furnace starting, or someone closing a door or being disturbed when the child’s sibling quietly walks across the kitchen as the child is attempting homework. A third dimension is not paying attention to the task at hand and observing relationships that are not appreciated by others. For example, noticing a pattern in wood siding when people are walking down the aisle at church. This may be mistaken for creativity. Impulsivity is often manifested as blurt out in church, not using an ‘inside voice’ or running after a ball into the street between parked cars.

Questions about social interactions focus on whether friendships can be established and maintained, age of friends, types of activities that are enjoyed. Other questions may focus on organisation (‘Is your child’s room a mess?’), time sense (getting ready for school in the morning), completion of chores and boredom.

Mental health status should be queried. Mood, worries, depressive symptoms, routines and stereotypies should be included. Can the child modulate humour or anger? Qualitative assessment of the frequency and severity of anger/tantrums and the post tantrum insight are important aspects to consider. Stealing, fire-setting and cruelty to animals are not usually part of ADHD.

The child’s activity level should be noted. While absence of hyperactivity in an office setting does not exclude it in the classroom, its presence supports the diagnosis of ADHD. Fidgetiness and restlessness is more frequently seen but may be due to anxiety related to the evaluation. Tics may take the form of exaggerated eye blinks, throat clearing or shoulder shrugs. Lapses of attention and staring spells may be an indication for hyperventilation manoeuvres if there is no history of cerebro-vascular disease, hypertension, sickle cell disease or trait, or severe asthma.

Assessment of the child’s use of language yields important information. Can the child follow the instructions for the examination or is visual demonstration required? Is the vocabulary age appropriate? Are modifiers (adjectives and adverbs) used? Can the child tell an organised story with a beginning, middle and end? Can the child tell or understand a joke?

The physical examination should include growth parameters (including head circumference), a comprehensive physical examination including a focus on dysmorphisms, and a complete age-appropriate neurological examination. Physical findings often show subtle asymmetry of growth of the face, chest (downward and lateral displacement of the nipple) and leg. Tone is usually decreased and asymmetrical. Occasionally leg tone is increased compared to arm tone.

Soft neurological signs are developmental signs that are not diagnostic or localising but occur more frequently in ADHD. There are many of these signs but in composite they serve to demonstrate subtle abnormalities of tone, symmetry, or coordination. They have prognostic ability and relate to later behavioural outcomes. Previously, they were thought to distinguish functional from organic disorders.

Neuropsychological evaluation is not required to establish the diagnosis of ADHD. A comprehensive neuropsychological evaluation is useful for delineating the dysfunctions in learning and behaviour that are associated with ADHD and identifying disorders that mimic ADHD. Speech and language evaluations are useful in discerning difficulties in language usage, pragmatics and connected language. Educational specialists may augment the neuropsychological evaluation by using instruments that emulate the classroom experience and making recommendations that are directly applicable to classroom function. Occupational therapists can quantify fine motor dysfunction and make recommendations about compensatory and circumvention strategies that may be employed to bypass the DCD. They may also address sensory processing disorders.

**MANAGEMENT**

The management of the child with ADHD requires creativity, persistence and a long-term perspective. There are a large number of dysfunctions that accompany the diagnosis of ADHD. Fortunately, not every child has every dysfunction. In addition, all children who have accompanying dysfunctions do not have them to the same degree. This means that there is no ‘garden variety’ of ADHD and that programmes must be individualised. ‘One size fits all’ approaches will fail.

The foundations of a successful management programme are: delineation and treatment of associated dysfunctions, knowledgeable parents, educational accommodations, maintenance of the child’s self-esteem and medication.

**Delineation and Treatment of Associated Dysfunctions**

ADHD is functionally defined and, thus, is a final common pathway. It has multiple aetiologies and many associated dysfunctions that are present to varying degrees. These disorders
may limit function in the absence of ADHD. Indeed, they may be the initial diagnostic focus and the ADHD identified as a comorbid condition.

There is limited data that suggest that ADHD in combination with associated dysfunctions have worse outcomes than ADHD or the associated dysfunction occurring separately (Sexton et al. 2012). The reasons for this observation have not been elucidated. However, associated dysfunctions may be impairing by themselves and therefore, impact the ADHD management programme.

If the associated dysfunction is severe, the goals of the management programme may have to be adjusted. For example, if the ADHD is associated with severe intellectual disability, independent function as an adult is unlikely. The coexistence of a specific reading disorder may limit literacy and, ultimately, vocational choices.

Failure to recognise associated dysfunctions may delay treatment and result in suboptimal outcomes. Some associated dysfunctions may be masked by the ADHD. Anxiety may be mistaken for inattentiveness or hyperactivity. Other associated dysfunctions may not be evident until situational demands increase. Disorders of written language may not be evident in early elementary school when the tasks require only limited pencil control but they may be devastating to older students who are required to take notes in class. Associated dysfunctions, such as tics, may require ongoing monitoring but only intermittent interventions.

**Knowledgeable Parents**

Knowledgeable parents are key to a successful management programme. They will know ADHD, know how to deal with their child’s ADHD, effectively advocate for their child, and identify and establish relationships with the practitioners who work well with their families.

Parents must recognise that ADHD is a neurodevelopmental disorder and not the result of poor parenting, dietary imbalances, immunisations, or lack of sleep. They should know how to make the diagnosis of ADHD, the symptoms that define the syndrome and the broader aspects of ADHD. Parents should realise that ADHD has many expressions and that each child is unique. Children with ADHD are not lazy, stupid or oppositional, and parents should consider that their child’s failure to complete a task may be because the child is unable and not unwilling. They should be aware of the variability that is seen in ADHD; the child is not out to ‘get them’.

Parents should not only know text book ADHD, but also know how their child expresses the disorder. Some children get overwhelmed and cannot plan multipart tasks such as cleaning their room. ‘Place your dirty clothes in the hamper’, ‘Put your books on the shelf’ and ‘Put your toys away’ are more likely to have positive results than ‘Clean your room’. Setting out clothes for school the night before, using a checklist for morning activities and ensuring that completed homework is in the book bag are effective techniques that parents have used.

Children establish different routines. Some have to attend to homework as soon as they come home and complete it before dinner. Others need time to place their brain in neutral in front of a screen (television or videogame) and recover from the tremendous effort required to perform in school. Children may find the question ‘How was your day in school?’ to be intrusive and overwhelming. Parents who encounter this may do well to delay the question until the information comes out spontaneously or ask it at a time when the child is relaxed.

A knowledgeable parent can advocate for their child. They need to negotiate accommodations with the school, extracurricular activities and social situations. They need to identify and choose practitioners who are used to managing children with ADHD. Parent groups, particularly those with professional advisory boards, are useful sources of information. The sharing of information and experiences by parents provides a filtered source of information that often provides useful answers than random internet searches.

**School Accommodations**

Most children with ADHD can have their educational needs met in a general education setting with accommodations. In contrast to children with specific learning disabilities, children with ADHD are able to master the content but experience academic underachievement because inattention, hyperactivity and impulsivity impede the educational processes. Some of the accommodations used are for behaviour, some for organisation and some for disorders of written expression. Special education services should be reserved for students with SLD, autism spectrum disorder or intellectual disabilities.

Students with ADHD do better with active learning. Classroom discussions, study partners, simulations, movies and CDs, field trips and experiments are preferred over textbook or lecture-based learning. Some children require environmental modifications; seating away from the windows, doors, or noisy students, or near the teacher. Extra time, frequent breaks and alternative methods of evaluation serve to ensure that the student can demonstrate their capabilities.

Homework is a common cause of strife. The student should develop a routine for doing homework with guidance from the parents. If the written language demands are an impediment, they should be circumvented by a parent acting as a scribe. If the work load is too great, then negotiations with the teacher should take place to determine the minimum amount that is required to meet the educational objectives and demonstrate mastery of the material. A folder with two pockets, one for incoming work and the other for outgoing, will help ensure that completed homework will get to the proper place.

**Maintenance of Self-Esteem**

Children with ADHD face many challenges. Often they do not measure up in family, academic or social domains. In
families that are not knowledgeable about ADHD, they may be perceived as the ‘behaviour problem’. Their impulsivity, hyperactivity, inattention, poor pragmatics, dysmodulation and variability may create social issues with age peers. The academic difficulty that students with ADHD experience is well known.

Children with ADHD should be closely monitored for symptoms of defeat. Self-depreciating remarks such as ‘I am dumb’, ‘I have no friends’, ‘Nobody likes me’ or ‘Why can’t I be like …’ are cause for concern. More worrisome are the statements ‘This family would be better without me’ or ‘I wish I were dead’.

A preventive mental health approach is often successful. Defining roles wherein the child can successfully participate is a vital part. Chores are useful family interventions. If the child cannot set the table because he or she is too clumsy with the glassware, he can set the knives and forks and the pate is a vital part. Chores are useful family interventions. Defining roles wherein the child can successfully participate is a vital part. Chores are useful family interventions. Defining roles wherein the child can successfully participate is a vital part. Chores are useful family interventions.

Statements ‘This family would be better without me’ or ‘I wish I were dead’. A preventive mental health approach is often successful. Defining roles wherein the child can successfully participate is a vital part. Chores are useful family interventions. If the child cannot set the table because he or she is too clumsy with the glassware, he can set the knives and forks or clear the table after dinner, or the family can decide to use paper cups. Allowances should be provided and should be contingent on chore completion. They are tangible demonstration of worth but may have to be paid more frequently than weekly and conditions established to enable partial payment. ‘First born privileges’ are those privileges that are accorded to the older child because of his age. They serve to limit conflict when younger children are performing as well or better than their older sibling. In the school setting the child with ADHD can be the messenger that makes deliveries to the office. Older children may assist with announcements or act as a crossing monitor. Extracurricular activities need to be chosen carefully. While some children with ADHD excel at sports many do not. Team sports are particularly difficult because of the additional social aspects. Sports where the individual’s progress is measured against themselves, such as martial arts, cycling, running or swimming, may be preferred. Some children bypass sports and choose music, drama, photography or art. Others develop interests that are further off the beaten path, such as nature, chess, woodworking, hunting or fishing, or choose to interact with older or younger children. Scouting and church youth groups offer adult supervised activities, but the leader needs to have experience working with children who have ADHD.

Medication

Stimulants are the pharmacological foundation of ADHD treatment. No behavioural or alternative medicine intervention is more effective in treating ADHD. Stimulants are relatively free of side effects and have no demonstrated long-term adverse effects. Stimulants used for ADHD either belong to the methylphenidate or amphetamine class of drugs. Methylphenidate may be found in short-acting, long acting, single isomer, liquid, capsule and transdermal forms. Amphetamine may be found in short-acting, long acting, liquid, capsule and a pro-drug form. Second-line drugs for ADHD are alpha adrenergic agents (guaifacine and clonidine), atomoxetine and bupropion. The use of tricyclic antidepressants and pemoline have been markedly curtailed because of associated fatalities.

Just as other aspects of ADHD management must be individualised, it is also true of medication management. The effective dose must be determined empirically. It is not weight dependent. There is variability in the duration of drug effect. Some young children have a prolonged drug effect and may only require single day dosing of short-acting agents. Other children may metabolise the agent more quickly and need multiple doses. The timing of the dose may also vary according to the student’s needs. College students who have a first class at 11am may not need to take stimulants at 7:30am while an elementary school student who starts class at 8:15am will.

When the stimulant effect wears off some children exhibit rebound. They may return to their unmedicated state with return of the inattentive and hyperactive/impulsive symptoms. Occasionally the rebound is more severe than the baseline condition. Some children are discomfted by rebound because they do not feel in control of themselves. Homework and extracurricular activities may be more difficult. Children who are rebounding may experience difficulty settling for sleep because they cannot stay still or organise for sleeping. This has lead people to incorrectly conclude that the stimulants are responsible for the insomnia. In fact, a short-acting dose of stimulant in the late afternoon will facilitate homework, extracurricular activities and sleep.

Families may choose not to administer stimulants on the weekend and when school is not in session. This may be ill advised for children who squirm too much in church, have to do homework, or who have social interaction difficulties that are due to their ADHD. In addition, the moodiness that is occasionally encountered when a child initiates stimulant therapy may be prolonged by intermittent administration.

The most common side effects of stimulants are moodiness when the medication is initiated, anorexia, insomnia and tics. Most children have appetite suppression while on stimulants. Medication duration can be judged by monitoring when the child begins to eat. Tics are associated with stimulants. There is no evidence that stimulants cause the tics or that once a child has tics that stimulants worsen them. Some of the children with tics have Tourette syndrome but presented with ADHD symptoms. Changing stimulants or using a second-line drug may ameliorate the tics. Insomnia and other sleep disturbances are common in children with ADHD and may not be related to stimulants. Rebound must be considered when evaluating difficulty settling for sleep in children with ADHD. Less common side effects include over-focusing, sadness, headaches and stomach aches. The less common side effects may be ameliorated by lowering the dose or ensuring a late afternoon snack. Stimulant use in childhood has not been found to be linked to later substance use disorder.

The key questions about stimulants are when to start and when to stop. Starting the medication is a joint decision between parents and physicians. Usually stimulants are used for a defined time and the effects and side effects are monitored.
At the end of the trial it is determined that the effect is sufficient to merit continuation or not. Stimulants may have dramatic effects on student performance but normalisation of function is uncommon. Consequently the other aspects of the management programme must be in effect for successful outcomes.

Adolescents often decide to discontinue their stimulants. Part of this decision is the result of normal adolescent behaviour – ‘There is nothing wrong with me’. Part is due to the perception that stimulants blunt the adolescent’s ability to socialise; decreased impulsivity is perceived as a lack of spontaneity. If an adolescent is desirous of stopping stimulants, then it is necessary to jointly develop criteria for continuing without medication or for reinstitution of stimulant therapy.

Further information on the pharmacological management of ADHD can be found at www.nice.org.uk/guidance/cg72/evidence.

ADHD is a neurodevelopmental disorder that is defined by developmentally inappropriate levels of hyperactivity/impulsivity and inattention. It usually is accompanied by cognitive, language, behavioural and emotional disorders and is expressed in family, academic, social and occupational domains. ADHD is best addressed with a multimodal approach that involves parental education, school accommodations, maintenance of self-esteem and medication. ADHD is a life-long disorder.

Management programmes must be modified to address the changing demands associated with maturation. The challenges associated with transitions are known and can be addressed proactively. Programmes must be modified to address the increased demands of school, more subtle social interactions and the emerging desires of the patient that occur as the child ages.

Disorders of speech, language and communication can either emerge during language acquisition in the developmental disorders or follow the onset of acquired disease. They are a ‘mark of a wide range of physical and developmental problems’ (McLaughlin 2011): within the developmental conditions the term ‘primary’ denotes that speech and/or language disturbance is the principle or only problem while the term ‘secondary’ refers to where it is associated with a wide range of conditions which include intellectual impairment (Shevell 2003; Riou et al. 2009), autism spectrum disorder (ASD) and sensory neural hearing loss (O’Hare 2009a; Pimpannon and Kennedy 2012). The distinction is helpful but not always immediately apparent from the clinical features as secondary conditions may masquerade as primary when speech is affected before the more classic symptoms emerge, exemplified by delayed speech milestones before motor deterioration in Duchenne muscular dystrophy. Secondary causes may also have distinctive features which suggest a primary cause but are nevertheless characteristic of a particular syndrome with wider implications such as in 22q11 deletion where velopharyngeal insufficiency, hypernasal phonation and verbal dyspraxia may initially suggest a primary speech production difficulty (Shprintzen 1997).

Disorders of Speech, Language and Communication

Anne O’Hare

Although speech, language and communication can be separately assessed most of their disturbances have some degree of overlap. Within the acquired disorders this often follows the diffuse nature of the insult to the developing brain whereby, for example, dysarthria, dyspraxia, dysfluency, dysphonia and dysphasia may together impair speech intelligibility following traumatic brain injury. In developmental situations the distinction may be difficult to apply because of the hypothesised cause: phonological speech delay/disorder problems, when the difficulty aligning speech sounds into intelligible speech, is considered linguistic or language based in nature. Another example would be verbal dyspraxia, where despite the same underlying genetic abnormality individuals in one family have severely affected speech in a relatively isolated fashion and yet in most other family members there are associated significant deficits in language and cognition (Lai et al. 2001). Finally, the distinction between developmental and acquired can be difficult to apply in some conditions that appear to have a very early onset or are associated with anomalies on cranial imaging as seen in some of the pseudo bulbar palsies. Despite this the broad division into developmental and acquired has some merits, bringing structure to the discussion of disorders of speech, language and communication, as well as being informed by international classifications.

DEVELOPMENT DISORDERS

DEFINITION

Language is a system for communication acquired through usage (Tomasev 2003). Speech is simply one mechanism for expressing a language, and components are defined in Figure 31.1. A language relies on symbols sequenced with a desire to employ these to share attention with another, the latter being an important pre-linguistic skill termed ‘joint attention’ (see Chapter 29). Gesture, sign and/or iconic symbols can be alternative methods to speech with which to communicate.

The most common conditions that specifically disrupt acquisition of language are primary developmental disorders of speech and language defined on inclusionary and exclusionary criteria. A number of definitions exist but all specify some level of significance to the measure of how delayed the child is in comparison to their peers. The exclusionary criteria operate discrepancy concepts such as language delay in the presence of a normal nonverbal IQ and an absence of an alternative explanation for the impairment.

Although current classifications tend to composite speech and language features to determine inclusionary criteria an alternative is the classic neurological criteria based on the features of the affected speech and language, for example, syntactical/lexical or semantic (Rapin 1996). Speech therapists/pathologists will also define conditions on the basis of speech and language
inclusionary criteria which may include comments about the speech sound system with reference to whether the child is employing a speech sound range that would be recognisable in a younger child, the so called ‘delay’ or whether it is ‘disordered’ and would not be observed in the normal development of speech sound inventory. Children therefore may have widespread inclusionary difficulties affecting the processing of phonological, semantic or syntactic information in the exclusionary presence of normal intelligence and an adequate learning environment, as well as in the absence of a neurological disorder, hearing problem or primary emotional difficulty.

Table 31.1 illustrates the normal progression of mastery of speech sounds in the phonetic English language.

The two main clinical classifications that define speech, language and communication disorders are the ICD-10 (WHO 1992) (Table 31.2) and the DSM-5 (American Psychiatric Association 2013). The ICD-10 approach of distinguishing between receptive, expressive and mixed disorder has been redefined within the DSM-5 where language disorder is now subsumed under communication disorders and includes language disorder, speech sound disorder, childhood-onset fluency disorder (stuttering), social (pragmatic) communication disorder and unspecified communication disorder. The definition of language disorder still covers inclusionary criteria but incorporates the concept of ‘persistent difficulties in the acquisition and use of language across modalities (i.e. spoken, written, sign language or other) due to deficits in comprehension or production and language abilities that are substantially and quantifiably below age expectations’. The definition of speech sound disorder has the key diagnostic criterion of ‘persisting difficulty with speech sound production that interferes with speech intelligibility’.

The category of dysfluency refers to a disorder manifest by repetitions of sounds, syllables and words with prolongations of sounds. There may also be difficulty initiating the voice or silent blocks with avoidance of certain words or speaking situations and the presence of associated body or facial

complicated by elements of dysarthria where there is spatially drive placement of the articulators or a disruption of many affected children there is disruption of temporally and debate as to what exactly is the underlying deficit, but for or verbal dyspraxia, as it is sometimes termed, still generates significant motor component. Childhood apraxia of speech speech production is affected with what appears to be a language there are some rare and severe conditions in which those affected by ASD.

**PREVALENCE**

Around 15% of 2 year olds have delayed speech and are designated as ‘late talking toddlers’ (Law et al. 2003; Desmarais et al. 2008; Buschmann et al. 2009; O’Hare 2009b; Reilly et al. 2010; O’Hare and Bremner 2016) with causes multifactorial although these toddlers are more likely to have a family history of delayed language acquisition. There is also a relationship between late talking and socioeconomic and parental factors such as poverty and low maternal education with the former also having a relationship with reduced social skills and problems with behaviour although the causal direction is unclear (Desmarais et al. 2008). Although clinical studies identify what appear to be risk factors for speech and language delay such as male sex, family history and preterm birth (Boyle and Boyle 2013), as well as possible good agreement between parent report and direct assessment of children’s abilities at 2 years of age (Johnson et al. 2008), there is no evidence that targeted screening for speech and language delay such as male sex, family history and preterm birth would result in better identification or outcomes (Nelson et al. 2006) and so it is not presently recommended. Most children, therefore, are identified through surveillance or clinical presentation (Kasper et al. 2011).

Children in early school with a phonological difficulty with persistent deletion/substitution errors in their speech have an increased risk of difficulties in reading, spelling and other academic areas that can persist. In addition, persistent speech production problems have been reported as posing an increased risk for social acceptability in school. The prevalence of speech delay in 6-year-old children is 3.8% and 1.5 times more prevalent in boys (4.5%) than girls (3.1%) with the comorbidity of speech delay and language impairment 1.3% and 0.51% if that language impairment was specific, that is, nonverbal intellect was in the normal range: looked at alternatively, approximately 5–8% of children with persisting specific language impairment (SLI) have speech delay (Shriberg et al. 1999). There is an association of intellectual impairment in persisting speech and language delays in 50% of girls and 20% of boys at kindergarten stage.

The prevalence of primary specific speech and language disorders varies according to the discrepancy criteria employed and age group examined (Law et al. 2000). When defined by a

*Continued*
The anteriorly articulated consonants ‘p, b, t, d’ are the phonemes mastered quickest, followed by ‘k and g’. The later phonemes mastered include ‘t, d’ (Tomblin et al. 1997). Speech is a highly complex skill requiring integrity of the 46 phonemes required for the English language, how-ever, speech is a highly complex skill involving rapid, precise and accurate movements of the organs of articulation. Speech production requires integrity of multiple systems including phonological (cognitive and linguistic), articulatory (sensory-motor), praxic (planning/programming of spatiotemporal parameters of movements of the articulators for speech) and prosodic (stress, intonation and voice quality conveying meaning and affect). The anteriorly articulated consonants ‘p, b, t, d’ are the phonemes mastered quickest, followed by ‘k and g’. The posteriorly articulated consonants are a later developmental phenomena so that during normal speech development one sees common substitutions for example, ‘t’ for ‘k’, ‘d’ for ‘g’. The later acquired consonants ‘r, l, s, th, y and z’ are more difficult to articulate and give rise to classic developmental omissions, substitutions and reversals in speech (McLeod and Bleile 2003).

There is a wide range of normal for the onset of speech, with the 97th centile for single words being 20 months for girls and 23 months for boys, with the 97th centile for three words being 3 years for both boys and girls. Table 31.3 illustrates the normal milestones of speech sounds and language comprehension.

A summary of expected progress in a typical phonemic language would encompass syllabic babble for example, ‘ba, da’ characteristic of infants of 6–7 months, with the development of two to three words with meaning at the age of 1 year to two to three word combinations at the age of 21–24 months. There is a rapid increase of up to 500 items of vocabulary during the 6 months after onset of word combinations in typically developing children (Gale et al. 2013).

A rough guide to the mean length of utterance for typically developing children can be calculated from the child’s age in years +1, with an average 3-year-old having a mean length of utterance in their sentences of four morphemes as well as girls and first-born children showing significant advantages in using sentences. Intelligibility improves with improving speech pronunciation and there is a rule of fours with respect to intelligibility: divide a child’s age into four and the quotient is approximately equal to the amount of speech that should be understandable, with a 1-year-old 25% of the time, the 2-year-old 50% of the time, a 3-year-old 75% of the time and a 4-year-old close to 100% of the time (Coplan 1985). This development can be measured between 16–30 months by ‘communication development inventories’, for example, MacArthur Communicative Development Inventory (Fenson et al. 1993) and the UK SureStart Language Measures (2005). They are most accurate when language skills are emergent rather than when relying on recall (Law and Roy 2008).

Speech and language therapists/pathologists have a wide range of standardised validated measures to establish the level of a child’s speech and language development (McCauley 2001; McCormack et al. 2012) as well as outcome measures that assess impact on daily life (McCormack et al. 2010).

<td>A disorder in which the child, having previously made normal progress in language development, loses both receptive and expressive language skills but retains general intelligence, with the onset of the disorder accompanied by paroxysmal abnormalities on the EEG and in the majority of cases also by epileptic seizures. Usually the onset is between the ages of three and seven years, with skills being lost over days or weeks. The temporal association between the onset of seizures and loss of language is variable with one preceding the other (either way round) by a few months to 2 years. An inflammatory encephalitic process has been suggested as a possible cause of this disorder with about two-thirds of patients left with a more or less severe receptive language deficit.</td>

*Intellectual disability.*

Composite language score of below 1.25 SD at the age of 5–6 years it was 7.4% overall (8% boys and 6% girls) in a United States kindergarten study. There was an association identified between this SLI and lower levels of parental education (Tomblin et al. 1997).

**SPEECH PRODUCTION**

Most children who present with problems in speech production have difficulties with their phonological system. Speech is a phonemic system in which groups of sounds are combined to convey meaning with the phonological component of speech having rules of contrast (the sound system) and sequence (sound structure). By 6 months of age infants can make most of the 46 phonemes required for the English language, however, speech is a highly complex skill involving rapid, precise and accurate movements of the organs of articulation. Speech production requires integrity of multiple systems including phonological (cognitive and linguistic), articulatory (sensory-motor), praxic (planning/programming of spatiotemporal parameters of movements of the articulators for speech) and prosodic (stress, intonation and voice quality conveying meaning and affect). The anteriorly articulated consonants ‘p, b, t, d’ are the phonemes mastered quickest, followed by ‘k and g’. The posteriorly articulated consonants are a later developmental phenomena so that during normal speech development one sees common substitutions for example, ‘t’ for ‘k’, ‘d’ for ‘g’. The later acquired consonants ‘r, l, s, th, y and z’ are more difficult to articulate and give rise to classic developmental omissions, substitutions and reversals in speech (McLeod and Bleile 2003).

There is a wide range of normal for the onset of speech, with the 97th centile for single words being 20 months for girls and 23 months for boys, with the 97th centile for three
LANGUAGE

Language comprehension and spoken word recognition is a very complex process in which the child has to handle the auditory information and assess it against knowledge of sounds in their language to achieve meaning. There is the potential for this to break down at many levels with poor auditory language comprehension possibly resulting from problems in the basic acoustic processing, a difficulty with a fully developed knowledge of speech sounds (phonological processing), abnormal word level knowledge (lexical processing) and/or deficits processing meaning (semantics). Difficulties with spoken word recognition are a hallmark of SLI (Malins et al. 2013).

The critical underlying deficits in SLI are still debated (Bishop 2006, 2016). Some children are reported to have a deficit specific to the domain of language such as in the grammar component, whereas for others there is opposing evidence to suggest it is primarily a processing deficit and in particular a temporal auditory processing problem (Tallal et al. 1993) or that the deficit is underpinned by generic cognitive difficulties resulting in reduced capacity and processing of procedural memory (Boyle 2010). These underpinnings may not be mutually exclusive.

The type of language impairment relates to the form of these generic cognitive difficulties. There is some evidence that verbal and visual short-term memory, (i.e. immediate short-term storage and recall of untransformed information) as well as working memory (i.e. where there has been further processing of the material to be remembered) function in different ways depending on whether the language disorder involves expressive language only or is mixed and also involves receptive language or understanding. The verbal memory appears to be more affected for children who have expressive language impairment whereas for children who have both receptive and expressive difficulties there is involvement of both visual and verbal short-term as well as working memory (Baird et al. 2010).

In very young children the differential diagnosis between specific receptive language impairment and ASD can be challenging (see Chapter 29). Some features such as echolalia, while commonly seen in the preschool child with ASD, also feature in receptive language difficulties. An important clue to ASD is language regression in the second year of life (Baird et al. 2008). Any child presenting with lack of speech/ language development should be assessed with both disorders in mind (SIGN 2007; O’Hare 2009a; NICE 2011; O’Hare and Bremner 2016) (see Chapter 29).

Neural Basis

Electrophysiological and haemodynamic imaging studies indicate that normal language functions develop and become established in the child’s brain in a similar pattern to
those of adults (Leroy et al. 2011; Brauer et al. 2013). The expected lateralisation is identifiable at birth, with progression of phonological processing ability during the first months, semantic processing at 12 months and syntactic processing around 30 months. Children with language impairment display functional abnormalities accompanied by structural abnormalities in the inferior frontal and temporal brain regions (Friederici 2006).

Evoked response studies in children also support that the neural basis of language in children is similar to adults (Duffy et al. 2013), reflected by the n400 linking the lexical semantic process with the middle and superior temporal gyri as well as possibly the left inferior frontal gyrus. The syntactic processes (which have been shown in adults to rely on the left superior temporal gyrus in anterior and posterior portion mainly and the left inferior frontal gyrus) and the prosodic processes (which rely on the superior temporal and frontal opercular cortex of the right hemisphere), while appearing to change in their latency and duration in childhood, do not alter in their basic morphology during development from childhood to adulthood.

The mismatch negativity (MMN) component of auditory event related potentials (ERPs) indexes the automatic neurophysiologic response to sound discrimination and experience dependent central sensory representations of speech sounds in the human brain. MMN provides a link between fine-tuned perceptual abilities and the physiological processes of preconscious stimulus processing correlating with perceptual sound discrimination. Jansson-Verkasalo et al. (2004) used this technique to demonstrate that very low birthweight preterm children have a difficulty in discriminating changes in syllables in a pre-attentive manner which correlates with their sustained naming difficulty in any impaired language development.

Neurophysiological mismatch negativity investigation also reveals early differences in infants from families at high risk of SLI in support of delayed brain responses for the discrimination of syllables, even from the age of 2 months. The children also show later ERP patterns for lexical semantic processes that differ from their age matched controls.

There has also been some support for the deficits in phonological and lexical semantic processes with functional MRI (Hugdahl et al. 2004). Abnormalities in the temporal orbitofrontal dorsolateral and medial frontal cortex and inferior frontal regions have been reported in children with SLI. Leonard (2002) also described reduced left asymmetry in the planum temporale for children with SLI, a region involved in the segregation and identification of sound patterns in speech as well as other acoustic patterns containing spectro-temporal information in adults.

The two hemispheres also appear to be differentially specialised in auditory language comprehension in their processing of segmental and suprasegmental features of language. Syntactic and lexical semantic information (segmental) is predominantly assigned to the left hemisphere and prosodic accentuation while boundary marking (suprasegmental) involves the right hemisphere. The speech processing streams in the left and right hemispheres appear to communicate through the posterior portion of the corpus callosum underpinning the neural basis for the coordination and integration of local syntactic and prosodic features during auditory speech comprehension (Sammler et al. 2010).

Connectivity in the brain suberving language can be demonstrated early in life and relates to patterns seen in the fully developed brain. Language comprehension and production both involve cortical pathways with intrahemispheric topographical connectivity between specialised frontotemporal and parietal areas important for language via white matter fibre bundles such as the arcuate superior longitudinal or uncinate fasciculi in the left or right hemispheres. There are important interhemispheric pathways to link the right hemisphere language functions (which include processing of pragmatic and prosodic aspects) with the left hemisphere.

These basic components of the neural language substrate involving inferior frontal and temporal cortices interconnected across hemispheres are present in the newborn and demonstrated in 2-day-old infants with fMRI and diffusion tensor imaging. These basic components of the neural language substrate involving inferior frontal and temporal cortices interconnected across hemispheres will still require further development of functional connectivity and maturation of the intrahemispheric fibre bundles in order to arrive at a highly specialised language system that can manage the lexical and syntactic complexity of the developed brain. There are two fibre connections that link the inferior frontal and temporal language regions in the human brain and the ventral connection that associates the temporal area to the inferior frontal gyrus is already in place at birth, while the dorsal pathway from the temporal cortex to the premotor cortex is also observable at this early age. However, the dorsal pathway to the inferior frontal gyrus matures at a later stage in development and might play a role in more complex language functions (Brauer et al. 2013).

Perani (2011) suggests that in developmental language disorders there may be a disconnection of the language relevant brain regions and a consequent lack of proper functional connectivity during brain maturation.

GENETICS

Primary speech and language impairments have a strong genetic background supported by a family history of late talking predicting ‘late talking toddlers’ (Zubrick et al. 2007) and twin studies (Dale et al. 1998). However, the genetic component is heterogeneous and multifaceted with several linkage regions and genes identified, including on chromosome 16q and 19q (SLI Consortium 2004; Newbury et al. 2005; Bishop 2006; Abrahams et al. 2007). One such common variant is in the Exon 13–15 region of CNTNAP2 which
appears to influence early language acquisition when assessed at the age of 2 years in a general population: CNTNAP2 variants may also increase susceptibility to SLI or autism when occurring together with other risk factors. A language endotype, the nonsense word repetition task (considered to be a measure of phonological working memory and a heritable behavioural marker of SLI (Newbury and Monaco 2002; Newbury et al. 2005) is associated with CNTNAP2 polymorphisms involving a gene that encodes a neurexin expressed in the developing human cortex (Vernes et al. 2008; Whitehouse et al. 2011). These are neuronal transmembrane proteins involved in cell adhesion and have enriched expression in the language related circuits of the brain (Abrahams et al. 2007). The gene is regulated by FOXP2 which is a transcription factor mutated in a very rare monogenic form of speech and language disorder described in the so-called ‘K family’ (Fisher et al. 1998; Fisher and Scharff 2009). Despite these advances in the genetic understanding of language impairment the multifactorial polygenic transmission is not amenable to clinical investigation at present, however, genetic investigations should be considered in some presentations that appear primary and will of course be indicated in many of the secondary causes. The phenotypes of some of the sex aneuploidies including Klinefelter syndrome and XXX and XYY may overlap with that of primary SLI and require investigation (Leggett et al. 2010; Bishop and Scerif 2011; Lee et al. 2012). (Table 31.4) Microarray analysis is also recommended as a first line test in all children with velopharyngeal insufficiency where there may be hyper or hypo nasal phonation with up to a third of children affected by 22q11 deletion (Burnell et al. 2014; Ockeleon et al. 2014).

### VERBAL DYSPRAXIA

Childhood apraxia of speech or verbal dyspraxia is a severe intractable impairment of speech production that disrupts intelligibility (Morgan and Vogel 2009). Children with verbal dyspraxia appear to have difficulties with precision and patterns of movements underlying their speech production with errors inconsistent and including impaired co-articulatory transitions between sounds and syllables as well as unusual prosody. They have no weakness on a formal examination of the oromotor muscles and their involuntary motor function in chewing, biting and feeding is spared (Morgan and Vogel 2009). It is thought childhood apraxia of speech is a speech motor programming abnormality but effects can be widespread and some consider it to be a more complex linguistically influenced disorder. The boundaries between it and a very severe phonological disorder of speech can be difficult to establish on purely clinical grounds and it may be the better progress of the latter that confers a retrospective diagnostic confirmation.

Some children display almost some degree of spastic dysarthria conferring hypernasality and impaired laryngeal quality resulting in difficulties modulating pitch and loudness. Childhood apraxia of speech is usually associated with receptive and expressive language disorder and reading as well as spelling impairments but verbal skills may be generally poorer than nonverbal skills and some individuals have average nonverbal skills. Hurst (1990) described an extended family with a severe form of verbal apraxia and subsequent study has shown that these affected individuals have a range of difficulties involving processing of phonology and syntax as well as nonlinguistic oral praxis. Imaging abnormalities have been confirmed in speech and language areas in the temporal and
inferior frontal cortex and also structures in the basal ganglia including caudate and putamen known to be crucial for controlling and selecting motor sequences necessary for articulation (Volkmann 1992), while the disorder has been linked to FOXP2 expression on chromosome 7q31 (Fisher et al. 1998; Lai et al. 2001). There are a number of underlying genetic mechanisms for conditions that affect speech and are related to FOXP2 expression such as a range of point mutations, large deletions, chromosomal structural variations including translocations and uniparental disomy (Turner et al. 2013).

DYSARTHRIA IN SYNDROMIC CONDITIONS

Developmental dysarthria arises secondary to bilateral perisylvian or perirolandic anomalies of polymicrogyria and schizencephaly, vermal anomalies including agenesis, atrophy or hypoplasia of the cerebellum and as part of a Joubert syndrome. The dysarthria is usually severe (Liegges and Morgan 2012) and these conditions can also be associated with childhood apraxia of speech. An important differential diagnosis from childhood apraxia of speech is Worster-Drought syndrome, sometimes termed congenital suprabulbar paresis, a permanent movement disorder of the bulbar muscles. There are swallowing, feeding, speech and saliva control impairments, the bulbar dysfunction is severe and persistent and there is poor speech prognosis (Clark et al. 2010). The clinical syndrome of Worster-Drought, characterised by bulbar cerebral palsy and a mild spastic tetraplegia, can be associated with bilateral or unilateral perisylvian polymicrogyria but alternatively these imaging abnormalities can be present without the clinical syndrome of the bulbar involvement. Children who have the imaging abnormality do appear to have a high risk of epilepsy and regression and there may be considerable impairment as over half of the children in this large series of those with bulbar cerebral palsy and perisylvian polymicrogyria had no speech (Clark et al. 2010). Dysarthria also arises secondary to brainstem dysgenesis which has been described as accompanied by congenital hypotonia, multiple cranial nerve involvement and oculomotor apraxia (Roig et al. 2003).

INTERVENTION

Late talkers between 24 and 30 months may respond to a range of direct and indirect speech as well as language therapy interventions by increasing their vocabulary and mean length of utterances (Buschman et al. 2009; Allen and Marshall 2011; Cable and Domsch 2011; Yoder et al. 2011; Fricke et al. 2013). Both therapy given directly by speech and language therapist/pathologist or indirectly by education or clinical staff under their direction can be effective for school-aged children with expressive language impairment (Boyle et al. 2007; Boyle 2010; Boyle et al. 2010). Receptive language skills in this age group are less responsive to therapy (Law et al. 2003) although it may support skills underpinning reading comprehension (Fricke et al. 2013).

The current evidence base for intervention for children with primary speech and language delay or disorder is assembled within the ‘What Works’ database hosted by the UK Communication Trust (www.thecommunicationtrust.org.uk/whatworks). This is a searchable and interactive database designed for use by practitioners such as speech and language therapists/pathologists as well as educational psychologists and specialist teachers and integrates information that has been distilled from the Cochrane Collaboration Systematic Review on Speech and language therapy interventions along with practitioner and parental feedback on current practice.

The information is grouped into target groups, for example, speech, language, communication along with the age range, what kind of intervention is the focus, who it is to be delivered by and how it is to be delivered (Law et al. 2015).

Some of the severe speech production problems such as childhood apraxia of speech and Worster-Drought syndrome are seemingly intractable with a poor evidence base for treatment efficacy (Morgan and Vogel 2009) so intelligibility remains poor and augmentative alternative communication may be indicated (Baxter et al. 2012).

PROGNOSIS

Around half of children with previously delayed speech and language development will have shown substantial catch up at the age of 3–5 years (Johnston et al. 1999; Law et al. 2000) although they may still have a reduced mean length of utterance despite having developed normal vocabulary, with children who have an underlying receptive language delay more likely to have persisting problems. In a large general population cohort, early language ability measured with expressive vocabulary at 2 years and receptive language at the age of 4 years, both made a moderate but important contribution to emotional and behavioural functioning at 6 years of age. Some biological risk factors such as the child’s sex, maternal smoking in the first 3 months of pregnancy, birth weight, as well as social risks including the father’s occupation and mother’s level of education also play a role in behavioural difficulties at the age of 6 years. Performance IQ was protective as were maternal characteristics such as knowledge of child development and maternal language and literacy skills (Clegg et al. 2015). There is a variable long-term pattern to nonverbal IQ for children with a history of SLI, with some children showing a fall continuing into adolescence (Botting 2005).

The long-term outcome for some children with persisting speech and language impairment can also be poor when there is associated reduction in academic achievement, an increase in emotional and behavioural difficulties and reduced prospects for employment and training (Reilly et al. 2010). Language skills are frequently strongly associated with literacy difficulties, both of which are predictive for educational attainment even after
A wide range of insults to the brain result in acquired disorders of language: aphasia and dysphasia and/or speech, dyspraxia, anarthria and dysarthria often with dysphonia and dysfluency (O’Hare 2016). Severe receptive aphasia can be difficult to distinguish from auditory agnosia where comprehension difficulties extend to non speech sounds. Mutism is an early feature in non-fluent aphasia although fluent aphasia can less, commonly occur. The long-term outcome depends on timing, the location and extent of the lesion, specificity of the underlying neural substrate and age of the child (Stiles 2000; Johnson 2008). While young children appear to recover more effectively from aphasia than adults, with the concept of plasticity evoked to explain this, greater sophistication of imaging and assessment of functional outcomes confirm that the long-term effects are potentially widespread and impairing, particularly for infants. There is an increasingly evidenced literature for the treatment of dysarthria, mostly for children with cerebral palsy. The evidence base for therapy and interventions in childhood aphasia is poorly developed beyond individual and case series and is in the domain of the speech and language therapist/pathologist so is not discussed in detail. There is, however, often a role for augmentative and alternative communication, particularly in the acute management of expressive aphasia and longer term when dysarthria severely disrupts speech intelligibility, with this covered as and when appropriate.

DYSPHONIA

Dysphonia is an abnormality of the pitch and volume of the voice resulting in hoarseness and reduced voice volume. Voice disorders essentially arise from two broad groups of disorders, anatomical and neurological, with the former including changes to the larynx and vocal cords which may be acute following infectious causes such as laryngitis and conditions including a laryngeal web, papillomata, granulomas, vocal cord palsy, tumours or endocrine aetiologies such as hypothyroidism. Sometimes the disorder can be attributed to vocal abuse and misuse which can be occurring in combination with vocal nodules (Gale et al. 2013) while neurological causes include damage to the superior and recurrent laryngeal nerves, myasthenia gravis, brainstem haemorrhage and pontine gliomas. Occasionally it can have a psychogenic aetiology (Gale et al. 2013).

DYSPHONIA

Dysarthria is an impairment of speech articulation that reduces speech intelligibility, particularly through effect on consonant production but also a range of additional impacts on phonation, resonation and prosody. Speech can sound slurred and effortful and there may be associated dysphagia as well so the clinical assessment of the integrity of the airway protection is crucial. Dysarthria is a long-term and severe speech disorder of neuromuscular control of speech sound production and signals bilateral disruption of neural pathways (Lieggois and Morgan 2012; Morgan et al. 2013). It is associated with lesions in the white matter along the cortico bulbar and spinal tracts (incorporating corona radiata, central semiovale, internal capsule), midbrain, grey matter lesions within the persylvian and perirolandic cortices, basal ganglia of putamen, caudate nucleus, thalamus and cerebellum. The best predictor of an outcome of dysarthria is involvement of the dorsal corticobulbar tract. Dysarthria affects around one third of children with cerebral palsy (Pennington et al. 2013), 20% of survivors of moderate to severe traumatic brain injury (Morgan et al. 2010) and a third of children who have undergone resection of a neoplasm in the posterior fossa (Mei and Morgan 2011; see also Chapters 8, 13 and 14).

Table 31.5 separates dysarthria into flaccid, that is, lower motor neurone bulbar palsy, spastic dysarthria (pseudo bulbar palsy), extrapyramidal where involuntary movements interfere with articulation and ataxic dysarthria where dysfluency is prominent.

Figure 31.2 shows features of cerebellitis that gave rise to an ataxic dysarthria.

All the different types of dysarthria can feature in cerebral palsy but spastic and hyperkinetic predominate. A quarter of children affected by cerebral palsy have no speech with their level of gross motor functioning predicting functional communication at school entry (Coleman et al. 2015). The Communication Function Classification System (CFCS) is a tool to describe the functional communication performance view of daily life for an individual affected with cerebral palsy that conforms to the World Health Organization's International Classification of Functioning Disability and Health (ICF) (Hidecker et al. 2011).

Acute dysarthria following paediatric traumatic brain injury is often accompanied by oromotor deficits with facial nerve dysfunction affecting buccal and labial movement, as well as a history of receptive developmental language disorder have significant impairments in ‘theory of mind’ skills, that is, the ability to impute the thoughts of others, verbal short-term memory and phonological processing resulting in substantial difficulties with social adaptation and an increased risk of psychiatric disorder (Clegg et al. 2005).
hypoglossal nerve dysfunction with reduced tongue strength and coordination, while there may also be trigeminal nerve impairment affecting jaw movements and vague nerve involvement that impairs velopharyngeal function, all of which conspire to reduce intelligibility. Ten per cent of children in one series of those sustaining moderate to severe traumatic brain injury had accompanying dysphagia (Morgan et al. 2010).

Posterior Fossa Syndrome

Eight per cent of children develop the classic picture of ‘posterior fossa syndrome’ after tumour resection in the posterior fossa characterised by cerebellar dysfunction, oculomotor dyspraxia, oral motor dyspraxia, emotional lability and mutism. Up to a third of children overall will experience dysarthria in the acute postoperative phase with recovering speech showing deficits that include distorted vowels, slow rate, voice tremor and monopitch, features that differ from those found in adult onset ataxic dysarthria (De Smet et al. 2012). While the postoperative mutism is associated with a poorer long-term prognosis with long-term dysarthria even non-mute children experience long-term speech deficits of mild dysarthria affecting consonant production, pitch and rate (Morgan et al. 2011).

Rarer Causes of Acquired Dysarthria

Herpes virus infections of the brain have a predilection for the temporal lobes and can have a devastating encephalitic presentation. However, the neurological manifestations in
childhood can also rarely include opercular syndrome with facial palsy, dysarthria and dysphasia. These conditions constitute a medical emergency requiring urgent treatment with high dose intravenous acyclovir and so the second, slightly more unusual, presentation needs to be recognised as a herpes virus brain infection (Britton and Jones 2014).

There is a small number of reports in which dysarthria is associated with metabolic disorder (Liegeois and Morgan 2012). In contrast to adult practice dysarthria resulting from basal ganglia dysfunction is very rare but seen in juvenile Huntington’s chorea and pantothenate kinase associated neurodegeneration. Dysarthria can result from white matter impairment across the cerebral hemispheres in leukodystrophies and, with disease of the cerebellum and basal ganglia, in gangliosidosis and Wilson’s disease.

Onset dysarthria may arise from treatable conditions such as some of the rare motor neuron diseases of childhood, for example, Brown-Vialetto-Van-Laere syndrome and Fazio-Londe syndrome where riboflavin may slow down the degenerative process. Timely diagnosis is also important because there can be rapid progression of wider neurological features after the disease onset: for example, Fazio-Londe syndrome can manifest with onset dysarthria and the child may then show rapid progression with stridor, respiratory distress, prosis as well as facial and limb weakness over the ensuing 16–18-month period. Investigation including neurophysiology and electromyography confirms anterior horn cell involvement in the cranial nerve nuclei and spinal cord (Spagnoli and de Sousa 2012).

**APHASIA/DYSPHASIA AND AUDITORY AGNOSIA**

Aphasia/dysphasia are terms only now usually used in relation to acquired disruption of language function which may be expressive or mixed receptive/expressive and fluent or non-fluent. Aphasia is frequently comorbid with dysarthria and dyspraxia especially if the insult to the brain was diffuse: there is a wide range of causes including acquired brain injury from trauma, cerebral vascular events and stroke as well as infection, for example, herpes simplex encephalitis, temporal lobe abscess and cortical thrombophlebitis, tumours and neurodegenerative diseases such as Niemann Pick disease and adrenoleukodystrophy (Paquier and van Dongen 1996). The latter may involve auditory agnosia.

Figure 31.3 shows acute changes in the left parietal temporal region in keeping with encephalitic process with acute changes of cortical thickening, high signal on T2 weighted imaging and restricted diffusion on diffusion weighted imaging.

A sudden onset of loss of speech which looks like non-fluent aphasia, without other clinical clues to the aetiology such as motor loss or encephalitic symptoms or impaired consciousness, should trigger consideration that this might be selective mutism (Standart and le Couteur 2003), deafness, ASD regression or epileptic aphasia as in Landau-Kleffner syndrome.

Acute fluent aphasia/dysphasia is manifest with telegramatic speech, word finding difficulties, phonemic paraphrases, logorrhoea, semantic jargon, neologistic jargon, that is, scrambled sound structures that result in none words, abnormal speaking rates and impairment of comprehension. The jargon aphasia, paraphasia and perseveration has a similar pattern to that seen in adult aphasics (Van Dongen et al. 2001).

The dysphasia in ‘occult’ and paroxysmal aetiologies, including temporal lobe neoplasms and Landau-Kleffner dysphasia, may be challenging to recognise. Characteristics described in non-fluent and fluent aphasia may not be recognised as such in children who are otherwise considered to be ‘odd’ in their presentation of fluctuating behaviour.
and communication, risking valuable loss of time in these conditions that can be devastating but potentially treatable. Such an example might be herpes simplex encephalitis which may present the classic frontotemporal syndrome of fever, personality and behaviour change. There may be fluctuating aphasia, with or without hallucinations in a minority, while over 90% have nonspecific features (Britton and Jones 2014). The acute phase may be followed by longer term speech production and high level language impairments even though children generally show far greater recovery from acquired aphasia than adults. There can be relative preservation of comprehension in the acute phase and subsequent rapid improvement in speech and expressive language.

**Acquired Epileptic Syndromes Associated with Language Regression/Aphasia/Agnosia**

Landau-Kleffner syndrome is an epileptic aphasia occurring in childhood (see Chapter 16) which can start insidiously or appear as an auditory agnosia in a child who was previously either developmentally normal or had straightforward developmental delay in speech and language acquisition (Fandino et al. 2011; Deona and Roulet-Perez 2016). It has a peak presentation of between 5–7 years with an age range of 3–10 years with onset difficulty interpreting speech and sometimes environmental sounds and gestures which may be associated with unusual behaviour arising from intense difficulty understanding language and verbal instructions, resulting in a rapid and severe loss in spontaneous speech. While the EEG shows prominent epileptiform activity, there may be no outward signs of seizures meaning that the actual epilepsy may not be recognised although it is a disorder of language associated with such. It is important to record the EEG in drowsiness and sleep as the abnormalities which include classically sharp waves in the bitemporal areas and sometimes frontal dysrhythmias may not be immediately evident in a routine EEG (Fig. 31.4).

This acquired epileptic aphasia is one of the epileptic encephalopathies of childhood and is related to continuous spike wave discharges in non-REM sleep (Deonna and Roulet-Perez 2005). The diagnosis can be delayed as a child might appear deaf or there may be behaviour disturbances and anxiety with the child being unable to understand what is happening and relate their experience. Sometimes when Landau-Kleffner syndrome has been longstanding there can be more of an ASD picture emerging but in the early stages of Landau-Kleffner syndrome there remains a desire to communicate and make social overtures. In contrast, the regression seen typically in the second year of life in ASD is associated with a clear regression in nonverbal communication and reciprocal social interaction.

It is important to think of dysphasia/auditory agnosia arising from an epileptic encephalopathy because although clinical epileptic seizures will ultimately occur in 70–80% of children with Landau-Kleffner syndrome they may not be very evident initially. Auditory agnosia can result from bilateral dysfunction of primary auditory cortical areas with a range of potential aetiologies from vascular, traumatic or infectious including bilateral opercular syndrome with pseudobulbar palsy as an outcome of encephalitis, however Landau-Kleffner syndrome is most likely to be the diagnosis when auditory agnosia appears to arise spontaneously. The diagnosis of Landau-Kleffner syndrome must be considered with repeat EEG study: the EEG abnormalities can be highly variable with interictal epileptiform discharges that are multifocal, bilateral and predominate over the temporal and parietal regions (Van Bogaert et al. 2013; Duffy et al. 2013) (see Chapter 16).

![Figure 31.4 EEG appearances in Landau-Kleffner dysphasia. Sleep recordings would show a continuous spike-waves pattern (see Chapter 16).](image-url)
INVESTIGATION
All children have to be thoroughly evaluated by a child neurologist. Cranial imaging is indicated in the investigation of onset dysarthria and dysphasia guided by the context in which these symptoms are occurring, for example, a stroke or cerebral vascular accident, infectious process (Fig. 31.5) or post-traumatic injury. Sleep VEEG is also an important diagnostic investigation.

PROGNOSIS
Dysarthria
There can be a wide variation seen in individual responses to therapy although preliminary investigations suggest that gains in intelligibility and communicative interactions can be demonstrated in young children with dysarthria after brief intensive speech and language therapy (Pennington et al. 2013; Coleman et al. 2015). Overall the evidence base for treatment efficacy is limited (Morgan and Vogel 2008).

Dysphasia
Functional brain imaging studies confirm recovery from aphasia is protracted but ‘dynamic’. The respective roles of the impaired left hemisphere and the greater right hemisphere lateralisation change over time. While right hemisphere lateralisation follows the acquired brain damage in children with cerebral vascular accident and aphasia greater subsequent recovery is seen in those where there is some degree of reorganisation in the left hemisphere (Elkana et al. 2011; Liegeois and Morgan 2012). Proficiency in linguistic tasks and a better prognosis is associated with increasing lateralisation to the left hemisphere in the anterior language regions. Despite significant recovery of aphasia many individuals show persisting dysphasic features characterised by reduced naming and phonetic fluency in spoken and written language (Lauterbach et al. 2010; Elkana et al. 2011): long-term management for these children should include multidisciplinary liaison in conjunction with speech and language therapy/pathology colleagues as well as with education staff so they can remediate the impact of these dysphasic outcomes. This support is likely to be needed long term in some capacity into high school where the child will encounter a huge increase in technical vocabulary.

Traumatic brain injury is associated with poorer outcomes in language related cognitive delays. Impairments in spoken and written language comprehension occur more commonly in children with moderate to severe traumatic brain injury and particularly affects higher cognitive skills such as non-literal language, affecting an ability to make inferences and deal with inferred meanings such as sarcasm and metaphor. This type of language difficulty is linked to problems in working memory, processing speed, social cognition and the child’s executive functioning (Turkstra et al. 2015).

INTERVENTION
Despite the importance of acquired dysarthria and dysphasia for disrupting quality of life there is very little evidence on which to base treatment (Morgan and Vogel 2008), however the increasing understanding of the long-term effects and impact of unintelligible speech and communication effectiveness on activity and participation framed with the ICF should improve the drive for evidence towards meaningful outcomes (Hidecker 2010; Hidecker et al. 2011) (Table 31.6). The Focus on the Outcomes of Communication Under Six (FOCUS) (available at www.focusoutcomemeasurement.com) is such a tool derived from parents descriptions of their children’s communication that complies with the ICF and the ICF – Children...

Intervention also needs to build on a detailed assessment of the child’s speech, language and communication for both spoken and written modes as appropriate (Table 31.7). This is the domain of the speech and language therapist/pathologist within a multidisciplinary team which can avoid misconceptions about the breadth of a child’s disabilities. Experienced therapists can evaluate the clinical picture through informal language measures and assess narrative as well as functional communication (McCormack et al. 2012). Children with cerebral palsy and those such as the preterm survivor with periventricular leukomalacia with an intelligence level above 70 but nevertheless significant motor speech problems may respond to conversation rather than start it, seem to avoid elaborating within conversation and seldom ask questions (Pirila et al. 2007): this may result in an underestimation of the child’s comprehension. Commonly used standard language tests for comprehension of spoken language may have limited utility for children with severe cerebral palsy who have no intelligible speech (Geytenbeek et al. 2010) but this may be circumvented to give a true picture of understanding with the appropriate modifications to psychometric instruments or necessitate the development of bespoke instruments to assess comprehension in such children (Geytenbeek et al. 2014, 2015).

### AUGMENTATIVE AND ALTERNATIVE COMMUNICATION

There should always be appropriate consideration of augmentative and alternative communication (AAC) to allow a child to develop as an independent communicator if severe impairment of speech intelligibility or lack of speech occurs acutely or in the long term. AAC includes unaided modes such as gesture and aided communication modes that can be low technology systems such as photographs and pictograms or high technology systems which include voice output communication aids. People with a disability have a right to access a chosen form of communication but there are a wide range of factors that influence how successful or not the introduction of an AAC device might be. The impact of high technology AAC depends on a whole range of factors as diverse as the availability of technical support, reliability of the device and the sound of the voice output to the individual and family perceptions as well as knowledge and skill of the staff supporting the AAC user (Baxter et al. 2012). Families may need to be reassured that AAC will not prevent the recovery of speech as they can worry that the child becomes dependent on that system. As speech recovers the child will always opt to employ it.

Some children with severe cerebral palsy, particularly of the dyskinetic type who have no language, may nevertheless have well developed language comprehension emphasising the importance of introducing AAC devices from early childhood. Children with spastic cerebral palsy have more severe language comprehension difficulties than children with dyskinetic cerebral palsy: because of the severe motor implications affecting speech and the use of gesture it is important to have methods of evaluating receptive language and not assume that it is severely affected in non-speaking children with severe cerebral palsy (Geytenbeek et al. 2015). It is vitally important to maintain communication and a fundamental component of good quality of life following recovery from these devastating acquired dysarthric and dysphasic conditions.

Treatment of Psychogenic Neurological Disorders

Prognosis
The neurologist seeing a child with a psychogenic neurological disorder (PND) faces two main tasks. The first is to make the diagnosis without undue delay. The second is informing the child and family of the diagnosis in a way that allows the diagnosis to be accepted.

The diagnosis of a PND is sometimes easy, especially in the younger child, but often it is difficult, and sometimes extremely difficult. A careful history and examination, a detailed knowledge of anatomy and rare presentations of neurological disorders, the ability to detect ‘psychogenic’ signs, and an understanding of human behaviour are basic requirements, but making the diagnosis is only the beginning. What is meant by the diagnosis has to be explained in such a way that it will hopefully result in the child making a full recovery, avoiding an entrenchment of the symptoms, and a state of affairs where illness becomes a way of life for the child. As Sir Francis Walshe (1965) observed more than 50 years ago: ‘the measure of accuracy in diagnosis is a measure of the experience of the observer, and upon his having the courage of his convictions when he does diagnose hysteria, for the diagnosis is never popular’.

That the first reaction of many parents to the diagnosis of a PND in their child is disbelief, or immediate rejection of the diagnosis, is to be expected. The diagnosis can come to them as an unprovoked slap in the face. Rather than their child having a neurological disease, the parents and child may understand that they are being told the problem is a mental illness. They may feel that, embedded in the diagnosis, there are suggestions of incompetence or dishonesty in the child, poor parenting, and an abusive atmosphere at home. An approach to this difficulty has been to try to find an ‘acceptable’ word. Far more important than the word used, is the explanation of what is meant by the diagnosis.

In Chapter 19, dealing with movement disorders, the obstacles that accompany some words were discussed. These difficulties are multiplied many fold when dealing with PND. In quoting various authors in this chapter, the words they employed will be used, realising that hysteria is now regarded as an unacceptable term. Terms such as hysteria, conversion disorder, psychogenic disorder, symptoms unexplained by organic disease, medically unexplained illness, and functional neurological disorder will be taken as broad terms that have similar meanings, with some differences related to the prevailing concepts at the time the papers were written.

When not making direct quotations from the literature, the term ‘psychogenic’ will be used, realising it has problems. Lewis (1972) observed: ‘The term “psychogenic” is much used, but seldom defined – its meaning is assumed to be self evident’. Here psychogenic is used in the sense of ‘not organic’, or as defined in Webster’s Dictionary emanating from ‘the human soul, spirit or mind’. In dealing with children and their families, the author has found, that ‘stress-related’ is a more useful term. The problems with the words will be discussed below in more detail.

The signs of a PND are much the same in adults and children, and this review will not be limited to papers written by paediatricians or paediatric neurologists. Psychogenic non-epileptic seizures are covered in the Chapter 16 and are not discussed here. Mass hysteria is also not covered, but the reader is directed to the review of Mink (2013).
Teodoro and Edwards (2016) have noted a recent ‘revolution in the approach to functional movement disorders’ (FMD).

A review of the past adult and paediatric literature reveals that many areas of current interest have been examined in the past, and are now being ‘re-discovered’. Examples include the ‘positive signs’ of a PND described by Babinski and others, and famously by Head in 1922. Other examples include the presence of a model for the illness (Shill and Gerber 2006; Pelliciari et al. 2014), which was described by Paget (1873), and Taylor (1986). There is a report of familial psychogenic movement disorders (Stamelou et al. 2013), which does not make reference to the work of Briquet in 1859, who found that girls with a hysterical mother were 12 times more likely to have hysteria than those of non-hysterical parents (Maï and Merskey 1980). There are inevitably many such examples, as the past literature on PNDs is vast and often hidden in obscure places, and may be of little interest to those with ‘neurobiological’ leanings. However, they serve as a reminder that a knowledge of the past is essential in trying to have a full grasp of the complexities of PNDs. This historical review has to be brief, and can only provide a limited outline. It leaps over a story thousands of years old, touching down briefly, and then moving on. The author accepts that with such a large literature and limited space, the selection of material is influenced by his own leanings and biases, but he is not alone in this fault.

In the past terms such as ‘hysteria’ were used for a broad group of patients, including some with problems such as pain or anorexia. This historical review concentrates mainly on descriptions that are relevant to our current conception of what constitutes a PND.

Wilson (1930) observed: ‘Leprosy, rabies and malaria are ancient diseases, but epilepsy and hysteria are older still: are they as old as human nature itself?’ Traditionally a review of the history of PNDs goes back to ancient Egypt and ancient Greece. Given the difficulties in making the diagnosis of a PND with a patient in front of you, making it from descriptions written thousands of years ago in archaic languages, has its limitations. Nevertheless, it seems clear that the ancients regarded the womb as a source of multiple symptoms, some of which would now be regarded as evidence of a PND.

From Plato’s Timaeus (approximately 360BC) comes the following description: ‘The so-called womb or matrix of women. The animal within them is desirous of procreating children and when remaining unfruitful long beyond its proper time, gets discontented and angry, and wandering in every direction through the body, closes up the passages of the breath, and, by obstructing respiration, drives them to extremity, causing all variety of disease.’ It has been suggested that here Plato is not actually talking about a wandering womb, but the psychological consequences of suppressed sexual desire (Adair 1995). Nevertheless standard practice at the time was to regard the problem as ‘organic’ with the aim of treatment to drive the womb back to its natural position. ‘If the uterus had moved upwards, this could be done by placing malodorous and acrid substances near the woman’s mouth and nostrils, while scented ones were placed near her vagina’ (Tasca et al. 2012). Many women in the ancient Mediterranean world wore amulets and charms to protect them against uterine movement (Adair 1995). The ancients do not appear to have used the word ‘hysteria’. However, for thousands of years dysfunction of the womb was seen as a source of widely varying symptoms, including in particular, difficulties with breathing, and loss of consciousness. When the word ‘hysterical’ first appeared in the English medical literature, it reflected the view of the ancients, describing an ‘organic’ disorder caused by dysfunction of the uterus. ‘For so many writers in the history of hysteria, the womb has become a vast, mysterious and infinitely powerful organ’ (Micale 1989).

Travelling forward nearly 2000 years, little progress had been made. In 1603 Edward Jorden published a book entitled A Briefe Discourse of a Disease Called the Suffocation of the Mother (Brain 1963). This followed a trial the previous year where Elizabeth Jackson had been charged with bewitching a 14-year-old girl named Mary Glover, causing her to have seizures. Jorden had appeared in court and attributed the problem to natural causes, but the jury was convinced by evidence (including from other doctors) of witchcraft, and Jackson was found guilty. The message of Jorden’s book was that such symptoms were not supernatural in origin, but due to problems with the uterus. (The term ‘suffocation of the mother’ referred to a sense of choking caused by uterine dysfunction.) It is sad to reflect on the lack of progress in medicine at that time, with Jorden arguing that it was the uterus and not the devil which was responsible for the symptoms, returning to an error thousands of years old. There was some progress, mainly from the great physicians of that time. Both Willis and Sydenham proposed that it was the brain that was the source of the symptoms of hysteria (Brain 1963; Micale 1989).

Jumping forward to 1861, Thomas Chambers in an article in the British Medical Journal (BMJ), (then 21 years old), began with the following statement. ‘Will you please to forget at once and for all that hysteria is derived from the Greek? … In reality, it has no more to do with the organ of reproduction than it has with any other part of the female body; and it is no truer to say that women are hysterical because they have wombs, than that men are gouty because they have beards’ (Chambers 1861).

Chambers goes on to say that ‘the deficient vitality of which hysteria is a manifestation is in that puzzling part of the circle of life which lies between mind and matter’. In his summary he notes that with hysteria: ‘In some cases the mental, in others the bodily, phenomena predominate’. He discusses a number of cases starting with the story of a 17-year-old girl. She had been ‘in service’ from the age of 12, and had no problems until: ‘She went home for a holiday, having heard of no illness in her family, and found her father in his coffin.’ Subsequently, she developed multiple symptoms including palpitations and emotional instability. She lost her position repeatedly. She presented to Chambers with diffuse pains, and paralysed and extremely painful legs. These symptoms followed a minor illness. Examination convinced Chambers that her problems were ‘distinctly mental’ in origin.
Chambers then outlined his method of treatment for patients when the symptoms seem to be psychogenic in origin, using this girl as a model. The first step was admission to hospital. ‘You will find in practice that, however good your theory of the treatment of hysteria may be, it is much more difficult to carry out and much less effective when the patients are at home, than when you can remove them for a time from their ordinary habits and associations.’ If the patient were rich, an alternative was a holiday away from home. However, this had to be carefully chosen as: ‘Much harm is often done by sending them to travel in Italy.’ In Chambers’ view, the eternal city, Rome, was a particular danger. (Florence was not mentioned.) If the family was neither poor nor rich: ‘One good plan that can sometimes be adopted, to the saving of pride and pocket together, is to negotiate an exchange of patients, where two families in about the same social position are simultaneously afflicted with an hysterical member.’

The reason for getting the patient out of the home was that ‘the patient’s mind, by running in its habitual groove, and being perpetually subjected perhaps to the influences which originated the disease, less readily takes a turn towards health’. In the model proposed by David Taylor (which will be discussed below) this could be seen as an alleviation of a predicament. In addition to a change of scene, Chambers recommended an exercise programme, cold shower-baths (for their bracing effect, in winter preceded by a warm bath), and valerian. The aim of treatment is ‘restoring the control of the mind over the body. A link is dropped and is becoming paralyzed for want of use’.

The exercise programme involved progressively increased movement, and used music. ‘Let the patients be exercised in voluntarily obeying specific orders for the direction of the will; moving the limbs to time, at first slowly, and afterwards more rapidly, till at last the culminating point of dancing can be arrived at. This is the perfection of the cure; and when a girl can be got to join a quadrille in the evening, you need not fear a relapse into hysterical paralysis.’

Opponents of Cartesian dualism would be appalled by the frequent use of the mind and body as separate concepts in Chambers’ article. He also talks about the value of ‘Christian charity’ in treating patients, (and urges doctors to take into their own family the children of colleagues who develop hysteria). Nevertheless, his treatment is kind, caring, and compassionate in trying to help a young girl, clearly lost and alone in her grief. It also has much in common with ‘recent advances’ in the treatment of PNDs.

In the English literature between 1840 and 1860, a number of British authors, including Thompson, Laycock, Carpenter and Carter described the importance of emotional disturbance in causing hysterical symptoms (Kane and Carlson 1982). Whereas others felt the emotions acted on a vulnerable person, Carter believed that an undischarged, strong emotion was sufficient to cause hysteria in an otherwise normal person. Carter’s book On the Pathology and Treatment of Hysteria was published in 1853. In this he described primary, secondary and tertiary forms of hysteria. The tertiary form would now be called factitious disorder. ‘Carter writes of girls who bound their limbs with tight ligatures to induce swelling of their joints. Patients may burn their skins with corrosive substances to form ulcerations or place local irritants into their vaginas to create discharges. Two common complications are hemoptysis and hematemesis, the former produced by applying leeches inside the mouth, the latter by swallowing and then vomiting the blood of animals’ (Kane and Carlson 1982). In this tertiary form, Carter believed complex psychological processes are at play. ‘The patient soon finds herself unable to stop thinking of the emotions that produce her paroxysms, and her introspective ideas become automatic. The hysteric increasingly loses her control over her symptoms until finally her illness is completely out of her hands’ (Kane and Carlson 1982).

Old ideas die hard, but sometimes with modifications. If not the uterus, other parts of the female genital tract must be responsible. In 1866 in The Lancet, Baker Brown passionately defended his practice of clitoridectomy in the treatment of hysteria (among other ailments), claiming great success. His views were not shared by his surgical colleagues, and he was soon thereafter expelled from the Obstetrics Society. As late as 1884, Walton writing in the Boston Medical and Surgical Journal (later to become the New England Journal of Medicine), firmly believed that removal of the ovaries had a role in selected patients with hysteria. Displaying the zeal found in so many who insist they have found both the cause and cure of PNDs, Walton stated: ‘In such cases the hysterical symptoms may not only furnish an additional indication for the removal of the source of irritation, but they alone may make life such a burden to the patient as to render the operation not only justifiable but imperative.’

It was not only surgeons who focused on the ovaries. As will be discussed below, ovarian pressure to abort hysterical seizures was a standard procedure in the Salpêtrière during the era of Charcot. It was also used by Tilt and others: ‘It has been possible, in cases published by Romberg and Schulzenberger, to produce the succession of phenomena just described by simply pressing on the ovaries; and I have repeatedly brought on unconsciousness in a nervous patient of mine by pressing the left ovary’ (Tilt 1871).

The half-century commencing with Briquet’s 1859 treatise on hysteria was an incredibly rich period in the discussion of the diagnosis, the cause, and the treatment of PNDs. This time will, therefore, be discussed in some detail.

PAUL BRIQUET (1796–1881)

In 1859 Briquet published Traité Clinique et Thérapeuétique de l’Hystérie. This was not translated into English until 1980 and then only in part (Mai and Merskey 1980). Briquet’s Treatise was a monumental clinical and epidemiologic study of 430 patients seen over a ten-year period.

Briquet defined hysteria as a ‘neurosis of the brain in which the observed phenomena consist chiefly of a perturbation of vital activities, which serve as the manifestation of affective
feeling and passions'. He also acknowledged the difficulties with the word 'hystera'. 'I shall adopt, therefore, the term hysteria because it is the one that has been used at first, because it is the most widely used, because everyone knows it, and finally because I hope that with time it will have lost its etymological value and become quite simply another proper noun like gold, iron, or lead.' Mai and Merskey note: 'He quotes Galen favorably. "One must attach little importance to these disputes, considering that physicians have quite enough to do being interested in circumstances associated with hysteria, not to amuse themselves by wasting their time in arguing over words."

Briquet found that hysteria occurred in women and men, but the ratio was 20 women for every man. One-fifth of Briquet's cases had an onset before puberty and in the majority the onset was before the age of 20 years. Of 100 hysterical mothers who had 220 daughters, hysteria developed in 124 of the daughters. Briquet compared them to non-hysterical patients and concluded: 'Persons born of hysterical parents are, because of this fact, 12 times as likely to have hysteria develop as those born of non-hysterical parents.' He also found a higher incidence of ill-health and mortality among the children of hysterical mothers, with their daughters faring worse than their sons.

Briquet observed: 'Anything that disturbed the equilibrium of the nervous system could theoretically provoke hysteria. Joy, happiness, and physical and moral pleasure never provoked hysteria, whereas grief, worry and sadness, jealousy, fear, and apprehension most strongly predisposed to hysteria.' One-third of the children had been 'habitually maltreated or held constantly in fear or had been directed harshly by their parents'. His hysterical patients exhibited typical symptoms such as seizures, paralysis, and sensory change. The sensory disturbance included pain and anaesthesia which more commonly affected the left side. In general, those influences that calmed the nervous system improved hysteria, and those that excited the nervous system aggravated it. In treatment, he emphasised the importance of an environment that provided a lack of worry and relief from harshness. "No illness is more difficult to cure than hysteria … half of all hysterical women recover only when advancing age dulls their sensitivities. One-quarter never recover or have the illness their entire lives. Some young girls who become hysterical before the age of 12 or 13 years are condemned to a lifetime of suffering, malaise, and sometimes serious illnesses. They may spend a year or more in bed, completely incapacitated. They are always sick, abort easily, or if they go to term, give birth to more hysterics. Some remain ill until an advanced age, become cachectic, thin and irritable, and old before their time, leading but a wretched life for themselves and those around them.'

JAMES PAGET (1814–1899)

In 1873 James Paget wrote a series of articles in the Lancet on the 'Nervous Mimicry of Organic Diseases'. The first of these will be discussed in some detail, not simply because it is beautifully written, but because it reveals that much of what is sometimes presumed to be 'modern' thought on PNDs, was already established around 140 years ago. Paget described nervous mimicry as occurring when a nervous disorder produces an imitation or mimicry of organic local disease. In some of these cases the mimicry occurs without any substantial disease whatever; in others it gives features of extreme severity to a disease which, in a normal condition of the nervous system, would be trivial or unfelt.

Paget continued: 'Cases of this kind are commonly included under the name Hystera; but in many of them none of the distinctive signs of hysteria are ever observed, and from all of them it is desirable that this name should be abolished. For it is absurdly derived, and, being often used as a term of reproach, is worse than absurd. To call a patient hysterical is taken by many people as meaning that she is silly, or shamming, or could get well if she pleased; and no doubt there are patients of whom some of these things may be fairly said; but in many more, hysteria, especially in the form of an unwilling imitation of organic disease, is a serious affection, making life useless and unhappy and not rarely shortening it.' From the Greek, Paget suggested, 'neuromimesis' as a better word than hysteria.

Paget thanked Reynolds and Anstie who had gone before him, and pointed out that the mimicry of organic disease can be 'so close as to make diagnosis difficult'. He noted the frequency of a minor injury in provoking an episode. 'In some the sensibility is always too keen, whether for pain or pleasure. In these the pain of an injury is much more severe than what we may suppose to be the proper average of pain producible by that injury: it lasts longer; outliving all the other consequences of the injury.' He found 'a singular readiness to be painfully fatigued by slight exertion'. Paget also observed that neuromimesis can occur in people who do not in any way appear 'hysterical'. 'Nothing can be more mischievous than a belief that mimicry of organic disease is to be found only or chiefly in the silly, selfish girls among whom it is commonly supposed that hysteria is rife or an almost natural state. It would be safer for you to believe that you are likely to meet with it among the very good, the very wise, and the most accomplished among women.'

Paget found that whereas people with organic disease tended to get on with life, and as far as possible ignore their symptoms, the reverse applied in those with nervous mimicry. 'Few patients with real hip-disease or real spinal disease, for instance, think half so much about their ailments as they do whose nervous systems imitate those diseases.' He made a famous observation on the 'will'. 'A girl who has will enough to人事 in other things to rule the house has yet not will enough in regard to her limbs to walk a step with them, though they are as muscular as ever in her life. In will these patients are as those who are colour-blind. They say “I cannot”; it looks like “I will not”; but it is “I cannot will”.'
Paget also observed the common presence of a ‘model’. ‘I think it is to this same weakness of will that we may attribute other things often observed in the worst cases of neuromimesis especially the disposition of the patients to assume symptoms of disease that they have seen or heard of, such as the deformities of diseased joints, the lameness or paralysis associated with spine-disease, and the supposed distinctive pains of cancer. No doubt there is sometimes intentional fraud and lying in these cases; but in many more I think you may be sure that patients do not study the imitation or deliberately determine to practise it. Rather they are, in respect of will, like children, who almost involuntarily imitate diseases …’ Paget believed that this tendency to imitate was present in many people, and had to be controlled by an act of will. ‘I think that many persons, even such as have good nervous systems, must be conscious that it requires effort – that is, a full exercise of will – to avoid these imitations, and to disbelieve or disregard sensations imitative of those endured by others.’

Paget is not convinced that all manifestations of nervous mimicry are psychological in origin. He begins with: ‘If you study nervous mimicry in all the varieties of mental strangeness that may be associated with it, it may often seem to you an entirely mental disorder, due only to imagination, or to intense attention directed on one place, or to adoption of signs heard of, or, in many cases, to an insanity of the intellect; and it is not easy to find sufficient evidence that it is not so.’ However: ‘I may assure you, that to regard all mimicries of organic diseases as essentially mental errors would be bad pathology and worse practice … in some mimicries it is hard to discern any mental influence at all.’

Paget ends by noting that for many people including himself, it is not possible to mimic the symptoms encountered: ‘among the sane there are many who cannot bring about a mimicry of disease by an effort of imagination or direction of the mind. Among these I am happy to count myself. I have tried many times carefully, and with good opportunities, but have always failed’.

Paget was not alone in having doubts about the cause and nature of hysteria. Bristowe (1885) delivering The Cavendish Lecture observed: ‘I have quoted a series of cases which I have labelled “hysteria”, and have compared them with other cases, some of which I have regarded as not hysterical. But what right have I to make this distinction between them? Again, I ask what is hysteria?’

JEAN-MARTIN CHARCOT (1825–1893)

Jean-Martin Charcot was a medical colossus, both as a general physician and as a neurologist. Eponyms associated with his name include: maladie de Charcot (motor neuron disease), Charcot–Marie–Tooth disease, Charcot–Erb paresis, Charcot–Joffroy syndrome, Charcot’s artery, Charcot–Bouchard aneurysms, Charcot–Wilbrand syndrome, Charcot’s triad, Charcot–Weiss–Baker syndrome, Charcot’s joint, Charcot–Leyden crystals and Charcot’s biliary fever. Most of his working life was at the Salpêtrière in Paris, where he became superintendent physician in 1862. His patients there were all women who had chronic rheumatological and neurological diseases, at that time regarded as ‘incurable’. Following a French tradition, Charcot applied the méthode anatomo-clinique to his patients (Goetz 2010). This consisted of careful initial examination and then close clinical follow-up, followed by a detailed examination of the brain and spinal cord at postmortem.

Charcot gained world-wide fame not because of these discoveries, but because of his interest in hysteria. In no small part, this was due to dramatic demonstrations of patients with hystero-epilepsy in meetings at the Salpêtrière, which were open to the general public.

At least initially, Charcot believed that hysteria was caused by an ‘organic’ lesion of the brain, which was beyond the reach of current techniques of investigation. This view was summarised by Zenner (1883): ‘Hysteria is a disease of the nervous system, perhaps affecting the entire nervous system; at least the great nervous centres are particularly involved. It depends upon peculiar pathological conditions of those centres which the microscope or other tests at present in our possession do not reveal. We therefore term it a functional disease.’ Charcot felt that there was a strong hereditary component, and noted that the signs could be induced or resolve under hypnosis. He also found that minor injuries had a role in provoking episodes. Unfortunately, events got out of hand.

On 23 and 24 August 1878, Professor Arthur Gamgee, Professor of Physiology in Manchester, accompanied by several physicians, visited the wards of the Salpêtrière, where Charcot personally demonstrated the signs of hystero-epilepsy. Gamgee published a detailed account in the BMJ of that year. Gamgee noted that hystero-epilepsy was ‘that remarkable disease almost all our knowledge of which is due to the labours of M. Charcot’. The attacks of hystero-epilepsy typically had four phases; (1) the epileptiform stage; (2) phase des grands mouvements; (3) phase des attitudes passionelles; and (4) recovery.

The first stage was consistently provoked by ‘peripheral irritation’, such as ‘suddenly “gripping” the skin of the breast on both sides, about on a level with the fifth rib’. During the second stage: ‘The back being somewhat opisthotonically arched, the body was thrown with great violence and astounding rapidity alternately on to the occiput and heels.’ Gamgee described the following sequence of events in one patient during the third stage. First there was a posture of ‘clenched fists and menacing expression’, then ‘cowering, abject fear’, then ‘saintly happiness, as of one who realised the blessedness of heaven’. This was followed by ‘intense joy; the patient sees one whom she loves; she beckons to him to come, to come quickly; he has come … Then succeed gestures which stamp this as the phase of lubricity’. Fear then returns and ‘fear takes possession of the patient; at first it israts which she sees, and which she appears to fear the attack of … it is obviously the fear of some human being which oppresses her, and causes her to beg for mercy’. The patient then hears strains of music; ‘she is pleased; she herself begins to hum the tune, but only for an instant’. Finally: ‘Her singing is followed by weeping, which is
broken by reproaches addressed to her parents as the cause of her misery. The fourth phase of ‘recovery’ could also be accompanied by hallucinations.

A characteristic feature of the attacks of hystero-epilepsy was that they could be stopped by pressure on an ovary: ‘At the instant pressure is made in the ovarian region, two results always follow: firstly, the patient’s mouth opens and the tongue is spasmodically extruded; and secondly the convulsions cease.’

There were other stigmata of hysteria including hyperaesthetic ovaries, anaesthesia and colour blindness (achromatopsia). There was a very distinctive form of hemi-anaesthesia and colour blindness as it could be transferred to the other side of the body by the use of magnets, solenoids, or metallic plates (phénomènon du transfert). Gamgee describes this in another patient. ‘There was complete anaesthesia on the right side, so that a needle could be thrust through the hand withoutoccasioning the slightest evidence of pain.’ There was no sensory deficit on the left side of the body. A solenoid ‘was made to envelope the little finger of the right hemianesthetic side. Almost instantaneously the sound side became hemianaesthetic and the previously normal eye became colour-blind for all colours but red whilst the powers of distinguishing colours on the usually colour-blind side became perfect. No sooner, however, was the finger withdrawn from the solenoid, than the anaesthesia and achromatopsia reassumed their usual distribution’.

Gamgee clearly believed that he was seeing an ‘organic’ problem. He was puzzled by the effects of magnets and solenoids ‘at a distance’ which were ‘absolutely inexplicable in the present condition of physiology’. He quoted Claude Bernard, who shortly before his death after witnessing one of Charcot’s demonstrations observed, ‘the facts show how little we do know’. Gamgee ended by making a plea for medicine and physiology to be more closely aligned.

Illustrations of the hysterogenic zones identified on the patient’s bodies by Charcot, and of the ‘ovarian compressor’ worn by patients for hours to ward off seizures, can be found in Shovron (2007).

Confirming that Gamgee was not somehow misinterpreting the situation, a series of lectures given by Charcot on the treatment of ‘grave hysteria’ with ‘metalloscopy’ and ‘metallo-therapy’ were published in The Lancet in 1878. Charcot described his treatment of hystero-epileptic attacks. ‘When I am called in under such circumstances the first thing I do is to practise compression of the ovary, and, to the utter astonishment of the parents, and perhaps also of the medical attendant, all the symptoms cease as if by magic. The young patient returns to consciousness with a look of surprise. But as soon as the compression is stopped the “fit” begins again. Consequently the treatment is not of any lasting value.’

Charcot went on to describe ‘metallo-therapy’ as a possible solution. Metals such as gold, copper, zinc and tin are in turn applied to an anaesthetic arm. With the correct metal there is a return of sensation sometimes within seconds, and usually within 15–20 minutes. At the same time, this previously weak arm develops ‘the strength of a man’. The transfer phenomenon may also occur. Once a metal is found to be effective, it could be dissolved in solution and given to the patient to drink. ‘We administer ten drops before each meal in a tumbler of distilled water.’

The memoirs of Jane Avril (Jeanne Beaudon), the dancer immortalised by Toulouse Lautrec, provide an insider’s account of life in the Salpêtrière at that time (Bonduelle and Gelfand 1999). Avril tells us: ‘I lived for two years in this “Eden” – which it was for me, so much in this world being relative … There were those deranged girls whose ailment named Hysteria consisted, above all, in simulation of it … How much trouble they used to go to in order to capture attention and gain stardom. That prize went to the one who would find something novel to overshadow the others when Charcot, followed by a large group of students, stood at the bedside and observed their wild contortions, “arcs de cercle”, various acrobatics, and other gymnastics. These patients had nothing to hide from little me – I was of so little consequence! – thus they didn’t hesitate to let me know about what they used to call “the secret”. They gave me the following directions: “when you see one of them come in, be sure to come to my bed and press hard on my ovaries”. It was understood that this simple manoeuvre would suffice to interrupt the attack immediately, permitting the “patient” – recovering her wits – to have a conversation with the special person of the moment. When they sensed that the time of Charcot’s visit was approaching, several threw a fit and I, now that the time had arrived, cooperated by doing what they had requested of me … ’

Avril concluded: ‘I was astonished every time to see how such eminent savants could be duped in that way, when I, as insignificant as I was, saw through the farces. I have said to myself since that the great Charcot was aware of what was happening … ’ However, there were no confessions from the women with hystero-epilepsy. Baudouin in 1925 questioned Blanche Wittman, the ‘Queen of the Hysterics’, on her deathbed about what had happened: ‘if we fell asleep, if we had attacks, it was because we were helpless to do otherwise. What’s more, it was very unpleasant … Fakery! Do you think it would have been easy to fool M. Charcot? Yes, there were tricksters who tried; he used to glance at them and say: “Be still!”’ (Bonduelle and Gelfand 1999).

Charcot was aware of the possibility of deception (Goetz 2016). He also knew that outside the Salpêtrière, his actions were coming into question, but seemed untroubled by this. Pierre Marie wanted to denounce Dr JM Duncan, who at a meeting of the British Medical Association attended by Marie, had expressed doubts about ovarian compression stopping hysterical spells. Charcot advised not bothering about it. ‘Let him, therefore, stumble as he wishes; it is simpler and perhaps more appropriate. To start up a debate would involve, not a conversion, but a full education – lost cause. What does it matter to us?’ (Goetz 2003).

However, it seems clear that hystero-epilepsy in all its glory was an iatrogenic condition. It died with Charcot. For example, Clarke from Bristol writing in 1893, in a review of 70
cases found that in contrast to the prevalence in the Salpêtrière: ‘I have not yet met with a case in which there were distinct hysterical stigmata, and conclude that such cases are rare.’ In 1909, Babinski, Charcot’s pupil, published a paper with the brutal title The Dismemberment of Traditional Hysteria where he described Charcot’s views as ‘both insufficient and erroneous’. Babinski believed that the stigmata of hystero-epilepsy were produced by suggestion. ‘For some years I have not found the stigmata in hysterical patients not previously in contact with those capable of suggesting them.’ Babinski introduced a new word ‘pithiatism’, meaning induced by suggestion and cured by persuasion, which he felt should replace ‘hystéria’. He warned: ‘Realizing the extent of his influence upon suggestible patients, a doctor, while observing the sick person, should observe himself, and guard his words, remembering always that a question awkwardly put or an inopportune reflection may give a suggestion.’ Janet another pupil said of Charcot: ‘he described a type of hysterical which disappeared with him; nobody nowadays any longer describes the attack of hysteria as Charcot did’ (Janet 1920, p. 21). Wilson (1911) was less kind. ‘With the passing of the years the professional hystériques of the Salpêtrière, so assiduously cultivated by Charcot, have gone, or almost gone – or as Dubois reminds us, some, like old circus horses can still be found doing their turn.’

How Charcot accommodated an ‘organic’ concept of hysteria due to a functional lesion in the brain, with his practice of ovarian compression and the external and internal use of ‘metallo-therapy’ is not known. ‘Despite the fact that a great deal of literature has been devoted to Charcot’s work on hysteria, it must be said that he developed no general conception of the disorder that could be compared to Babinski’s. In the lessons devoted to hysteria, many of Charcot’s statements are repetitive or contradict each other. Moreover, the chronology of the lessons is not easy to establish, and Charcot’s thought is both complicated and evolved over time. Therefore different interpreters could emphasize different aspects of his work’ (Derouesné 2009). In 1892, the year before he died, in a preface to a monograph of Janet, Charcot wrote: ‘These works confirm a point of view that I have oftentimes expressed – which is that hysteria is for the most part a mental illness’ (Goetz 2016). However, there is little else published in his works that supports this position. Exactly what Charcot thought, and how the Salpêtrière itself became a hysterogenic zone, will probably never be entirely clear.

The story of Charcot and hysteria has been outlined in some detail because of the important lessons to be learned from it. The first is that when a ‘great’ gets it wrong, the results can be disastrous, as their opinions often go unchallenged. Charcot’s views were ‘expressed with authority and enunciated with dogmatism’ (Wilson 1911). Dogmatism has been a recurrent theme in the history of PNDs. A dominant figure and his followers insist that others show obedience to a particular theory. This is then passively accepted, with a loss of common sense, so that everyday patient experience that is at odds with the theory is ignored. The second lesson is that the Charcot’s ‘neurobiological’ approach so effective in delineating organic diseases, was not well suited to the challenges thrown out by hysteria. Janet’s view in 1920 was that Charcot did not sufficiently consider psychological causes. ‘Carried along by his habits as a clinician, he has, I think, sought these general laws too much in the physiological domain, which led him to a certain number of regrettable errors’ (p. 17).

It must also not be forgotten that, for many of the patients, the Salpêtrière was a place of refuge from a life of misery. The extreme hypnotisability, and the profound power of dissociation evident in the women of the Salpêtrière, suggest they may have been victims of severe sexual, physical and emotional abuse in their past lives. For them to be under Charcot’s care was as Jean Avril observed ‘this Eden’.

That by 1910, Charcot’s ‘functional’ meaning ‘organic’ theory had been replaced by the view that hysteria was mostly a psychological disorder, is clearly seen in an editorial published in the Lancet in May of that year. ‘The days of elaboration of comparisons and analogies between hysterical and organic phenomena, such as are associated with the school founded by Charcot, have been succeeded by a period when the interpretation of the disease is being sought in the realm of mind, when the symptoms of hysteria are being assigned to a disturbance of a psychological nature that maybe traced with precision through all hysterical manifestations. The revolt has been led by Babinski, Janet, and Freud, each of whom has played a noteworthy role in the dismemberment of the traditional hysteria.’

SIGMUND FREUD (1856–1939)

Charcot’s reputation has suffered because of his involvement in hysteria, but much of his work continues to be highly regarded, as it should. In contrast, in the last 20 or so years, Sigmund Freud, once routinely described as a genius has had an amazing fall from grace. His entire reputation has fallen into the ‘dark, unbottomed, infinite abyss’ of Milton. As an example, in 1967, in Collier’s Encyclopedia, Kardiner wrote: ‘The influence of Freud on contemporary civilization has been enormous. Though more recently it has been on the wane in Europe, psychoanalysis continues to be the dominant psychiatric method in the United States, and to a lesser degree in England … Psychoanalysis has thus in a way become the handmaiden of the society’s liberal-democratic assumptions and romantic belief in the possibility of almost limitless self-improvement … In the United States psychoanalysis has had a profound influence on literature and drama, most recently in the works of Eugene O’Neil and Tennessee Williams.’

Flem (1991) went further. ‘In two or three centuries, when psychoanalytic treatment will have long disappeared, there will be no doubt remain on the shelves of libraries, alongside the names of Shakespeare, Dante, Sophocles, Goethe, Proust, Borges, Perec and Celan, the name of Sigmund Freud.’ Contrast this with Tasker (1996) in an essay entitled ‘Burying Freud’: ‘The verdict has been uniformly negative: Freud as
Part XII  Developmental and Neuropsychiatric Disorders of Childhood

a scientist, metapsychologist, and diagnostician of society emerges as a quack.’ Tasker continued: ‘The sheer crankiness of Freud’s ideas was concealed by his marvellous prose, which gave the ideas a veneer of clarity and a feeling of inevitability. Most cranks write badly. Moreover, his lunacy came from an unexpected angle: just like real science, analytical theory was difficult, technical, tough minded, and counterintuitive’.

Freud’s theory of psychoanalysis arose from his treatment of patients with hysteria, and there can be no doubt he made important observations. For example, in April 1896 Freud delivered a lecture, ‘The Aetiology of Hysteria’, before the Society for Psychiatry and Neurology, in Vienna (Masson 1984). In this Freud defined ‘the hysterical state’ as ‘a long persisting after effect of an emotion experienced in the past’. In trying to find the ‘traumatic scene’ that resulted in this state, he identified two requirements of the scene: ‘It possesses the relevant suitability to act as a determinant and it recognizably possesses the necessary traumatic force.’ Freud observed: ‘Here we meet with our first great disappointment.’ Although sometimes there is a clearly traumatic scene such as the sight of a decomposing dead body, ‘incomparably more frequently’ than finding a clear explanation the content of the scene bears no relation to the nature of the symptom, or the experience seems innocuous. Often it appears both unrelated to the symptom and innocuous. Further, ‘we also fail to secure any therapeutic gain’. In other words Freud observed that most people with hysteria did not have a clear psychological trigger for their problems, and treatment was often unsuccessful; very ‘modern’ observations.

Freud then unveiled to the audience his theory that sexual experiences in childhood were the cause of hysteria. These at times seemed ‘astonishingly trivial’. His lecture was not well received. In a letter to Fliss he describes the reaction of the audience: ‘an icy reception from the asses, and from Kraft-Ebbing, the strange comment: It sounds like a scientific fairy tale. And this after one has demonstrated to them a solution to a more than thousand-year-old problem, a “source of the Nile”’ (Masson 1984).

Ormerod (1914) described Freud’s subsequent revision of his theory: ‘At one stage of his investigations, on the basis of 13 cases, Freud stated that the events which started these ideas were actual criminal assaults on the patient in early life. This statement, as you may easily imagine, had to be given up; the stories of the assaults were simply phantasies of the patient, which both he and the psycho-analyst erroneously took to be true. The factors originating the hysteria had then to be sought still further back in life. From this necessity, it would seem, arose Freud’s theory of sexuality in the infant. This theory is ingenious and interesting, but to my mind improbable and extremely disagreeable.’ In an accompanying editorial in the Lancet was the following observation: ‘if it is ridicule that kills, it is a sense of humour that saves; and could some of the Freudian school show even traces of the latter they would not expose themselves so fatally to the former’.

The term ‘conversion disorder’ came from Freud but trying to understand exactly what Freud meant by it, seems difficult (Kanaan 2016). However, as a general concept it is extremely useful in discussing the diagnosis of a PND with the child and family. The simple idea that the child is under stress, but does not want to worry others, and tries to keep this out of her conscious mind, but it has to come out some way, and this happens in the form of physical symptoms, is something that many children and families find acceptable. It serves well in the crucial phase of breaking the news of the diagnosis.

It seems likely that Freud’s works will survive in some form, and it will be no surprise if at least some of his ideas come back into fashion in the not too distant future.

PIERRE MARIE FÉLIX JANET (1859–1947)

Following in the steps of his uncle Paul, Pierre Janet, initially trained in philosophy. He became interested in hysteria, and following completion of his medical studies, in 1893 he was appointed by Charcot to head a new experimental psychology laboratory at the Salpêtrière. (Charcot died unexpectedly weeks later.) We do not need to rely on a translation of Janet’s views on hysteria, as we mostly have to do with Briquet, Charcot and Freud. In 1906 Briquet gave 15 lectures on hysteria at the Harvard Medical School. These became the basis of a book written in English, The Major Symptoms of Hysteria, published in 1907, with a revised second edition in 1920. The citations discussed here are from the second edition. Janet’s ‘encyclopaedic scholarship, his meticulous and subtle clinical observations, his intellectual stature, and the originality of his theorizing’ (Gregory 1987) can all be found in this book. He was a man of strong views supported by extensive clinical experience.

In the first chapter Janet emphasises the importance of correct and early diagnosis. ‘This early diagnosis is much more important still from another point of view: it will keep you, allow me to tell you plainly, from making blunders. It is perhaps not very serious not to recognize a hysterical accident and not to treat it; but what is always very serious is to mistake a hysterical accident for another one, and to treat it for what it is not. You cannot imagine the medical blunders, and too often also the medical crimes, committed in this way’ (p. 11).

He describes the consequences. ‘Then the physician interposes, frightens the family, agitates the patient to the utmost, and prescribes extraordinary diets, perturbing the life and exhausting the strength of the sick person. Finally, the surgeon is called in. Do not try to count the number of arms cut off, of muscles of the neck incised for cricks, of bones broken for mere cramps, of bellies cut open for phantom tumours, and especially of women made barren for pretended ovarian tumours. Humanity ought indeed to do homage to Charcot for having prevented a greater depopulation’ (p. 12).

Illustrating that Janet’s message is not out of date, is the paper by Ferrara and Jankovic (2008), describing 54 children with psychogenic movement disorders. ‘Twelve (22%) children had a total of 17 surgeries for symptoms related to their psychogenic movement disorders (PMD) or for associated symptoms eventually determined to have no identifiable
organic basis. Procedures directly attributable to PMDs included: ulnar nerve transposition for arm stiffness and finger curling due to hemidystonia, shoulder stabilisation for painful arm posturing due to bibrachial dystonia, three surgeries for painful thumb posturing due to bibrachial dystonia, two arthroscopic knee explorations for pain associated with hemidystonia, bilateral ocular surgeries for misalignment due to convergence spasm, percutaneous endoscopic gastrostomy for dysphagia due to cranial dystonia … Edwards et al. (2011) described two patients who had limbs amputated for ‘fixed dystonia’ (discussed in The Syndrome of Fixed Dystonia section below) noting that: ‘The outcome of amputation in fixed dystonia is invariably unfavourable.’

Returning to Janet, in the chapter on hysterical paralysis he quotes Babinski and others: ‘According to these authors, this ensemble of signs is absolutely characteristic, and it is possible to recognize a hysteric hemiplegy solely through this objective examination which requires nothing of the patient’s psychological observation. The thing is perfect theoretically, but practically it is much more difficult than is supposed’ (p. 148).

When discussing hysterical sensory signs Janet notes that these ‘attend to the popular conception of the organ rather than to its anatomic conception’ (p. 157). He addresses the ‘apparently voluntary’ nature of hysterical symptoms: ‘The anesthesia of hystericals is extremely changeable and contradictory. These patients pretend not to feel, and by very simple artifices we can prove to them that they feel perfectly well. Their insensibility is, therefore, simulated, and our processes are only means to deceive a deceiver and unmask a fraud. This résumé of facts is, to our mind, altogether crude and insufficient. Do hystericals take any particular interest or pleasure in having their arms pierced through with needles? … How is it that, in all civilized countries, hystericals should have agreed to simulate the same thing ever since the Middle Ages to the present day?’ (p. 171).

Janet was not convinced that hysterical problems were entirely of psychological origin, but accepted that for 20 years, ‘the psychological conception has the mastery’ (p. 323).

Janet’s theories on hysteria were complex and philosophical. Key elements included a narrowing of the field of consciousness (analogous to a narrowing of the visual fields), and dissociation (Van Der Hart and Horst 1989). ‘Dissociation’ is from the French désagrégation, and means that functions such as moving, remembering or feeling, can be walled off into separate compartments, unable to be assessed by the conscious mind. ‘The function is far from being destroyed. It continues to exist and often even develops to an exaggerated degree. It is only suppressed from one very special standpoint; it is no longer at the disposal of the will or the consciousness of the subject’ (p. 319).

THE ECLIPSE OF HYSTERIA

From 1900 to 1965, speaking generally, ‘hysterical’ symptoms were ascribed to psychological problems. In the English-speaking world at least, this changed when Eliot Slater (1965) published a paper in the BMJ that had a profound effect on the way doctors viewed PND for the next 30 or more years. This paper is analysed in detail elsewhere (Morris and Grattan-Smith 2015), and will only be briefly discussed here. It was a follow-up study of patients seen at Queen Square in London, who had been diagnosed with hysteria. Slater ended the article with: ‘What, then, is our conclusion? Looking back over the long history of “hysteria” we see that the null hypothesis has never been disproved. No evidence has yet been offered that the patients diagnosed as suffering from “hysteria” are in medically significant terms anything more than a random selection … The only thing that “hysterical” patients can be shown to have in common is that they are all patients. The malady of the wandering womb began as a myth, and a myth it yet survives. But, like all unwarranted beliefs which still attract credence, it is dangerous. The diagnosis of “hysteria” is a disguise for ignorance and a fertile source of clinical error. It is in fact not only a delusion but also a snare.’ Slater took the view that the diagnosis of hysteria harmed patients, as it resulted in the underlying organic disease being missed, the contrary view that the diagnosis of hysteria was made by neurology consultants, or by psychiatrists, or by junior staff. Nor was there a discussion of whether the symptoms on which the diagnosis of hysteria had been made, could be related to the subsequently identified organic illness.

Accompanying Slater’s paper, the BMJ published an editorial entitled ‘Eclipse of Hysteria’. The unnamed author, presumably a psychiatrist, completed the pincer movement. ‘Dr Eliot Slater … advocates that the diagnosis of hysteria should be completely abandoned … A follow-up study of cases diagnosed as hysteria in the National Hospital has confirmed him in his conclusion that a syndrome or disease entity “hysteria” does not exist. Dr Slater’s conclusions, striking and provocative though they are, will be acceptable to most psychiatrists.’

The defence of the diagnosis of hysteria fell to Sir Francis Walshe, whose paper was published in the BMJ in December 1965. Walshe was then 80 years old. There was little response from younger neurologists. Slater’s rhetoric was accepted without analysis of the details of his paper. For many years his claims became accepted fact. Although the effect was probably greater in adult neurology, paediatric neurologists who diagnosed hysteria were constantly warned that they were ‘missing something organic’. Large textbooks on paediatric neurology first published in the 1980s and 1990s such as those of Aicardi, Brett, and Swaiman and Wright, made only fleeting reference to hysteria.
The proposition that patients diagnosed with ‘hysteria’ were highly likely to have an underlying organic disease, which seemed to defy common clinical experience, went substantially unchallenged until 1998 when Crimlisk et al. published a paper entitled ‘Slater revisited: 6 year follow-up study of patients with medically unexplained motor symptoms’. This and multiple subsequent papers, including a huge study by Stone et al. (2009), have made it clear that an undetected organic disease is uncommon in patients diagnosed with PNDs. Accompanying this change in position has been a revival of interest in the study of PNDs, particularly from a neurobiological perspective, accompanied by attempts to find a more acceptable name, with a return to ‘functional’ the latest suggestion.

PAEDIATRIC PAPERS

Looking specifically at papers describing PNDs in children, between 1897 and 1907, four articles were published in the Journal of the American Medical Association with the identical title, ‘Hysteria in Children’ by Mayer, Burr, Biller and Hecht. Brief excerpts from these papers show that we face the same questions, and experience the same difficulties, as doctors did more than 100 years ago.

THE PREDICAMENT OF THE CHILD

Mayer (1899): ‘Often the cause of the child’s hysteria is fright caused by a drunken father nightly beating mother and child, or fear of a whipping by a stern teacher.’

Biller (1898): ‘[children with hysteria] suffer greatly from competitive examinations at school, and from the extra work that is often imposed upon them in preparing for school entertainments – especially in preparing for public recitations’.

THE PROVOCATION OF A PSYCHOGENIC NEUROLOGICAL DISORDER BY MINOR INJURY OR ILLNESS

Hecht (1907): ‘That hysterical symptoms are frequently engrafted on symptoms of organic disease and long outlast the latter, is, of course, not to be lost sight of … Slight cause, then, and grave consequence should arouse immediately a suspicion of hysteria.’

CONTROVERSIES OVER THE CAUSE

Mayer (1899): ‘Before proceeding further let us see what the basis of hysteria is. It is a question often asked, but never answered. Still, there is an underlying groundwork to every case. We do not refer to hypotheses. Many of these have been advanced, as that of Janet, that hysteria is due to a weakening of the psychologic synthesis; of Myers, that it is due to a disease of the hypnoid stratum, and of Liebermeister that it is a subcortical disturbance.’

THE DIFFICULTY IN SEPARATING ORGANIC DISEASE FROM PSYCHOGENIC NEUROLOGICAL DISORDERS

Hecht (1907): ‘The greatest difficulty lies not so much in mistaking organic disease for hysteria, and vice versa, as in failing to appreciate that organic disease may be and frequently is complicated by hysteria.’

MALINGERING

Mayer (1899): ‘Just as hard as it is to diagnose the hysterical or organic nature of an affection in some cases, is it to distinguish simulation from hysteria.’

TREATMENT OF THE SYMPTOM OR THE UNDERLYING CAUSE?

Burr (1897): ‘I have used the word cure several times. I wish it to be understood to refer only to the specific attack and not to the inherited predisposition. We usually cure not the hysteria but the attack … ’

TREATMENT DIFFICULTIES AND THE TENDENCY OF FAMILIES TO SEEK ALTERNATIVE METHODS

Biller (1898): ‘the patient becomes dissatisfied and passes, frequently, into the hands of some quack or charlatan, who thrives by accidentally – and probably unconscious – knowing how to take advantage of some of the tricks of this powerful but susceptible enemy of the human family’.

PROGNOSIS

Hecht (1907): ‘Just a word in reference to the prognosis, which in children is infinitely better than adults.’

Relevant quotations from the greats of the past will continue to be included in the discussion that is to follow, because of their clarity, and as a reminder that PNDs may well be ‘as old as human nature itself’ (Wilson 1930).

FREQUENCY AND PRESENTATION OF PSYCHOGENIC NEUROLOGICAL DISORDERS

David Taylor (1986) observed that hysteria ‘is a commonplace reaction, and those who become dignified by a formal diagnosis are a severe, extreme or fortuitous selection’. It is likely many children will have a brief episode that passes without either diagnosis or sequelae. Reflecting this, the study of Ani et al. (2013) was confined to children with ‘non-transient’ conversion disorder. Children who had a duration of illness less than 7 days, were excluded from their study.

There have been two recent surveillance reports of the incidence of conversion disorder (CD) in childhood. In the study
of Ani et al. (2013), over a 15-month surveillance period there were 204 confirmed cases in United Kingdom and Ireland, giving an estimated 12 month incidence of 1.30/100,000. The age range of the 204 confirmed cases was 7–15 years, with a median age of 12.5 years. The incidence was 0.26/100,000 among children younger than 10 years, and 3.04/100,000 for children 10–15 years old. Three-quarters of the patients were females, and a female predominance was noted both in those older and younger than 10 years. There was no child younger than 7 years at the time of diagnosis.

In the study of Ani et al. (2013), core conversion symptoms included weakness (63%), abnormal movements (43%), non-epileptic seizures (40%), anaesthesia/paraesthesia (32%), diminished consciousness (29%), visual loss (23%), limb paralysis (22%), loss of speech (19%) and hearing loss (8%). Most children (69%), presented with more than one core symptom, and 16% had four or more symptoms. Pain (55%) and fatigue (34%) were commonly reported alongside the core symptoms, with la belle indifference found in 27% of children.

In the earlier surveillance study of Kozlowska et al. (2007), of 194 Australian children under 16 years of age, the annual incidence of conversion disorder was 2.3/100,000. In children younger than 10 years of age, the incidence was 0.8/100,000. In the state of New South Wales the overall incidence was 4.2/100,000 perhaps due to more diligent reporting. Seventy-one per cent of the children were female. The average age at presentation was 11.8 years, and 55% had multiple conversion symptoms. The most common presentations were disturbance of voluntary motor function (64%), including motor weakness, limb paralysis, abnormal gait, abnormal movements and difficulties with speech or swallowing. Sensory symptoms (24%), pseudoseizures (23%), and respiratory problems (14%) were also found. As well as the conversion symptoms, pain (56%) and fatigue (34%) were commonly reported.

Surveillance studies can only paint a broad picture, but a number of earlier case based series described similar results to those found in these two surveys (Schneider and Rice 1979; Grattan-Smith et al. 1988; Leslie 1988). In the review of Grattan-Smith et al. (1988), the records of 52 children admitted to hospital with conversion disorder over a 10-year period were reviewed. The findings were almost identical to the surveys of Ani et al. (2013) and Kozlowska et al. (2007). Seventy-five per cent of the children were female and 62% were between the age of 10 and 12 years. There were only three children under the age of 8 years. An abnormal gait was present in 66%. Of those with an abnormal gait, 44% could not move at all with leg pain, and most of the remainder had classic presentations such as monoparesis, paraplegia, hemiparesis and ataxia. Other presentations included non-epileptic seizures, sneezing, stridor, aphasia, and globus hystericus. Overall, 77% of the patients complained of pain, paraesthesia, or anaesthesia. This co-existence of motor dysfunction and sensory disturbance in patients with PNDs has long been recognised. Briquet observed: ‘Pain in the muscles is so common that there is not a single woman with this neurosis who does not have some muscle pain during the course of the illness’ (Mai and Merskey 1980). Janet found anaesthesia was a feature of two-thirds of hysterical presentations (Janet 1920, p. 276).

From multiple sources, a consistent picture emerges of the presentation of a child with a PND. The child is most often between 10 and 14 years of age, is female, has multiple symptoms and, as well as loss of function, frequently also complains of pain, sensory disturbance and fatigue. The condition is uncommon under the age of 8 years.

THE ‘POSITIVE SIGNS’ OF A PSYCHOCGENIC NEUROLOGICAL DISORDER

The diagnosis of a PND is primarily based on the physical signs which reveal that, although the child complains of not being able to move, or feel, or see normally, these functions are intact. Normal investigations and the child being in a stressful situation add further weight to the diagnosis, but they are nothing without the signs.

In 1922 Henry Head described the ‘positive signs’ of hysteria. ‘These physical signs are as definite and specific as those of any other disease. Hystera is sometimes said to “imitate” organic affections; but this is a highly misleading statement. The mimicry can only deceive an observer ignorant of the signs of hysteria or content with perfunctory examination.’ Subsequent authors adopted a more cautious approach and described ‘red flags’ that alert the examiner to the possibility of a PND. In their review of psychogenic movement disorders in adults, Gupta and Lang (2009) list ten clues obtained from the history, and 16 found in the examination that suggest the diagnosis, warning that ‘no single clinical finding is pathognomonic’. More recently it has again been claimed that, in experienced hands, certain signs are diagnostic of a functional movement disorder (Espay and Lang 2015).

In this section the various signs that are seen in PND are reviewed. Most of these have been recognised for more than 100 years (see Clarke 1893). More detailed accounts can be found in the older textbooks such as Walsh (1952), and De Jong (Haerer 1992) and the monograph by Weintraub (1977). There has also been a more recent review of the signs of conversion disorder (Daum et al. 2014), and a video-based ‘Manual’ demonstrating some of the signs (Morris and Grattan-Smith 2015). Most recent is the comprehensive review of all aspects of PND found in an edition of The Handbook of Clinical Neurology devoted to PND (Hallet et al. 2016).

ABNORMALITIES OF GAIT

Abnormalities of gait are particularly common in children with psychogenic disorders. When the child cannot walk normally,
the message that help is needed is inescapable. Mayer (1899) provides a beautiful description of the psychogenic gait: ‘The gait resulting from functional paralysis of the lower limbs is peculiar. It is jerky, not halting nor hesitating, the steps taken being small and noticeably forced. There is no spreading of the legs, as in organic incoordination, no high-step with foot-drop, as in infantile paralysis and multiple neuritis, no scythe-like motion as in organic hemiplegia with the turned-in toes catching on the floor at each forward step. The muscles impress you as being unnecessarily used rather than being useless.’

Clarke (1893) described a dramatic case in a 12-year-old boy. ‘On Feb. 9th, 1892, he was carried to the hospital as he could not walk. When placed on his feet he did not fall, but could not stand still, constantly shifting his feet. He could not walk, run or stand still, but on being placed on his feet went round and put in a chair. He moved with a curious, quick, dancing step, in which the feet were brought rather forcibly to the floor. The movement is difficult to describe, but one of the nurses said the step was known in country dances as the ‘monkey hornpipe’. Whether the eyes were closed or open seemed to make no difference to him. There were no other signs of nervous disease. The next day he was still entirely unable to walk or run, but could get along very well by jumping with his feet close together or by going on all fours, and was able to hop down the ward and back. In a few days he recovered the power of walking and running.’ Such dramatic presentations continue to be seen.

In the so-called ‘magnetic’ gait, the feet may seem stuck to the ground and the steps are short, slow and done with considerable effort. At the same time the child may groan and give the impression of a diffusely painful body. Dubowitz and Hersov (1976) noted a variant of this: ‘Three of the cases also demonstrated what we have come to regard as a very useful sign of hysterical paralysis, namely an inability to raise the foot off the floor when attempting to stand or hop on one leg (almost as if the foot were glued to the floor). The effort is always associated with exaggerated movements and contortions of the other limbs.’

At the other extreme is a staggering gait with the child lurching from side to side, and continually threatening to fall, but actually displaying superb balance in the ability to, without mishap, continually move from one precarious posture to another. This is often called ‘astasia-abasia’.

The fact that a gait is bizarre does not make it psychogenic. Dystonic gaits may look very strange, and patients with DYT1 dystonia may be forced into severe twisting postures without falling. Chorea can also produce a bizarre gait that is often mistaken as being psychogenic.

Once the question of a psychogenic gait has arisen, the child needs to be examined carefully in bed. The absence of any abnormalities of tone, the finding of normal reflexes, and a negative Babinski sign are all helpful. However, often it is the presence of additional psychogenic signs, such as non-dematomal sensory loss or monocular double vision, that is decisive in making the diagnosis of a PND. Sometimes the child will be seen to walk normally when, for example, going to the toilet and unaware of being observed. In very difficult cases it may only be the return of a normal gait with treatment that finally sets the clinician’s mind at rest that the problem is definitely a PND.

**PSYCHOCGENIC WEAKNESS**

Testing of psychogenic weakness can be difficult, as at times it relies on the subjective impressions of the examiner. As an example from Walsh (1952): ‘The hand grasp of a partially paralysed arm in the case of hysterical weakness has characteristic features: the hand is closed round the observer’s and held firmly set in a grasp which exerts but the slightest pressure and the sense of power withheld is one that once felt is not easily forgotten.’ From Head (1922): ‘Sometimes movement is positively inhibited; the patient says, “I cannot move my leg”, and it hangs inert, or is dragged behind him like a log.’

A sign probably first described by Beevor has had a number of different names including ‘defective inhibition of the antagonists’ (Wilson 1930). Walsh (1952) called it the ‘law of antagonistic effort’ – ‘if the request be made to the patient to flex the forearm strongly on the arm against resistance, a distinct movement of extension may be felt’. It is also described in Head’s paper. ‘On each occasion he responded to your command by an exactly opposite movement’ (Head 1922). Wilson (1930) regarded this initial activation of antagonist muscles as ‘unquestionably the most common motor sign’ of hysteria.

In 1908 Hoover made an observation that has become the basis of a useful test for detecting psychogenic weakness of one leg. ‘If a normal person, lying on a couch in the dorsal position, be asked to lift the right foot off the couch with the leg extended, the left heel will be observed to dig into the couch as the right leg and thigh are elevated.’ The Hoover test can be performed in a number of ways, and the following is one method. The child lies supine and is asked to lift the ‘good’ leg from the bed and resist the examiner, who exerts downward pressure on that leg with one hand. The examiner’s other hand is placed under the ankle of the ‘weak’ leg as ‘unquestionably the most common motor sign’ of hysteria.

Toilet and unaware of being observed. In very difficult cases it may only be the return of a normal gait with treatment that finally sets the clinician’s mind at rest that the problem is definitely a PND.
If it can be demonstrated that not only does the patient have normal strength when claiming to be weak, but reacts to this demonstration by some form of counter move, then the diagnosis of a PND is even more secure. Head (1922) gives an example: ‘In the milder examples of loss of power or inability to stand on one leg, the nature of the affection is revealed by the following trick. If it has been determined to the satisfaction of the patient that he cannot support his weight on the right foot, tell him you are quite satisfied that the right is affected, but that the left is his “good leg”. When he is standing steadily, give a sudden command, “Kick out your good leg”; this he will do, although it necessitates balancing himself upon the affected foot. On the other hand, follow this quickly with the order, “Kick out your bad leg”, and he will fall, although he is supported on the normal limb.’

These tests are important in making the correct diagnosis, but at the same time it is important to avoid making the child feel like a ‘fraud’, which can easily cause both an escalation and an entrenchment of the symptoms. If, in front of his parents, you suddenly lob a soft toy at a boy who plays cricket, and before he knows it his ‘paralysed’ arms springs out and catches the toy, from that moment on you are unlikely to have much of a relationship with the boy. (If he does not react and the toy lands on his chest, and he cries out in pain and shock, things will be even worse.)

Potentially painful tests should also be avoided. For example, a test used for unilateral arm weakness in adults is to lift the weak arm above the patients head, and let it drop. In psychogenic weakness rather than falling straight down towards the face, the arm tends to veer away and land on the bed next to the patient. Psychogenic coma is not discussed in this section, but if this is suspected, jiggling a rolled up tissue back and forward in a nostril is irritating, but harmless, and is to be preferred to methods such as strong supra-orbital pressure, or squeezing the nipples. An example of a painful test from the past used on adults is the test for hysterical paraplegia attributed to Gowers (Pryse-Phillips 1995). It consists of suddenly pulling on the pubic hair of the patient with paralysed legs, causing the legs to immediately adduct. Such painful tests may be a reflection of the level of anxiety in the doctor, rather than a desire to punish the patient. However, they are a high-stakes game as the patient may pass the test, ‘proving’ that they do not have a psychogenic problem. An example can be found in the movie Dirty Rotten Scoundrels where the ‘celebrated Liechtenstein psychiatrist’, Dr Emil Shaffhausen (Michael Caine), mercilessly whips the allegedly anesthetic legs of Freddy Benson (Steve Martin) who manages to stay silent throughout the ordeal.

LATERALISATION OF SIGNS

A common belief in adult patients with PND, perhaps going back to Briquet, was that when the signs were lateralised, this was more likely to be to the left. However, Stone et al. (2002) reviewed 121 studies, involving 1139 patients, and found that this was probably incorrect. Regan and LaBarbera (1984), found that ten of 11 children and adolescents with unilateral conversion symptoms, showed symptoms on the right side of the body. All were right handed. The only person with left-sided signs was a girl who developed pain in her left knee, and she had experienced an injury to that knee in the past. Schwingschuh et al. (2008) found that when an abnormal movement started in one limb, it was the dominant side in nine of ten cases. In many studies, lateralisation is not discussed, and although these findings are interesting, it would be unwise to suggest that a problem is or is not psychogenic, based only on whether or not the dominant side was involved.

POSITIVE BABINSKI SIGN AND ANKLE CLONUS

It might be assumed that a positive Babinski sign, or what appears to be sustained ankle clonus, would be clear indications of an organic disorder. However, interpretation of the Babinski sign is difficult, and if the toe appears to be going up without any other signs of an upper motor neuron lesion, it should be viewed with caution. Psychogenic clonus can be very impressive, but has long been recognised as a clinical entity (Wilson 1930; Hallet 2010). Obviously great caution is required and the clinical setting is important. The author vividly remembers as a registrar being involved in the treatment of a teenage girl who had psychogenic seizures lasting 30 minutes or more. When examined she had very brisk reflexes and sustained ankle ‘clonus’. Both diagnosis and management were extremely difficult. The admission lasted months, and although while in hospital the girl vehemently denied any possibility of her having psychological problems, she later wrote to the consultant saying that she had been abused, and why did it take so long to make the diagnosis?

PSYCHOCGENIC CHOREA AND DYSTONIA

The more common error in the setting of chorea and dystonia is to wrongly assume that the child has a psychogenic disorder. The emotional lability, the restlessness, the facial grimacing, the motor impersistence, and the dancing quality of the movements, can all lead to chorea being misdiagnosed as a psychogenic problem. Sydenham recognised this more than three centuries ago: ‘At first it shows itself by a halting, or rather an unsteady movement of one of the legs, which the patient drags. Then it is seen in the hand of the same side. The patient cannot keep it a moment in its place, whether he lay it upon his breast or any other part of his body. Do what he may, it will be jerked elsewhere convulsively. If any vessel filled with drink be put into his hand, before it reaches his mouth he will exhibit a thousand gesticulations like a mountebank. He holds the cup out straight, as if to move it to his mouth, but has his hand carried elsewhere by sudden jerks. Then, perhaps, he contrives to bring it to his mouth. If so, he will drink the liquid
Dystonia also has many features that may suggest to the unwarey that the problem is psychogenic. At rest, tone may be normal, but it rapidly increases when movement is attempted. Dystonic patients may have gait abnormalities. A rapidly onset of dystonia is likely to be regarded as psychogenic by those who have not seen this characteristic sign of dystonia before. A rapid onset of symptoms is commonly cited as suggestive of a psychogenic problem, but this is also a feature of rapid onset dystonia parkinsonism (Brashear et al. 2007). Particularly difficult is the situation where the patient carries a known dystonia causing gene, and possibly has a PND (Bentivoglio et al. 2002).

With the advent of the internet it is likely that psychogenic chorea or dystonia will be more commonly seen than in the past. [Avila and Cohen (2010) discuss the story of Desiree Jennings, a cheerleader, who provoked considerable online controversy as to whether she had organic or a psychogenic dystonia.]

If there is doubt about the diagnosis of psychogenic chorea or dystonia, it is prudent to get an opinion from an experienced and sensible colleague.

THE SYNDROME OF FIXED DYSTONIA

Causalgie-Dystonia, Post-traumatic Dystonia

There has been considerable controversy over the nature of this syndrome (Bhatia et al. 1993; Schrag et al. 2004). Typically after minor trauma, a limb develops a fixed immobile posture often associated with severe pain. Common postures include sustained foot inversion with plantar flexion, and wrist and finger flexion. There is overlap with Chronic Regional Pain Syndrome Type 1 (van Rijn et al. 2007). There is no space to cover the controversy about this condition in any detail but Hawley and Weiner (2011) have made their views clear: ‘Evidence supporting a pathophysiologic mechanism for peripheral trauma inducing or provoking dystonia is virtually non-existent … The literature clearly supports the view that fixed dystonia is a psychogenic movement disorder.’

Once again a knowledge of medical history is useful in dealing with this very difficult condition. In 1956 Macalpine and Ross described two young woman, aged 22 and 20 years who had been referred for sympathectomy or amputation because of the severity of their symptoms. The authors used Charcot’s term *œdème bleu des hystériques* and noted that both Brodie (1837) and Paget (1873) had described the same condition. Macalpine and Ross cited Charcot who in 1890 had observed that this disorder is characterised by ‘non-pitting oedema, coldness, purplish discoloration, altered sensation, often total anaesthesia, paresis, and contracture of either hand or foot’. Pain was sometimes, but not always, a feature. Gold (1965) subsequently described six children with the same condition but used the term ‘hysterical contractures’.

PSYCHOGENIC TREMOR

When movements are repetitive and rhythmic, the child is usually described as having a tremor. In psychogenic tremor the movements may be of high amplitude and violent. When the patient is distracted, there may be a pause, or a change in frequency, amplitude or distribution. There can also be an alternating tremor where one arm rises as the other falls. Complex movements that resemble arm waving, patting or stroking can also be seen.

Distraction and entrainment are commonly used in the diagnosis of a psychogenic tremor. An example of distraction is as follows. The patient is asked to hold her arms out in front, and then do ‘serial 7s’ (taking 7 from 100, and then 7 from that number, and continuing downwards). With an organic tremor, the movements tend to worsen, whereas with psychogenic tremor they may disappear entirely. It is important to ensure the mental task is challenging. For example, asking a adolescent to count backwards from 10, or say the days of the week backwards, may not require sufficient mental effort, defeating the purpose of the task. If the child, who otherwise seems cognitively intact, gives answers that are hopelessly wrong, the test is not reliable, except in the sense that it raises the possibility that the problem is psychogenic.

Entrainment is used when the patient, for example, has a tremor of the right arm. The examiner sitting opposite the patient begins to tap against his leg with his right hand, and asks the patient to follow this exactly with her left hand. The examiner then taps on his leg varying the frequency, rhythm and amplitude. As the patient follows with her left arm, the tremor in her right arm changes, and in a classic situation takes on the identical rate and rhythm of the examiner. More often there is a perceptible change in what previously had been a consistent movement. If the patient inexplicably does not make a reasonable effort to follow the examiner’s movements, the test is not useful, apart from again fostering the suspicion that the problem may be psychogenic.

Certain patterns of tremor also raise the possibility of a psychogenic cause. A resting tremor is rare in children except for infants with inborn errors of dopamine metabolism (Grattan-Smith et al. 2002). A tremor that is present at rest, with posture and with action is also rare in childhood. (The exception is Holmes tremor, but here there has usually been a clear preceding cause such as severe head trauma.)
Tremor studies can be helpful. Canavese et al. (2008) found that with psychogenic tremor, polymyography showed a tremor activity with variable frequency and amplitude, which tended to decrease with distracting manoeuvres. It can be argued that this simply reflects the clinical findings. However, such studies can be very helpful in persuading the child and family that the problem is being carefully considered, and that sophisticated testing is being done to make sure the problem is not organic. To their minds it provides ‘scientific’ proof of the diagnosis, rather than it just being the opinion of a doctor.

Edwards and Bhatia (2012a) believe that the key clinical feature that helps to differentiate psychogenic tremor from organic tremor is that psychogenic tremor changes when attention is directed towards the affected limb. However, looking at the clinical features and neurophysiology (in adults) they concluded: ‘We found that no single measure had sufficient specificity and sensitivity to differentiate FT (functional tremor) from organic tremor.’

In the differential diagnosis of a psychogenic tremor, it is important to consider Wilson’s disease (which can present as a ‘psychiatric’ problem), and thyrotoxicosis (see Chapter 19).

**PSYCHOGENIC PALATAL TREMOR**

**Palatal Myoclonus**

Palatal tremor is a distinctive condition, and rare in childhood. Classically, palatal tremor is subdivided into symptomatic and essential palatal tremor (Deuschl et al. 1994). Symptomatic palatal tremor results from lesions involving the dentate-olivary pathway, and there may be hypertrophy of the inferior olivary nucleus, which can be demonstrated on magnetic resonance imaging (MRI) scans. The palatal movement is produced by contraction of levator veli palatini. There may be widespread jerks involving muscles of many areas including the face and diaphragm, which are synchronous with the palatal movements. There are no ear clicks. In essential palatal tremor, the movements result from contraction of tensor veli palatini. Ear clicks are commonly present, and the movements are restricted to the palate. There are no abnormalities of the inferior olivary nucleus on MRI.

In some patients with essential palatal tremor the problem appears to be psychogenic (Stamelou et al. 2012). The diagnosis is made on similar grounds to psychogenic tremor in other parts of the body, that is, changes with distraction. There is a dictum going back at least to Paget (1873) and Möbius (Hecht 1907), that if the examinee is unable to perform an unusual movement, then it is unlikely to be psychogenic. This is not reliable and psychogenic palatal tremor is an example.

**PSYCHOGENIC JERKS**

With psychogenic jerks, the movements are abrupt and short-lived. They may be difficult to distinguish from myoclonus, or an exaggerated startle response. A sense of generally exaggerated reactions is a clue to a psychogenic cause. A slight noise may cause the whole body to jerk. The knee jerk is tested and both arms and legs jerk. At the same time the patient complains that the light tap caused extreme pain over the patellar tendon.

In psychogenic myoclonus, especially if the jerks are not frequent, diagnosis can be very difficult. Neurophysiology can be helpful. A normal EMG makes typical epileptic myoclonus unlikely, but movement at the time of the jerk can obscure the recording. If, on surface electromyography (EMG), bursts are less than 50 ms then the person is likely to have a form of cortical myoclonus and the problem is not psychogenic (see Chapter 19 for a review of neurophysiology of myoclonus). Longer EMG bursts can occur in both organic movement disorders, and PND. The presence of giant somatosensory evoked potentials points to a cortical myoclonus, as does back averaging (Edwards and Bhatia 2012a), but this requires a sophisticated laboratory and a co-operative child.

Hypperekplexia needs to be considered in the differential of a psychogenic startle response, but usually the jerks have been life-long rather than of recent onset. With psychogenic startle, on neurophysiology testing the latency of the response and its EMG signature conform to that of a voluntary movement, rather than a true reflex response (Pal 2011). To a degree, this lag between the stimulus and the response can be identified clinically. The onset of stiff-man syndrome can be in childhood (Clardy et al. 2013), with emotional stress and anxiety provoking painful limb and paraspinal muscle spasms, and an exaggerated startle. Startle seizures also need to be considered (Aguglia et al. 1984).

**PSYCHOGENIC TICS**

Psychogenic tics were described many years ago (Dooley et al. 1994), but have received less attention than other PND. The diagnosis is particularly difficult as both tics and psychogenic movements can wax and wane, are made worse by stress, decrease when the person is distracted, and can look both voluntary and bizarre. In children with Tourette syndrome, typically tics start around the age of 5 years, and most often the initial tics are simple, such as shoulder shrugs or sniffing. Over time more complex tics develop. If a child of 13 years, who has never previously had tics, suddenly develops a complex movement that could be a tic, a psychogenic problem should be considered, realising that it could still be a tic.

In children with established Tourette syndrome, the diagnosis of psychogenic tics is especially difficult, and often can only be suspected. For example, the child develops deafening shrieks done at a time when they will have maximum impact. Is this a new vocal tic, an elaboration of a tic, or entirely psychogenic? Unless the child tells you it is not a tic, the differentiation is almost impossible. There can also be episodes labelled ‘tic attacks’, where there are sudden bouts of extremely severe tics often induced by anxiety (Robinson and Hedderly 2016). These may last hours with the child rushed into the nearest Accident and Emergency department, because of the
severity of the movements. In this setting the same questions is asked as to whether the movements are all tics, or is there an additional psychogenic component? A point of differentiation with motor tics and psychogenic movements is functional loss. For example, a child with blinking tics will not close his eyes at the instant a cricket ball is being bowled to him. Tics tend to slip in between important actions, rather than disrupting them. If the movements cause the child to drop his pen, or gouge a hole in the paper he is writing on, the cause is unlikely to be a tic, and could be psychogenic (or another movement disorder).

Baizabal-Carvallo and Jankovic (2014) described nine adults with psychogenic tics. All had other psychogenic movement disorders at the same time or during the follow-up evaluations, which is an obvious clue. Other features included a lack of a premonitory sensation, and an inability to transiently suppress the movements. Unfortunately these features are less helpful in children. Children with Tourette syndrome often report that the movements just happen without warning, and that they have no control of them. Dooley et al. (1994) felt a differentiating factor was that the psychogenic tics were not stereotyped from one instance to the next. Ahmed et al. (2008) noted that with psychogenic tics the movements disappeared completely when the patients thought they were not being observed, and reappeared suddenly when they were re-examined. This is suggestive of a psychogenic cause, but certainly can occur in children with tics.

**PSYCHOGENIC DISORDERS AFFECTING THE EYES**

Psychogenic disorders affecting the eyes may occur in isolation, or in the company of multiple other psychogenic problems. Sometimes they are ‘discovered’ during an examination. A close co-operation with an ophthalmologist is usually very important in the diagnosis, as the ophthalmologist has multiple tools to unequivocally demonstrate that visual function is normal, despite complaints of visual impairment. There have been a number of excellent reviews of these techniques (Chen et al. 2007; Bruce and Newman 2010).

Observing the patient can be helpful. The child may complain of severe loss of vision, and yet be able to walk around obstacles without difficulty. He or she may complain of being unable to see what the teacher is writing on the board, or be unable to read schoolbooks, but can watch television from a considerable distance in the waiting room, and retain the ability to send and receive text messages on a mobile phone. In adults, the wearing of dark sunglasses into the examination room may suggest the possibility of a psychogenic disorder (Bengtzen et al. 2008).

With monocular visual loss, it is important to look for an afferent pupillary defect (Marcus Gunn pupil). In unilateral retrobulbar neuritis with visual loss, the disc may be normal, but an afferent pupillary defect will be present. If the patient complains of profound unilateral visual loss and there is no afferent pupillary defect then the problem is likely to be psychogenic (Bruce and Newman 2010). Obviously this is dependent on the examiner’s familiarity with the test.

Methods which allow the ophthalmologist to demonstrate normal vision when the complaint is monocular visual loss, include testing stereopsis, coloured lenses, polarised lenses and ‘fogging’ lenses (Chen et al. 2007; Bruce and Newman 2010). These tests can prove that the ‘bad’ eye has vision, and also document the amount of vision present.

Bilateral psychogenic visual loss is a more difficult problem. With psychogenic partial visual loss, the visual acuity does not improve when the distance from the eye chart is halved. Plane lenses can be given with the suggestion that they will improve visual acuity. With psychogenic total visual loss, the patient may be unable to localise the examiner’s voice when asked to do so. Further, they may not even be able to point to the location of their own hands, or touch the tip of one index finger against the other, findings that cannot be explained by poor vision. Suddenly threatening to poke them in the eyes may cause them to jump backwards, but as discussed above, this is not advised as it has an element of exposing the patient as a ‘fraud’. Moving a mirror in front of their face, or inducing optokinetic nystagmus, are ways of demonstrating that an apparently blind person can see.

Great care must be taken when there is an acute or sub-acute bilateral loss of vision. Problems such as sudden bilateral optic infarction are rare in children, but there are a large number of potential causes of this symptom. Conditions such as Leber hereditary optic neuropathy, and retinal degenerations also have to be considered. In younger children with neuronal ceroid-lipofuscinosis visual deterioration associated with behaviour change can lead to a misdiagnosis of a psychogenic problem (Collins et al. 2006). Misdiagnosing an ‘organic’ problem as psychogenic is an abiding fear for most doctors. When the problem is visual loss the stakes are even higher than usual, as the organic disorder often has a catastrophic prognosis.

The commonest psychogenic visual field defect is ‘tunnel vision’ or tubular eye fields. Here there is bilateral loss of peripheral vision. The visual fields are circular without the usual temporal widening, the fields remain the same size no matter how far from the patient they are checked, and there is a sharp border. Sometimes jagged or spiral fields are found.

Double vision is a common psychogenic symptom, and may be easy to diagnose in the younger child. For example it may be present on looking straight ahead, and as a pen is brought towards the nose, the child may see an increasing number of pens – ‘two, four, six, lots’. Monocular double vision is a clue to a psychogenic disorder, but this is also rarely found with retinal disease, refractive errors, and abnormalities of the cornea and lens. It is one of many situations where an expert ophthalmological examination may be necessary before the diagnosis can be made.

An evolving abducens nerve palsy may produce double vision before obvious failure of abduction of the eye is noted. As another anecdote, the author remembers a girl in her early
adolescence who presented to the Accident and Emergency department and was thought to have ‘functional’ diplopia. She complained of double vision only when looking to the right. She was accompanied by her mother, a Shakespearian actor, and her father who wore an eye patch due to an earlier injury. A partial right lateral rectus palsy was noted. This was the first sign of her Guillain–Barré syndrome, and the following day she had to be ventilated because of a rapid progression of weakness with respiratory failure.

‘Convergence spasm’ is a psychogenic problem that can resemble either unilateral or bilateral sixth nerve palsies. The characteristic feature is that when the child is asked to look to one side, that eye does not move laterally but the pupils constrict. This is another example of the ‘signs’ of a PND being signs of normal function. The accommodation reflex is part of normal physiology, and occurs when looking at an object close to the nose. The eyes converge, the ciliary muscle contracts to increase the convexity of the lens, and the pupils constrict to increase the depth of focus. This reflex is activated in convergence spasm.

Disturbance of colour vision was common among the hysterics of the Salpêtrière (Gamgee 1878). It still occurs and usually the diagnosis is not difficult. Tiffany’s (1907) account of a 9-year-old girl remains relevant today. ‘She came from school and said that during the afternoon, while studying, the page suddenly became red. Thereafter she complained of all colors appearing red, with the exception of objects of red color, which looked white … While in my office the father designated several articles of red color and she would instantly call them white, or he would point to some white object and she would say it was red’. Testing with coloured lenses showed, what under other circumstances, would have been regarded as ‘malingering’. The girl had a slight convergent strabismus and it was suggested that an operation might be needed to cure the colour blindness. ‘The next day at 5 o’clock the problem disappeared as suddenly as it came’. Tiffany made the same puzzled observation that many have made. ‘If this phenomenon had occurred in a willful, intractable, disobedient child, one would not have been so baffled for a cause of the malingering, but M. is a modest, obedient, rather retiring little girl of an excellent family.’

Many apparently typically developing children complain of transient large coloured blobs in their visual fields that can move around, or objects that temporarily appear too large or too small. There is no associated headache, and no signs, and the symptoms do not interfere with sport, or their use of computer games or social media. Investigations such as MRI of the brain and EEG are normal. The parents can be reassured that this is a common complaint, which seems benign with usually no cause found, and there is no need to pay attention to the symptoms. Stress can be mentioned as a possible contributory factor, but if there is little else to support this possibility, it does not seem sensible to overly emphasise this.

In patients with visual snow there is a disturbance of the entire visual field which resembles the ‘static’ or ‘snow’ of a badly-tuned analogue television (Schankin et al. 2014).

There can be tiny dynamic flickering dots in the entire visual field and other phenomena such as positive after-images. The symptoms are continuous and can persist for many years, and are not thought to be psychogenic. Visual snow is not thought to be a manifestation to be a manifestation of migraine, and the cause is unknown. It occurs in childhood.

**PSYCHOGENIC SPEECH**

**GLOBUS PHARYNGEUS**

It is rare for a child to present only with a psychogenic disorder of speech. More often a very soft voice, or a return to a ‘babyish’ way of speaking accompany other psychogenic problems. Globus hystericus is a classic symptom of hysteria, but is not a common problem in modern paediatric neurological practice. It is a non-painful feeling that something is stuck in the throat. It has been renamed globus pharyngeus as it is felt that the cause is not always psychogenic (Lee and Kim 2012).

**SENSORY DISORDERS**

The sensory examination can be very helpful in the diagnosis of a PND. An example is the young child complaining of anaesthesia who is asked to close her eyes and to say ‘yes’ if she can feel the subtle touch of cotton wool, and ‘no’ if she cannot feel it. Every time she is touched she says ‘no’. Janet described this sign in an adult woman, but observed that she was ‘simple-minded’ (Janet 1920, p. 169).

A typical presentation of sensory disturbance is the child with psychogenic hemi-anesthesia. There is complete loss of sensation over one-half of the body, with a vertical dividing line running anteriorly from the head down to the pubis, exactly at the midline. (In organic hemi-anaesthesia sensation is spared at the midline anteriorly, because of the overlapping dermatomal innervation.) When tested, the child with psychogenic hemi-anaesthesia feels nothing at all on one side of the body, but has no ulcers, and no evidence of non-appreciated injury on that side. When vibration is tested one centimetre from the midline of the forehead on the affected side, it cannot be felt at all. When vibration is tested one centimetre from the midline on the unaffected side, it is appreciated normally.

Psychogenic sensory disorders do not follow dermatomal patterns or as Janet observed they follow ‘the popular conception of the organ rather than its anatomic conception’ (Janet 1920, p. 157). In the above example, vibration is conducted through the skull, and, therefore, the unilateral loss of vibration cannot be explained on an organic basis. Another example is total loss of all feeling in the fingers, with the palms having normal sensation. Sensation may be totally lost in a circumferential pattern at the wrist. Although complaining of sensory loss, the child may give vague answers when asked about the exact distribution. Getting them to precisely map out the affected areas on their skin with a pen, and then doing the sensory examination can be very helpful in bringing out
inconsistent answers and revealing a non-anatomical distribution of the sensory changes.

Except for clear-cut examples such as those given above, it is important not to put too much weight on unusual sensory findings in a child. They may have difficulty in describing exactly what is troubling them, or in understanding what the examiner expects.

Pain is a common complaint in PNDs, but is present as an additional feature to the characteristic loss of function. Where pain is the main complaint, the problem is usually regarded as a separate disorder, and the child may be managed by pain specialists, or if the limbs are involved, rheumatologists, rather than neurologists. If intense pain is a problem it is worth considering conditions such as Fabry disease (Politei et al. 2016), and SCN9A mutations (Emery et al. 2015). One of the difficulties is that chronic pain can have a demoralising effect on the person, and this may be misinterpreted as evidence of a psychogenic problem. Another problem is the difficulty in diagnosis of small fibre neuropathies in children, and the lack of knowledge about their frequency. In one study of 41 successive children and young adults with chronic diffuse pain, 59% were found to have ‘definite’ evidence of small fibre polyneuropathy (Oaklander and Klein 2013). Overall, only one patient in the study seemed to have no evidence at all of a small fibre neuropathy. Some of the causes of small fibre polyneuropathy may be helped by treatment, and therefore it is worthwhile keeping this condition in mind, realising that it is probably rare in childhood.

Janet gives an example of the curious nature of hysterical anaesthesia. A 20-year-old girl fell through a glass door sustaining an injury to her median nerve with loss of sensation over her palm. When examined it was found that as well as the organic signs in her right hand, she had hysterical hemianesthesia of the whole left side of her body.

Her doctor asked: ‘How is it, miss, that you come here complaining about an insensibility that affects but a small portion of the palm of your right hand, while you do not even notice the much larger insensibility of the whole of your left side?’ She replied: ‘Be that as you think, sir, I came here to tell you what ails me; it is the insensibility of the palm of my right hand that troubles me, and that of my left side has never given me any trouble. You are the doctor; explain it as you like’ (Janet 1920, p. 163).

‘La Belle Indifference’

The term la belle indifference was coined by Janet and is regarded as a classic sign of a PND. The patient appears to be unconcerned about physical disability. Pryse-Phillips (1995) defined it as: ‘The lack of emotional expression in the presence of an overt bodily disorder, shown by patients with hysterical conversion syndromes (when it is regarded as culpable) and by stoics (when it is regarded as laudable). Physicians who can tell the difference are called psychiatrists and those who cannot cynics.’

Much more commonly than showing la belle indifference, children with PND complain bitterly about their difficulties. They may burst into tears, insisting that all they want to do is to go back to school, or return to sporting activities, at a time when their symptoms make this impossible. When the question of stress is raised, the inevitable response from both the child and the parents is that anyone enduring such suffering would be under stress.

OVERVIEW OF THE SIGNS OF A PSYCHOGENIC NEUROLOGICAL DISORDER

Although, on paper, the signs of a PND may appear clear cut and easy to interpret, in practice this is often not so easy. As above from Janet when examining a hysterical hemiplegia: ‘The thing is perfect theoretically, but practically it is much more difficult than is supposed’ (1920, p. 148). The exception is the younger child where there can be an almost comical aspect to the symptoms. An example is the 9-year-old girl described by Tiffany (1907) cited above, who complained that all colours appeared red, except those with a red colour, which looked white. Such symptoms usually evoke a strong caregiving approach from the parents, and at the same time, the parents are usually content that there is no serious underlying disease.

In older children, especially when the problem has been of long standing and many doctors have been involved, diagnosis and management can be very difficult. ‘The presence of weakness, generalised limb pains, weight loss, and depression posed a wide differential diagnosis including malignancy and collagen vascular disease. Many were gaunt and miserable and seemed to be chronically ill’ (Grattan-Smith et al. 1988). Extreme anxiety and distress may reverberate back and forth between the child and the parents. Sometimes, when there is a single localised symptom, such as an immobile and painful limb that is cold and wasted, it may be even more difficult to be sure the problem is psychogenic. Although the signs of PND are reliable, it is by no means always easy to be certain they are present.

When there are a large number of symptoms and signs in someone who is otherwise well, combined with a long list of normal investigations (‘too much smoke and not enough fire’), or if there is a steady accumulation of clinical improbabilities, the diagnosis of PND is considered. However, it can take quite some time for the doctor to be convinced of this, and some families never seem to be able to accept it.

It is well to remember that although there is currently a return to Head’s concept of the value of the positive physical signs, Gould et al. (1986), perhaps influenced by Slater, found these unreliable. In an overview of FMD in adults, Espay and Lang (2015) took the view that neurologists experienced in the treatment of movement disorders can identify ‘a handful of unequivocal and reliably incongruent or inconsistent clinical features in each functional movement phenotype’, and these, when present, ‘allow a clinically definite diagnosis of FMD, regardless of any psychiatric symptom’. Further: ‘No psychiatric symptom, regardless of
severely, can match the specificity of the core phenomenological features associated with each movement phenotype.' However, this comes with a warning: 'only neurologists with expertise in movement disorders are qualified to recognize the phenomenologic range of FMD as unique and distinguishable from that of complex, and even bizarre, organic movement disorders'.

The current emphasis on the 'positive' physical signs is important, and represents a change in emphasis from post-Head, pre-Slater teachings on the diagnosis of PNDs, where the 'positive' component of the diagnosis was psychiatric morbidity. In the section on hysteria in Price's Textbook of the Practice of Medicine (Hunter 1956) is the following: 'the diagnosis (of hysteria) must be both negative and positive – negative, by excluding any organic cause for the symptoms; positive, by finding motives and relating the symptoms to them'. In the author's view, to rely only on the physical signs when making the diagnosis of a PND in a child, carries the risk of misdiagnosis. If, on the initial history, the child seems to have absolutely no reason to develop a PND, then it is wise to proceed cautiously, looking for more evidence of the child being in a stressful situation, and considering rare organic causes.

### THE 'APPARENTLY VOLUNTARY' NATURE OF PSYCHOGENIC SIGNS

A distinction has long been made between malingering where there is a conscious effort to deceive and to gain an advantage, and PNDs where the symptoms are 'unconscious'. This distinction is far from clear cut, and the label the patient carries may be influenced more by the reaction of the doctor to the patient, than the physical signs.

In 2012, Edwards and Bhatia stated: 'The key clinical feature that separates patients with FMD from those with organic movement disorders is that the movements have features that one would usually associate with voluntary movement (distractibility, resolution with placebo, and presence of pre-movement potentials), but patients report them as being involuntary and not under their control. There seems to be just two logical explanations for this feature: either movements are deliberately feigned or there must be a brain mechanism that allows voluntary movement to occur but to be experienced subjectively as involuntary' (Edwards and Bhatia 2012a).

The ‘apparently voluntary’ nature of the signs of a PND has been noted many times in the past. Brodie (1837) observed: ‘In hysterical paralysis, it is not that the muscles are incapable of obeying the act of volition, but that the function of volition is not exercised’ (cited in Stone and Aybek 2016). As discussed above, Paget's impression was: ‘They say “I cannot”; it looks like “I will not”; but it is “I cannot will”’ (Paget 1873). From Wilson (1911): ‘Thus I have seen a patient with a complete hysterical hemi-anaesthesia stand beside her bed looking out of the ward window, and at the same time fumbling in the drawer of her locker, with her anaesthetic hand to find a hairbrush, which she did quite easily. I have noted a patient with profound paraplegia of the typical hysterical sort move her immobile limbs while she lay half-asleep. I have observed another patient, whose hysterical right arm hung helpless by her side, move it briskly to her face to avoid coughing in front of the physician. In each instance, the patient offered no explanation of the incident, but simply repeated her tale of inability to move the limb, or of complete loss of feeling. These facts are of great interest and their explanation is difficult.' Wilson concluded: ‘It appears to me the movements are volitional only in appearance, and that the conscious ego does not participate therein.’

Sir Francis Walshe (1952) in his inimitable style, distinguished malingering from hysteria. ‘The malingerer is one who with full moral responsibility for her acts and with full awareness produces bodily disabilities. She is an actress who knows she is acting. In the hysterical subject, it is probable that neither full responsibility nor full awareness is always present. The latter certainly tends to diminish, for the hysterical often loses her acting and becomes progressively convinced of her own acting and may ultimately come to join the audience. Current theories of the genesis of the psychoneuroses require that the psychological processes underlying them should be below the threshold of consciousness, and the clear evidence to the contrary sometimes provided by clinical experience has been ignored or suppressed in the interests of theory.’

From Brain (1955): ‘it follows that the hysterical symptom is always the expression of an idea in the patient's mind. Thus hysterical aphonia expresses the idea “I have lost my voice”, hysterical paralysis the idea “I cannot move my limb” and so on. This fact is of great diagnostic importance, for it is impossible that the patient's idea of a symptom should correspond with a similar symptom produced by organic disease, and the resulting discrepancy renders possible the diagnosis of the one from the other'.

From Hamilton Bailey's surgical text comes the following in discussing hysteria affecting joints: ‘Gentle palpation may appear to cause intolerable pain, but if the attention is distracted, considerable pressure will pass unnoticed’ (Bailey and Love 1959).

Whatever the underlying mechanisms that are in play, it is the ‘apparently voluntary’ nature of the signs that is most useful in making the diagnosis of a PND. It answers Slater's question: ‘What are the positive signs of “hysteria”? Unfortunately Head could not describe any common characteristic by which these signs could be recognised, and he dealt with them by enumeration ... What is given is a list, which might be enlarged without limit’ (Slater 1965). The ‘apparently voluntary' nature of the signs can be applied to the ‘kaleidoscope’ of manifestations of PNDs, and is a guiding principle in approaching the ‘lists’ of signs of psychogenic disorders. It explains how for so long adult neurologists have been able to make the diagnosis of a psychogenic neurological disorder without relying on the psychiatric history.
RED FLAGS

For many patients and doctors the greatest ‘sin’ in medicine is to misdiagnose a person as ‘psychogenic’ when in fact they have an ‘organic’ disease. The impact of Slater’s claim, that a large number of patients diagnosed with hysteria actually have an underlying disease, has been discussed above. In a sense the pendulum has swung to the other extreme, and there is now a view that the positive signs of a PND are specific, and misdiagnosis is unlikely. For example in a large adult study, at 19 months follow-up of patients with ‘symptoms unexplained by organic disease’, only four out of 1030 patients (0.4%) had acquired an organic disease diagnosis that was unexpected at initial assessment, and plausibly the cause of the patients’ original symptoms (Stone et al. 2009).

There are a number of circumstances where the diagnosis of a PND should be made with particular caution and only after careful investigation. The first of these is when the patient is under the age of 8 years. Rivinus et al. (1975) reported 12 children who over a 12-month period were admitted to a single institution, and had initially been diagnosed as having a psychiatric disorder, but were then found to have life-threatening neurological problems including spinal tumours, metachromatic leukodystrophy, Batten disease and subacute sclerosing panencephalitis. At the time of their initial ‘psychiatric’ presentation, two of these children were 8 years old and a further seven were younger than this. The reason for caution in the younger child, is that a certain level of maturity is required before children can exhibit the symptoms and signs of a PND. As Taylor (1986) has observed: ‘Finally hysteria can only be promoted by persons with the necessary social skill or by those that derive that skill through their allies. This constraint, among others, precludes young children from hysteria.’

There are also certain symptoms that should always raise concern. Particularly if the child is 10 years or under, back pain, back stiffness and torticollis are all symptoms that require careful attention. Two of the patients in the Rivinus series misdiagnosed as hysteria, had spinal cord tumours, and presented with back pain or abnormal spine postures. In a study of Grattan-Smith et al. (2000), three children with serious spinal cord problems had been initially diagnosed as having hysteria by referring doctors. Another child had back pain that was after admission found to be psychogenic in origin. The stories of two children in this series highlight the importance of careful physical examination in making a diagnosis. An 11-year-old girl who was initially diagnosed as hysterical, had leg weakness and sensory signs from spinal cord trauma after a ‘human pyramid’ fell on her. This girl had every reason to develop a psychogenic disorder. Her father had died in a work-related accident 2 years earlier, and her uncle was paraplegic after a motorcycle accident. In contrast, a 12-year-old with a very worrying story of progressive back pain and weakness, was an extremely successful, high-achieving girl who had no obvious reason to develop a psychological illness. It was the physical signs in the first girl that led to a diagnosis of spinal cord injury, and the lack of signs and the ‘psychogenic’ gait that led to a diagnosis of a psychogenic disorder in the second girl, who danced 5 days a week and was a ‘perfectionist’ who hated making any mistakes. With treatment, the second girl made a full recovery.

The examination of the child with back pain should include a careful search for a motor or sensory level, with the sensory testing including the buttocks and perineal region, and plantar surfaces of the feet. The ankle jerks should not be checked casually. If anal reflexes or the bulbocavernosus reflex are to be tested, it is obviously important to explain the reason to the child and family, and sensible not to do this without a member of the nursing staff or colleagues present.

Although non-specific back pain is becoming an increasing problem in adolescents (Shah and Saller 2016), nevertheless it is a symptom to be respected especially in the younger child. Again, the lessons from the past should not be forgotten, and this paragraph ends with words of warning from two of the greats. ‘Back pain, so common in adults, in childhood is rare; if it occurs before 10 years of age, it is due to an organic lesion almost without exception’ (Apley 1976). ‘Indeed spinal cord compression is an even more serious emergency than raised intracranial pressure, and this possibility must always be present in the mind of paediatricians, while the diagnosis of acute myelitis, “hysteria” or malingering should never be accepted before cord compression has been clearly excluded’ (Aicardi 1992, p. 831).

Urinary retention has been described as a psychogenic symptom in adults (Hoeritzauer et al. 2016), and rarely in children who have suffered severe abuse (Parmar and Roberts 2013; Iskandar and Vance 2015), where it is usually associated with other psychogenic symptoms. As a general rule urinary retention, or the sudden onset of severe urinary and faecal incontinence are symptoms that point to an organic cause, and only after very careful examination and investigation, and in the presence of gross psychopathology, should a psychogenic cause be considered.

There are other situations where a psychogenic misdiagnosis is more likely to be made. These include the child who screams, and will not stay still or co-operate because of pain. A child who has had multiple psychogenic problems in the past, is at particular risk if he or she develops an organic problem. Families who are highly dramatic, and give colourful and emotionally charged descriptions, are also at risk. As Slater (1965) observed: ‘People with, say, a histrionic temperament naturally lend the stamp of their personality to their symptoms, whether they are suffering from an organic or neurotic disorder … Unwittingly, inevitably, from his very nature, the patient applies the hystero-diagnostic stimulus; unwittingly inevitably, from the long process of conditioned training through which he has gone the doctor reacts with the hystero-diagnostic response.’ As discussed above, movement disorders such as dystonia can produce what appear to be bizarre symptoms and signs which can be easily mistaken for a psychogenic problem.
Any discussion of an underlying cause of PNDs has to take account of the many different therapies that have apparently helped or ‘cured’ patients over the last 100 or more years. A short list includes (1) ‘rest cures’ (Weir Mitchell 1877; Playfair 1881; Saville 1907); (2) various forms of electrical stimulation, transcutaneous electrical nerve stimulation and transcranial magnetic stimulation (McWhirter et al. 2015); (3) electroconvulsive therapy (Russell 1950); (4) abreaction, which involves interviewing patients after they had been given a drug, typically a barbiturate (Poole et al. 2010); (5) exercise (Dallocchio et al. 2010), including the ‘training camp method’ (Orbison 1925); (6) hypnosis (Brown 1918; Deeley 2016); (7) antidepressant therapy (Voon and Lang 2005); (8) psychoanalysis (Macalpine and Ross 1956); (9) wrist braces and other physical treatment (Sauerhoefer et al. 2011); (10) physiotherapy (Nielsen et al. 2015); and (11) placebo (Scola et al. 2014; Rommelfanger 2016). Few if any of the original papers would be regarded as of sufficient standing as to be part of a Cochrane review, but this is the nature of PNDs, and we have to work with what is available.

Wilson (1911) reviewed the many theories active at that time as to the cause of PNDs and observed: ‘The mere enumeration of these conflicting hypotheses may overwhelm the reader with a deep sense of despair at their hopeless dissimilarity, and he may reasonably fear that finality is as far off as ever. But let him not be unduly distressed.’ Wilson then points out that what the many theories have in common, is that patients seem to respond to treatment whatever it is, and this makes the treating doctor sure he has the answer to the problem. ‘Odd as it may appear, many of these contradictory features have one feature in common. Not only are the respective originators alike in the earnestness of their advocacy of them, but there is a curious similarity in their appeal to their own clinical experience subsequent to the adoption or enunciation of their own particular theory, and in their resort for substantiation in its virtues to the results of treatment.’

Wilson continued: ‘To the individual who is not so absorbed in science as to lose his sense of humour it may seem that Hysteria, while she responds so nobly to the appeals of the advocates of these various theories, is quietly smiling in her sleeve. As of old the ascetic and the epicurean, the celibate and the polygamist, the socialist and the monarch by divine right turned to the pages of Holy Writ for support of their particular ways of living and views on life, and found it therein, so the exponents of sexual theory, the suggestion theory, the sleep theory, and the “hysteria-only-a-symptom” theory, alike appeal to experience for confirmation of their opinion, and find it.’

Wilson commented on the influence of the treating physician. ‘It is not merely that his hypothesis is apt to colour the physician’s way of looking at a case, but also that in some obscure and little understood manner the patients come in a sense to respond to his hypothesis, so that the wider his experience, the greater is the apparent confirmation of the truth.’

More often than a single method, it is a combination of therapies that have been used. Saville’s regime (1907) consisted of strict bed rest, removal of patient from their previous surroundings, good food, massage, electrotherapy, hydrotherapy and psychotherapy. Depending on the circumstances, Saville would also use unpleasant treatments: ‘Apomorphine hypodermically is, however, the most valuable remedy we have for the prompt cure of severe and recurrent hysterical convulsions; it produces copious emesis and the storm clears up like magic.’

‘NEUROBIOLOGICAL’ THEORIES

‘The student of the history of such an old-world disease as hysteria cannot fail to be impressed with the fact that the point of view from which it has been considered has varied greatly from one epoch to another, and that this point of view may be taken to be a reflex of the mental outlook of the age in which it has found an expression’ (Lancet 1910).

There is currently a great deal of interest in neurobiologic approaches to PND. These look at how the symptoms and signs of a PND can be implemented ‘alwithin the anatomy and physiology of the brain’ (Edwards 2016). Perez et al. (2015) summarised recent work and found that ‘convergent preliminary findings suggest alterations in neurocircuits mediating emotional processing, regulation, and awareness (ACC, vmPFC, insula, amygdala, vermis), behavioural inhibition and cognitive control (inferior frontal gyrus, DLPFC, dorsal ACC), self-referential processing and perceptual awareness (PCC/TPJ, precuneus), and motor preparation and coordination (SMA, cerebellum). Striatal-thalamic components of prefrontal-parietal networks may also play a role in pathophysiology’. It is the view of Perez et al. that the cause of PND, is not a psychological disturbance but brain-based dysfunction: ‘Improved understanding of the biological mechanisms underlying these conditions (and disorder subtypes) will improve recognition that these patients suffer from a biological, functional brain-based disorder and will help reduce stigma associated with this diagnostic category.’

Neurophysiological and imaging techniques have demonstrated differences in the brain of patients with PND when compared to controls. The subject is too vast to cover here but the warning of Edwards (2016) seems apt. ‘If we are studying a particular illness and an area of the brain “lights up” in a functional imaging study in our patients and not in controls, it is easy to start thinking that we have found the bit of the brain that is causing the illness. It is a short step from there to

WHAT IS THE UNDERLYING CAUSE OF A PSYCHOGENIC NEUROLOGICAL DISORDER?
saying that illness x is damage/dysfunction of brain area y. This naïve reductionism is attractive but very flawed.’

The difficulties inherent in applying neurophysiological techniques to PND, (and of PND in general), are well shown by the report of Ramos et al. (2015), where two young women with childhood-onset psychogenic dystonia were treated with deep brain stimulation under the misapprehension that they had an organic problem. Even in retrospect, no difference was found in the rate of firing of intraoperative microelectrodes inserted in the globus pallidus internus in these patients when compared with the firing rates of patients with DYT1 dystonia. One of the patients was implanted at age 18, and within 6 weeks had a remarkable improvement in her dystonia and tremor and was able to walk. ‘Improvement persisted and she was able to walk across the stage for her high school graduation and dance at her wedding.’ However, 4 years after implantation, she deteriorated markedly. It was then noted that her symptoms were unchanged whether the stimulator was on or off. In both patients, the stimulators were removed and they became essentially symptom free after intensive cognitive, behavioural and physical therapy. The authors concluded: ‘Although caution must be exercised in interpreting our results, it does highlight that there is still no neurophysiologic parameter, and thus no reliable diagnostic test, capable of differentiating between organic and psychogenic dystonia. As such, the diagnosis remains clinical and can be challenging for complex cases.’

Papers on the neurobiological approach have dealt with complex concepts that have philosophical underpinnings such as the sense of agency, attention (a subject of interest going back more than 100 years to William James, and discussed by Paget in 1873), and beliefs and expectations (Edwards 2016). Bayesian theory has also been incorporated into the discussion (Edwards et al. 2012b). ‘These concepts are of great interest, but thus far have not been formulated in such a way that they can easily be incorporated into a discussion of the diagnosis with the child or parents. Edwards (2016) also believes that neurobiological approaches are only part of the solution. ‘A one-dimensional approach to FNS (functional neurological symptoms), for example, a purely psychologic interpretation of symptoms and mode of treatment, or one that highlights neurobiologic mechanisms while ignoring the level of cognitive and psychologic experience, is doomed to failure.’

‘PSYCHOLOGICAL’ THEORIES

As discussed above, Freud’s theories have recently been heavily criticised, and his concept of conversion of emotional difficulties into physical symptoms, is no longer readily accepted. ‘There are, however, theories that attempt to explain PND on a psychological basis. Again, there is only space for a brief review. Rofé and Rofé (2013) have proposed a ‘Rational-Choice Theory of Neurosis’ (RCTN) which ‘incorporates Freud’s idea, implicitly expressed in his theory, that neurotic disorders are, in fact, rational behaviors’. In this theory repression is used as ‘a conscious coping mechanism which deliberately eliminates threatening stimuli from attention through the employment of distractive maneuvers’. The patients ‘consciously and rationally choose a neurotic behaviour which heavily occupies their attention to the extent that they become unaware of their stressor’. Contrary to psychoanalysis, in this theory, the symptoms arise in response to current stressors, rather than historical events.

According to RCTN the choice of a specific conversion symptom is determined by three main principles (1) needs; (2) availability; and (3) cost-benefit analysis. The concept of ‘needs’ is that patients usually choose a specific symptom that enables them to gain relief from a stressful situation. As an example, aircrew in World War II with psychological disorders were most likely to develop visual disturbance, which meant they could not fly. Availability is the use of previous experiences to develop a symptom, and is similar to Taylor’s concept of a ‘model’. In discussing ‘cost-benefit analysis’ Rofé and Rofé propose that ‘human behavior is based upon rational calculations of cost-benefit in the interest of maximizing personal utility’.

Rofé and Rofé propose: ‘The choice of a specific conversion symptom may be unconscious or spontaneous with no prior planning. However, the actual implementation of this choice is fully under conscious control.’ This is almost immediately followed by the activation of psychological mechanisms which make the patient unaware of that choice, and then preserve this unawareness. In the case of hysterical paralysis, the patient observes that the limb is not moving, and at the same time has a feeling of loss of control of the limb, consolidating the belief that there is a physical problem. ‘This evidence will lead to a self-deceptive diagnosis of illness where patients believe that there is something physically wrong with them that are beyond their control.’ As a result of the intense preoccupation with the symptom and the self-deceptive beliefs, the patient becomes unaware of the voluntary adoption of the symptom.

The cost-benefit principle also explains why people subsequently abandon their symptoms because of either reduction in the benefit or an increase in the cost. ‘As specified before, punishment procedures, such as withdrawal of attention or the application of noxious stimuli, motivate patients to abandon their conversion symptoms. While behaviourists account for the efficacy of this therapy by learning concepts, RCTN attributes it to the disruption of the cost-benefit equilibrium of the symptom. Once the symptom ceases to be beneficial, patients are motivated to consciously abandon their symptom.’ They cite a case history of Jung. ‘For example, when Carl Gustav Jung (1963) informed a middle-aged female patient, who had been suffering from hysterical paralysis for many years, that he was going to hypnotise her, the patient immediately fell into a deep trance, before the therapist started the process. She talked without pause for over a half-hour, resisting Jung’s attempts to awaken her. Soon afterward she declared herself cured, threw away her crutches and proceeded to walk . . . From RCTN’s standpoint, it seems likely that after so many years of suffering from the fake symptoms, the stressor was either removed or
she adjusted to it. The symptom became a burden and Jung provided her with the deceptive excuse required to abandon this behaviour.’

Although RCTN provides an explanation for the success of so many different treatment methods with PND, it carries with it a tone that many would find unattractive. It is reminiscent of Palliser’s Mr Pentecost: ‘Self-interest is all that drives us Mr Pentecost went on: “But we are infinitely resourceful in finding ways to disguise this truth from ourselves and others, and hence arises the prevalence of hypocrisy and self-deception’” (Palliser 1991).

Perhaps the last word on the difference between ‘neurobiological’ and ‘psychological’ theories should go to Janet. ‘Thus, I shall perhaps surprise you by telling you that there is no opposition between the definitions that gloriously entitle themselves physiological and those that modestly call themselves psychological’ (Janet 1920, p. 321).

TAYLOR’S APPROACH

The great English neuropsychiatrist David Taylor has provided a way of looking at the evolution of PNDs in children which the author has found useful in practice (Taylor 1986). Taylor’s position is: ‘I believe that hysteria is generated as a defence mechanism and propagated as a consensual phenomenon, as is magic. Like magic it has no real properties beyond belief.’ Further: ‘There is little evidence to support the idea of psychopathology in children with hysterical symptoms.’ ‘People exhibit distress through whatever scope is left to them. The body speaks what the tongue cannot utter.’

Taylor outlines the elements of a PND: (1) The first requirement is the child is in a predicament ‘which is intolerable but for which all apparent solutions are blocked’. Sexual abuse in the family is a well-known example, but there are equally painful alternatives. (2) The second component is an ally who helps to ‘promote the sickness’. The ally acts ‘like a manager; he too may have been innocently trapped, or else have his own psychopathology’. The ally ‘will vigorously defend the “right to be sick” and pursue disease explanations relentlessly’. The third component is a model of the sickness which has to be available, whether current of historical, real or contrived, chronic or ephemeral.

In this formulation doctors can be a decided problem when they become the ally. ‘Doctors in particular, and other health care workers to some extent, can provide well for all these elements. They can block alternative explanations by patients, or by failing to take an adequate history of their predicament fail totally to discern it. They are powerful allies in sickness promotion, and can be sucked into the system quite unwittingly, especially if they have an investment in a biomedical diagnosis. ‘They provide a variety of models and can offer suggestions which improve the credibility of the sickness.’

Taylor acknowledged his views are, in part, similar to others including Kretschmer and Slater. ‘Their view is that hysteria is a social construction set up in the doctor–patient relationship.’ Others have commented on the role of the ally. Walshe (1952) notes, ‘the hysterical requires a human background of family or of community, with which to interact. Thus an entire family or household may be influenced by a family member and come unwittingly to minister to the neurosis and build it up’. Fahn and Jankovic in discussing adults with psychogenic movement disorders observed: ‘Many of the affected individuals have a devoted spouse who responds readily to their pressing needs.’ From Sim (1966): ‘hysteria is a form of behaviour or communication designed to show society the distress of an individual or to elicit society’s support, and is not a form of private meditation but generally a public display’.

‘NO EVIDENCE OF A PSYCHOLOGICAL PROBLEM’

In the retrospective review of Grattan-Smith et al. (1988), the families had two broad patterns of behaviour. Thirty families (58%) were found to have an anxious home environment, with pervasive fears of loss and physical illness. In contrast, in 11 families (21%), there was a gross breakdown in family relationships with parents and children in open conflict. The symptoms were generally more obviously ‘psychogenic’, and the diagnosis more easily made in this second group.

It is with the first group of families where difficulties with diagnosis and management particularly occur. In both adult and paediatric practice, it is common experience for a person to be diagnosed as having a PND, only to then go and see a psychologist or psychiatrist, and be told that there is no evidence of any psychological disorder that might cause their symptoms. The ‘all clear psychologically’ verdict appears to result from a strange irony, that although much of what Freud wrote has been discounted, there is still a search for Freud’s ‘traumatic scene’, one of his earliest concepts and a scene that he, himself, had difficulty finding. What psychologists and psychiatrists are saying is that the person does not have an obvious severe psychological problem, and this is usually correct.

The two recent surveys of PND in children also do not show a picture of severe psychological disturbance. Antecedent stressors were reported in 62% of children by Kozlowska et al. (2007), and 81% by Ani et al. (2013). In the paper of Ani et al., the most common antecedent stressor was bullying at school. What about the psychological function of the children? In the study of Ani, 78% of children, with data on psychiatric history available, had had no mental disorder prior to the episode of conversion disorder. Of those with a premorbidity psychiatric diagnosis, anxiety disorder was reported in 21 out of 200 (11%), and depressive disorder in ten out of 194 (5%). How do we justify diagnosing such children as having a psychological disorder? Especially when as Slater (1965) correctly asserted, ‘trouble, discord, anxiety and frustration are so prevalent at all stages of life that their mere occurrence near to the time of onset of an illness does not mean much’.

As Freud in 1912 observed, the common cause is an accumulation of lesser stresses: ‘In ordinary hysteria instead of one
big trauma we not seldom find many partial traumas, grouped causes which can be of traumatic significance only when summarized and which belong together in so far as they form small fragments of the sorrowful tale.’

A common predicament currently encountered is the girl who is simply doing too much. She may be one of the top students in her class, the class captain, excel at multiple sports, do dancing or gymnastics, drama or debating and play one or more musical instruments. Often she has taken all this on willingly, and it is not due to parental pressure. Over time the need for continuous perfection in so many areas becomes too much, and sickness is the only defence. A minor injury or illness tips her over the edge into a prolonged illness. These children can exhibit the same determination and persistence in being sick as they do in all other areas of their life. Grattan-Smith et al. (1988) (looking at children mainly from the 1970s when life seemed a lot easier) identified a ‘difficult’ subgroup of children who presented particular problems in both diagnosis and management. ‘They were generally “good” children, serious minded, compliant and perfectionistic, who came from families with high expectations of them and were anxious about illness.’ Leslie (1988) made the same observation in a study of 20 children (13 girls and seven boys). An interesting finding, however, was the extreme conscientiousness not to say perfectionism of at least half of the children, and it was this characteristic which could have led paediatricians to agree with the families that such exemplary children who were doing so well academically and socially and who had had no previous psychiatric histories could not possibly have had psychiatric problems.’ Families with high levels of perfectionism will often vehemently deny that anything is less than perfect at home. A brief visit to a psychologist or psychiatrist, particularly if that person has a ‘neurobiological’ focus, is unlikely to do anything but confirm what the family already believes.

There are, of course, many other predicaments including physical or sexual abuse, but these seem to be a relatively uncommon cause in recent reports of psychogenic disorders of childhood.

**THE IMPACT OF DELAYED DIAGNOSIS**

In the literature on PNDs, emphasis is often placed on the role of delayed diagnosis and excessive investigation in prolonging the illness. However, some families simply refuse to accept that the diagnosis is possible, even if informed at the very beginning of the illness. In the study of Dale et al. (2010), of 12 children who presented acutely with PMD, three families refused to engage with psychological therapy at all. Further: ‘Despite resolution of the movement disorder in many participants, five of the children experienced multiple relapses in the context of families declining treatment of comorbidity anxiety or depression, or being unwilling to address ongoing psychological stressors. Three had intractable PMD over a period of 6 to 18 months.’

The concept that it is simply a delay in diagnosis that is responsible for some children with PMD having a prolonged illness, satisfies neither experience nor reason. ‘Much can be made of the role of excessive investigation, contradictory medical opinions, and failure of early recognition of the problem in this sort of prolonged course. It may be equally argued that these children were sicker, their predicament worse, their allies stronger, and their nature more obstinate’ (Grattan-Smith et al. 1988). If there is no resolution of the underlying predicament, then just identifying the problem as psychogenic in nature, may not help the child at all. Rather the child may be worse off, being no longer protected by the symptoms, and have no option but to develop new ones.

"The progress of medical knowledge has been so greatly hampered by persistent use of the two terms ‘organic’ and ‘functional’ that it is high time they should be discarded for ever’ (Wilson 1930).

The second task in seeing a child with a PND is explaining what is meant by the diagnosis. Controversy as to what is the correct name to be used goes back hundreds of years, as has been discussed above. Despite Briquet’s warning that physicians should not amuse themselves by wasting their time in arguing over words, the choice of word is important. The use of an unacceptable name can bring about an immediate halt in proceedings. It seems logical, therefore, to use a name that is, at least, neutral. Ideally, the meaning of the word should be easily understood by the child and family, and contain within it an indication of cause, and also the path for treatment.

Phrases such as ‘symptoms unexplained by organic disease’, or ‘medically unexplained illness’ have been tried but were found wanting, as they had no real meaning, except focusing on what the patient does not have. It has recently suggested that ‘functional’ should be the word used, and is to be preferred to, for example, ‘psychogenic’ (Edwards et al. 2014a, 2014b; Fahn and Olanow 2014; Ganos et al. 2014; Jankovic 2014; La Faver and Hallett 2014). As discussed above, ‘functional’ is an old word going back at least to Charcot. At that time it was used in the sense of an organic disease that had not yet revealed itself to scientific methods. Subsequently functional was used in the way we use psychogenic. In a recent review of the use of the word, the conclusion was that ‘functional’ is ‘a simplifying euphemism allowing neurologists to use one term to mean one thing to colleagues and another to patients’ (Kanaan et al. 2012). There are also practical issues because of the multiple uses of ‘functional’. In December 2016 a PubMed search for ‘psychogenic neurological disorders in children’ resulted in

**PSYCHOGENIC? FUNCTIONAL? WHAT IS THE CORRECT NAME?**
589 ‘hits’. For ‘functional neurological disorders in children’ the number was 17,655 with most not relevant to the purpose of the search.

‘Psychogenic’ is the word that has been used throughout this chapter, but it also has problems. According to Lewis (1972) the word was introduced into psychiatry in 1894 by Robert Sommer. The view of Lewis was: ‘Robert Sommer rendered psychiatry a disservice when he coined the word “psychogenic” and so gave currency to a confused but suspiciously attractive and convenient concept. The subtle arguments of French and German disputants have shown it to be at the mercy of inconsistent theoretical positions touching on the fundamental problems of causality, dualism, and normality. It would be as well at this stage to give it decent burial, along with some of the fruitless controversies whose fire it has stoked.’ More recently Edwards et al. (2014a) in promoting the alternate ‘functional’ criticise ‘psychogenic’ as ‘a term that defines the disorder with regard to a proposed aetiology, which is poorly defined and is not supported by current evidence’.

The current situation is not substantially different to the time of Clarke who in 1893, in respect to ‘hysteria’, observed: ‘The ancient meaning of the word and the ideas connected with it have been finally abandoned, and as yet no substitute for it has been found.’

It could be argued that no word will ever satisfy both patients and doctors, when there is centuries-old uncertainty about exactly what is happening when a ‘psychogenic’ neurological disorder occurs. The final choice may have to be the ‘least-unacceptable’ word. In this setting, the concept of the child being under stress, and the diagnosis of a ‘neurological disorder induced by stress’ is a useful formulation.

‘STRESS’

Although Webster’s Dictionary gives 13 different meanings to the word ‘stress’, most children and families have a good understanding of what stress means. Kostenius and Öhrling (2008) surveyed the concept of stress in 23 children (12 boys and 11 girls) between 10 and 12 years. These children listed multiple situations when they experienced stress. These included when there was not enough time to compete an allocated task; when they felt they were not good enough; when they worried what others would think about them if they revealed their real self; when they felt they were being run by others; when they were under pressure to perform; and when they felt powerless and had to unwillingly conform to other people’s decisions. All this fits well into Taylor’s concept of a predicament. The children also recognised that stress generates more stress, and can produce a downward spiral if not handled well, and that the stress of other people can spread and infect them. They also acknowledged the importance of some degree of stress for peak performance. As one child said: ‘it depends on how stressed I am … if I am very stressed I get very little done but if I am a little stressed I get more done’.

In those children who seem to be previously well adjusted, and develop a PND in the context of doing too much, the concept that the problems have arisen from external stress, can be helpful in both diagnosis and management. It will be discussed in more detail below, but the child is told that there are multiple individual areas of stress acting upon them. Alone they would not cause a problem but when combined, especially if the child then becomes sick or has an injury, they become too much.

Another advantage of stress as a concept is that chronic severe stress can cause structural changes in the brain (McEwen 2012; Eliand and Romeo 2013). A diagnosis of stress as the cause of the symptoms does not require an immediate commitment into either the ‘neurobiological’ or ‘psychological’ camps.

There is an adult study where 33 patients with FMD were studied and found to have salivary cortisol levels no different to normal controls (Maurer et al. 2015). Based on this lack of elevation of cortisol levels, the authors concluded ‘current stress levels are not altered in patients with functional movement disorders’ and that ‘the insistence on heightened stress levels in these patients is unjustified’. However, 76% of these patients had already had symptoms for more than a year when studied. It seems simplistic to assert that measurement of cortisol levels, even over a 2-day period, years after the onset of symptoms is an accurate measure of stress levels when the symptoms commenced, which is obviously the critical time. The patients were also admitted to hospital for the testing, and so away from their usual environment. Finally, it appears unlikely that such a complex process as stress is going to readily yield itself to routine laboratory tests.

INFORMING THE CHILD AND FAMILY OF THE DIAGNOSIS

For most paediatric neurologists, the task of diagnosing a PND is difficult enough, and they do not wish to be involved in the treatment of the child. This view is summarised by Ford (1960): ‘This is a psychiatric problem and if the neurologist is not prepared to undertake this responsibility, he should place the patient and the parents in the hands of the best psychiatrist available. It is my custom to follow this course and to wish both the patient and the psychiatrist the best of luck.’ However, the paediatric neurologist has a crucial role in informing the child and family of the diagnosis.

The discussion usually occurs after investigations have been done. ‘Taking one look’ at the child and then diagnosing a PND, will not convince many parents. They have read too many stories about the misdiagnosis of children with brain tumours, and ‘MS’, in the papers and on social media to simply accept the opinion of a doctor, except in the most obvious of cases. It is important to get all planned investigations done as soon as possible, and not have them strung out over weeks. These investigations have an important role in persuading the child and the family that the symptoms are being taken seriously, and there is no evidence of an underlying disease.
If, after the tests have come back negative, the possibility of a PND is raised for the first time, then a suspicion can easily develop that this diagnosis is being suggested because the doctor does not know what is wrong – ‘it doesn’t make sense so it must be in her head’. Therefore, at the time of ordering the tests when a PND is suspected, it is important to say to the child and family that there is a good chance that the cause is stress, and if this is the case it will be a good outcome, as a complete cure is possible.

There are many different ways of having the discussion and the following describes just one approach. To be effective, plenty of time has to be available as the first reaction of the parents is often shock and incomprehension, followed by many questions. The first step is countering suspicions that, cloaked in medical professionalism, you are accusing the child of ‘faking it’, something that siblings and other children have often already suggested. The child is seen with the parents and, given that most often the child is 10 years or older, the discussion is directed towards the child with the parents listening and free to ask questions as the discussion proceeds.

The ‘script’ has been described previously (Grattan-Smith and Dale 2016), and is reproduced to give an example of an approach that has proved effective. As discussed above, the term ‘stress-related’ is preferred to ‘psychogenic’ or ‘functional’. This approach applies in the common setting of the high-achieving child who is doing too much. If the cause of the PND were severe abuse than obviously a different approach would be needed.

“As I have previously suggested, your problems are very likely to be caused by stress. For more than a hundred years doctors have recognized that the signs and symptoms you have, indicate that you are under stress. This is good news. There are many diseases that leave children severely disabled or that are fatal, and here there can be a complete recovery.

I commonly see children with such reactions. From my own experience and many articles written by doctors, it is clear that children with these reactions are not disturbed or ‘crazy’, and are not being abused at home. Rather, they are usually high-achieving kids who are very thoughtful and considerate towards other people. At the same time they tend to want to keep their feelings to themselves so as not to worry others, especially their parents.

Over a period of time the child comes under the pressure of multiple stressful events. Each one by itself is manageable but they build up and act all together. The child tries to ignore them and keep them out of the conscious mind, but they are there. There is then often an injury or illness that would usually cause a problem that would only last a few days. However, the stress then takes over. The symptoms then last much longer and are much more severe than they otherwise would have been. It can take some time to get back to normal, but full recovery is expected.

One way of looking at this is that the body knows it is under pressure and as a defence against stress ‘shuts down’ to bring a change in the situation.”

The discussion usually includes many questions from the parents (and child), often initially with complete disbelief that a child previously so high-functioning could be brought down by stress. At that time historic examples such as Horatio Nelson and Florence Nightingale can be discussed as people who were very high achievers despite being subject to stress. The concept of the necessity of stress for peak performance is also covered, accompanied with the advice that stress is ‘a good servant but a poor master’. What is needed is some fine tuning, not a drastic change. The child is told that it is important to always put in a full effort, but it is impossible to be perfect at all times. Depending on how the meeting is going, giants of the past can be cited, such as, ‘perfect is the enemy of good’ (Voltaire) or ‘better a diamond with a flaw than a pebble without’ (Confucius).

This discussion is aimed at putting the concept of external stresses being brought to bear on a sensitive child before the child and family. It is emphasised that children with problems due to stress are often highly competent, good children who try to keep their feelings to themselves, and do not want to worry their parents. The children try to ignore the stress, but it has to come out in some way, and this takes the form of physical symptoms such as weakness and pain. There is no need to try to win every point in the discussion. Nor should it be expected that the child and family will agree with you immediately. Some families seem never to agree, but in the study of Ani et al. (2013), ‘over 90% of families had some level of acceptance for a nonorganic explanation’. Depending on how unwell the child is, and the response to these suggestions, plans can then be made for future management.

Although in PND the apparently voluntary nature of the signs is important in making the diagnosis, a discussion with the child and family of whether or not the signs could be ‘deliberately feigned’ is a recipe for certain disaster. Likewise, reference to Taylor’s concept of an ally is likely to result in the parents storming out of the room, dragging their child behind them.

The question of how ‘truthful’ you should be in such a discussion is difficult. Gupta and Lang (2009), for example, in dealing with adult patients with psychogenic movement disorders suggest not telling the patient the problem is ‘psychogenic’: ‘To maximise treatment compliance, it should be acknowledged that the patient has a movement disorder (i.e. a form of tremor, myoclonus, or dystonia) and a biological explanation provided.’ This is not a new approach. Brain (1963) quotes Edward Jordon who in 1601 wrote: ‘So that if we cannot moderate these perturbations of the minde, by reason and persuasions, or by alluring their minde another way, we may politikely confirme them in their fantasies, that wee may the better fasten some cure upon them.’ In World War I, Hurst and others performed mock operations on soldiers suffering from ‘shell shock’, and produced dramatic cures (Hurst 1917). Myers (1919) condemned this ‘therapeutic lying’. ‘Whatever the method of psychotherapy adopted the full truth is not always possible; explanations have to be couched in terms fitted to the mentality of the patient. But
...downright lies are to my mind never necessary and deserve vigorous condemnation, especially when carried over into needless and possibly harmful action..."

The approach suggested above using the concept of stress, employs a word well understood by children and families, and in that word can be found both the cause and remedy of the problems. Although this approach contains elements of Freud’s concept of conversion which has been criticised, nevertheless it is usually accepted by children and their parents and does not stray too far from the ‘truth’. It avoids the moral judgments implicit in terms such as unconscious, conscious, factitious, and malingering, and views the signs and symptoms neutrally, as a signal of distress, allowing plans to be made for the best way to help the child. By identifying stress front and centre as the cause, it will hopefully prevent the establishment of a recurrent cycle of stress-related illnesses in the child.

Stone and Edwards (2012) have suggested that as part of such a discussion the patient should be shown the reasons their signs are considered psychogenic, and as an example went over Hoover’s sign with a 42-year-old man with psychogenic leg weakness. The result was pleasing. At a follow-up visit he explained that understanding the physical basis of the diagnosis had made a dramatic difference to him. He and his partner now had confidence that it was the correct diagnosis and could see that further tests would not be helpful.’ This approach utilises ‘rational persuasion’ a term coined by Paul Dubois. Hoover (1908) himself did the same thing. ‘I demonstrated the character and significance of this sign to one of the patients described. He promptly abandoned a crutch and cane, an orthopaedic corset and blue spectacles and returned to work for the company against whom he had brought suit.’ Stone and Edwards (2012) are not concerned that increased awareness by patients of the ‘positive’ signs of a PND, will subsequently make the diagnosis more difficult, but this is a possibility. If this approach is taken up with children, it will be very important to avoid any hint that the child is being shown to be ‘faking it’.

**HOSTILE REACTIONS**

Hostile reactions are common when the diagnosis of a PND is made, and the treating doctor has to accept that the reactions are often illogical. For example, in the study of Macalpine and Ross (1956), both patients became angry when told their problems were psychological, and they needed neither sympathectomy nor amputation. Their responses included: ‘It is not imagination. ’I have only been sent for consent to amputation.’ ‘Why should I have had so much treatment, if nothing is wrong with my arm?’ Leslie (1988) noted: ‘A pronounced feature was the anger of many of the families about what they saw as the failure of the medical profession to diagnose or to treat their child’s illness properly.’ A typical reaction from a father was: ‘Almost every medical opinion we have had has proved to be wrong’. Leary (2003) found: ‘Refusal by parents to accept the absence of organic disease may be another major stumbling-block to effective management. Such refusal often goes with denial of any domestic tensions or disharmony and with anger directed at medical personnel – attitudes that can greatly hamper the institution of appropriate therapy, as can misguided support for any opposition to treatment expressed by the patient.’

There is not always an angry response to the diagnosis of a PND, but such a reaction is common, and one of the many reasons why plenty of time has to be available to discuss the diagnosis. By dealing calmly with anger, staying logical, and pointing out that the diagnosis of a PND offers hope of a complete cure, and is a far better diagnosis than an aggressive brain tumour or degenerative disease, the storm may gradually settle.

**TREATMENT OF PSYCHOGENIC NEUROLOGICAL DISORDERS**

After being told their problems are likely to be the result of stress, combined with suggestions of how to best reduce this, some children and their parents readily accept the diagnosis and the symptoms settle quickly.

Others have prolonged illnesses. These children require psychiatric evaluation, and often admission to hospital. Here the treatment is usually multidisciplinary and may include family therapy, individual psychotherapy, medication for comorbid anxiety and depression, physiotherapy and occupational therapy (Calvert and Jureidini 2003; Koslowska et al. 2012). ‘The stay is usually not short; ‘admissions typically last two weeks’ (Koslowska et al. 2012). Helping these children involves intensive and persistent effort from many people. There is an emphasis on getting the child moving again. For example, the child may be given a programme of walking progressively longer distances each day or two; for example, walk 10 metres on Monday and Tuesday, 25 metres on Wednesday and Thursday, 20 metres twice Friday and Saturday and 50 metres Sunday and Monday (Calvert and Jureidini 2003).

Faust and Soman (2012) highlight the importance of family involvement: ‘family involvement is essential as families must learn the role they play in the treatment plan. Siblings and parents undoubtedly affect the adolescent’s symptoms either by maintaining or exacerbating them. Without significant understanding of psychogenic movement disorders, parents and siblings might be seen as unsupportive and/or as enabling of the adolescent’s condition. Enabling certain anxious or depressive behaviors limit the success of the treatment’.

It is easy to criticise the amount of time and effort and the long hospital stays needed to help some of these children, but many are very ill. Trying to ‘force them’ to get better sooner can result in an escalation of symptoms and an even more prolonged illness. Long admissions are also common in adults with PND. For example, in one study of adults admitted...
for the treatment of motor conversion disorder, the median length of admission was 101 days (McCormack et al. 2014).

It seems likely that intensive inpatient programmes work by enabling the child to rest, and get better slowly without loss of dignity, while psychological and family problems are addressed. From the discussion above it can be seen that current inpatient programmes have much in common with previous methods of treatment going back to Chambers in 1861. An interesting part of the programme of Koslowska et al. (2012) involves a limitation of parental visiting hours. These are restricted to 2–3 hours at the end of the day. Koslowska et al. note: ‘We have retained this component of treatment because we have found that when parents remain on the ward at all times, the rehabilitation admissions have not been successful. Part of the reason for this is: the parents’ concern for the child is often expressed in strong non-verbal communications of anxiety, solicitous questions about the child’s symptoms, and caregiving responses to alleviate or manage the symptoms. Unfortunately, these “caring” behaviors often trigger and intensify the child’s symptoms.’

This requirement of reduction of parental contact was the advice given in the past although with greater severity. From Mayer (1899): ‘Unfortunately, it is just in these cases that the parents are unable to treat their children as desired. For this reason, isolation is necessary. The child, brought to a hospital, realizes itself alone; it cannot call on weak parents to act against the injunctions of the physician … Stop all visits, even letters.’ These days such advice would include all electronic devices, representing an even greater deprivation. The view of Hecht (1907) was: ‘When one is denied the intelligent and obedient co-operation of parents, and this is only too often the case, isolation becomes an imperative measure. Isolation to be complete and effective means no visitors, no letters, no messages; in short, no reminders of the past.’

It has to be acknowledged that there is a punitive element to such regimes, or in terms of the Rational-Choice Theory of Neurosis (Rofé and Rofé 2013), a change in the cost–benefit equilibrium of the symptom. Weir Mitchell, pioneer of the ‘rest cure’ in the United States, made this clear in 1877: ‘but the rest I like for them is not at all their notion of rest. To lie abed half the day, and sew a little and read a little, and be interesting and excite sympathy, is all very well, but when they are bidden to stay in bed a month, and neither to read, write, nor sew, and to have one nurse – who is not a relative – then rest becomes for some women a rather bitter medicine, and they are glad enough to accept the order to rise and go about when the doctor issues a mandate which has become pleasantly welcome and eagerly looked for’. Leslie (1988) had a similar approach: ‘We suggested to some of the children that it would not be right for them to go home before they were completely better. This was an effective technique if we could be sure that the child, though reluctant to stop faking illness, was even more reluctant to remain in hospital indefinitely.’

However, it is important not to allow the situation to degenerate into a contest of wills, which is highly likely to result in a lose–lose situation. Children in the 10–14 years age group can be extraordinarily strong-willed. One example is the ‘Welsh fasting girl’, Sarah Jacobs, who died rather than admit that she needed to eat (Spectator 1869; Lancet 1870; Grattan-Smith and Dale 2016). Emile Collyer in her poem, ‘Being good’, about a girl with anorexia, captures the self-destructive tenacity:

They ask: ‘why are you doing this?’
It used to make them happy when you were good.
Now they look scared. But you know what a feat it is, this control.
The host starving its unwanted parasites.

The impression going back to Hecht is that most children with PND do well. Goodyer’s impression (1986) was that: ‘Many of the children appear to be free from psychiatric disturbance and the outcome in terms of the presenting symptoms is generally good, with most of the children at follow-up 1–10 years later free of psychiatric, social or educational difficulties. However, for a small percentage the outcome is poor’. Seventy per cent of 32 children with conversion hysteria reported by Schneider and Rice (1979) required hospital admission for an average of 6 days. While in hospital, 20% had a spontaneous remission of symptoms. Following the initiation of psychiatric treatment, all but one of the inpatients recovered within 3 weeks of the diagnosis being made, including some who had had symptoms for more than 3 years.

In the study of Grattan-Smith et al. (1988), 44% were symptom free at discharge from hospital and another 17% were markedly improved. Leslie (1988) found that ‘Thirteen of the 20 children recovered from their physical symptoms within one month of the start of treatment, and 17 had recovered within three months.’ Ani et al. (2013), found that at one year, of those who could be followed, around 90% showed an improvement in neurological symptoms. In addition, 28% had been diagnosed with a new psychiatric disorder, including anxiety disorder (14%), depressive disorder (13%) and school phobia (9%).

Long-term follow-up studies of children with PND have proven difficult to implement, and although the full picture might not be seen until 30–40 years after presentation, the overall impression is that most do not go on to a lifetime of sickness.

CONCLUSION

Freud compared finding the ‘cause’ of PNDs to the discovery of the source of the Nile, and there is still no widely accepted explanation. As observed in the Lancet (1910) editorial:
‘The literature of hysteria is strewn with the wrecks of theories long since forgotten, as are the very names of their authors’. There are, however, a certain number of findings in PNDs that most would accept. These are: (1) A child has to attain a certain level of maturity, before the illness appears. (2) The vast majority of reports have found PNDs to be more common in females. The exception is during wartime, and in particular in the setting of the trench warfare of World War I, where a large number of young men on both sides were affected by ‘shell shock’. (3) The diagnosis of a PND is based on a careful history and examination. The examination findings are by far the strongest clue to the diagnosis, and the signs have been recognised for more than 100 years. (4) Many different treatment regimes have been used with success. It can be added that current treatment programmes have much in common with the approach recommended by Chambers in 1861.

What remains unresolved, is in the explanation of the ‘apparently voluntary’ signs of a PND. Authorities including Carter, Paget, Janet, Wilson, Walshe and more recently Edwards and Bhatia, have been unable to countenance the possibility that the symptoms could just be ‘deliberately feigned’. Somehow the illness seems to take over the person, and in some it will not let go. Whether this has a ‘neurobiological’ or ‘psychological’ basis, or both contribute, remains an area of uncertainty.

From a practical viewpoint, seeing the signs as a distress signal from a child in a predicament, and attempting to identify and relieve that predicament, provides an approach that allows the child to recover without loss of face and to get back on their feet again, even if, ‘what is really going on’, remains a mystery.

informing of families 1467–9
jerks 1457
overview of signs 1460–2
‘positive signs’ 1453–60
(problems of) terminology 1443, 1466–7
prognosis 1470–1
(risks of) misdiagnosis 1462
sensory 1459–60
tics 1457–8
treatment 1469–70
tremors 1456–7
underlying causes 1463–6
visual impairments 1458–9
weakness 1454–5
pulmonary diseases 232, 1334–5
see also pneumonia
purines
biological function 452
metabolic disorders 452–4
Parkinson cells 13–14, 15, 16, 20–1, 692
purpura fulminans
pyruvate dehydrogenase complex (PDHc)
pyruvate carboxylase deficiency 441–2
pyridoxine dependency 421, 427, 871, 872
p53-phosphate oxidase
pyridox(am)ine 552, 561
purpura fulminans
Purkinje cells 13–14, 15, 16, 20–1, 692
purines
radiotherapy 748, 760, 768, 771, 777, 782
radio-microphone systems 1168
radiotherapy 748, 760, 768, 771, 777, 782
after-effects 754, 756, 763
vs. chemotherapy 789
contraindications 758
rage, episodes of 938
ragged red fibres 439, 1163
Ramsay Hunt syndrome 520
rapid-onset obesity with hypothalamic dysfunction, hypoventilation and autonomic dysregulation (ROHHAD) syndrome 692–3
incidence/age of onset 693
RARS gene 500
Rasmussen encephalitis 628
Rational-Choice Theory of Neurosis 1470
reading, specific disability in 1410–11
recombinant human EPO 115
rectus muscle palsy 1141
Refsum disease 396, 398, 399, 483, 514
link with hearing loss 1163
treatment 400, 401
type 2 485
renal diseases 1338–40
chronic failure 1323–2
complications of treatment 1340
following transplant 1343
Rendu-Osler-Weber syndrome see hereditary haemorrhagic telangiectasia
reoviridae 617
reactive oxygen species (ROS)
repair defects 617, 618
recessive disorders 432–40
respiratory disorders 432–40
respiratory chain
ribavirinae 620
ribavirinae 1163
riboskinosis 1163
riboflavin deficiency 1324
riboflavin transporter deficiency 431–2
ribose-5-phosphate isomerase deficiency 431
rickets 1291, 1325
Riley-Smith syndrome 229
ripping muscle disease (RMD) 1279
RNA (ribonucleic acid) 66–7
rippling muscle disease 1282
road traffic accidents 703–5
Rogers syndrome 1165, 1327
rotavirus 620–1
cerebellitis 621
encephalitis/encephalopathy 621
seizures 620–1
rubella 620, 627, 1163–4
Ruvalcaba–Myhre syndrome 229, 230
ryanodine receptor 1 (RYRI) gene 1263, 1266, 1267, 1280
sacral radiculomyelitis 1235
sacroccocygeal teratomas 12
Saethre–Chotzen syndrome 290, 291, 293
Salla disease 382, 391, 478t, 497–8
salatory syndrome 97
Sandhoff disease 384
Sander syndrome 1104–5
Sanfilippo disease (MPS III) 387, 389
Sanatarov-Feuerstein-Mims disease see ceroid lipofuscinoses: CLN 1
sarcoidosis 688
sarcomas, cerebellar 761
SCALP syndrome 222
Scheie disease (MPS IS) 387, 388
Scheimpflug-Feuerstein-Mims syndrome see classic linear nevus
Schindler disease 384
schizencephaly 39–40, 40, 176, 179
schwannomas 212, 222, 1207
vestibular 1165
Schwarz–Jampel syndrome 1280
sciatic nerve
entrapment 1237
injuries 1237
SCN1 gene (A/B) 884–5
scoliosis 302, 367, 408, 415
Seckel syndrome 158–60
Segawa disease 418
Selittelberger syndrome 501–2
seizures
anoxic 929–32
and arterial ischaemic stroke 116–17, 117, 118
and bacterial meningitis 558, 560
and brain/CNS tumours 741, 752
and fragile X syndrome 263
hemifacial, spasm-like 1242
and HIE 112
and holoprosencephaly 155
malarial 631
psychogenic (nonepileptic) 938–9
and rotavirus 620–1
and SWS 224
toxic origin 939–40
and traumatic brain injury 711–12
see also epilepsy; febrile convulsions
self-stimulation episodes 1100
self-mutilation, and Lesch-Nyhan syndrome 1101–2
sex hormones
subcutaneous tissue anomalies; see Sjögren–Larsson syndrome
spinal cord injury/ies 719–21
spinal muscular atrophy 1181–97
common forms 1197
congenital distal variants (SMA-LED) 1189–91, 1192
monomelic see Hirayama disease
non-5q types 1189–97; classification 1190r
with progressive myoclonic epilepsy (SMA-PME) 1196
with respiratory distress 1193–5, 1334
X-linked, adult onset (SMAX1) 1195
X-linked, infantile (XL-SMA/SMAX2) 1195
see also 5-proximal spinal muscular atrophy
spinocerebellar ataxias 512–30
age at onset 517–18, 520, 521
case studies 519–20
classification 512, 513–17, 517
with coenzyme Q10 deficiency 522
diagnosis 517
differential diagnosis 524
dominant forms 512–20
with hypogonadotrophic hypogonadism 522–3
infantile early-onset (IOSCA) 522
maternal inheritance 524
non-progressive 529
with ocular motor apraxia (AOA) 523
recessive forms 520–4 (see also Friedreich ataxia)
type 1 518
type 2 518
type 3 see Machado-Joseph disease
type 4 519
type 7 519–20
type 17 520
X-linked 524
spinocerebellar degeneration see spinocerebellar ataxias
stapes footplate, congenital fixation of 1162
status epilepticus 890–1, 919–29, 939
and viral encephalitis 592
stem cell(s)
therapy 1189
transplants 1345
stenosis
aqueductal 320, 321, 321–2, 325–6, 333
foramen magnum 302–3, 304
stereotypes 1100–2
and autism spectrum disorder 1391
stiff person syndrome 1280
stress
twin pregnancies 61–3
selective fetal growth restriction 61–2
twin anaemia polycythaemia sequence (TAPS) 63
twin-twin transfusion syndrome (TTTS) 62–3, 62t, 64
tyrosinaemia type 1 (HTI) 403
tyrosine hydroxylase deficiency 418–19
infantile-onset dystonia 418–20
neonatal-onset encephalopathy 420
severity 418–20

UBA1 gene 1195
UBE3A gene 266–7
ultrasound
and arterial ischaemic stroke 117
and brain malfunction 192–3
and encephalitis 589
fetal 5, 67, 70
and HIE 112
and hydrocephalus 323, 328, 329
and IVH 96–7, 98
and white matter injury 101
see also Doppler ultrasound
undernutrition see protein energy
undernutrition
unidentified bright objects 210–11
unilateral spastic cerebral palsy (US-CP) see hemiplegia
urea cycle disorders (UCDs) 427–30
urine
continence, promotion of 721
copper levels 450, 451–2
retention 1462
uric acid/creatinine levels 453
uric acid/creatinine ratios 453
urticaria 689
Usher syndrome 1161

Valsalva manoeuvre 719–20
Van Bogaert-Scherer-Epstein disease see cerebrotendinous xanthomatosis
varicella zoster virus (VZV) 602–3
vascular malformations
aneurysms 826, 830–1
arteriovenous (AVMs) 829–30, 1007–8
cavernous 830, 1007–8
and headache 1007–8
vasculitis 682–3
associated syndromes 683–4
differential diagnosis 682
modification of MRI appearance 683
primary 682, 684
primary/secondary, common features 682–3
primary/secondary, distinguished 682t secondary 682, 683–4
vasculopathy, VZV-associated 603
veins
abnormal mechanisms/returns 327, 338
raised pressure in 296–7
Venezuelan equine encephalitis virus 617
ventral induction disorders 6, 153–7 see also holoprosencephaly
ventriculitis 559
ventriculomegaly 30–2, 37, 323–4
aetiology 31
diagnosis/classification 30
differential diagnosis 31
pathogenesis 30–1
prognosis 31–2
ventriculostomy 332–3

VZV-associated 603
West Nile virus 614–15
viral infections 578–628
acute agents 598–622
acute syndromes 578–98
chronic 622–7
encephalopathies related to 627–8
and hydrocephalus 325–6
respiratory 609–11
viral meningitis 578–81
headache as symptom of 1007
linked with hearing loss 1164
vision screening 1122–3
visual impairments 1119–38
aetiologies 1123–34, 1123t
and bacterial meningitis 560
cerebral 106
and cerebral palsy 352–3, 355
classification 1120t
and CNS conditions 792, 1123–4
cortical 1123–34
and craniofascial syndromes 297
and HIE 114
management 1122–3
ophthalmological assessment 1120–2
and optic pathway disorders 1124–9
and PAIS 118
psychogenic 1458–9
range of causes 1120, 1123
relationship with autism spectrum disorders 1389
relationship with hearing impairment 1158
and retinal disorders 1129–34
and SCAs 519–20, 523
structural causes 1133–4
and traumatic brain injury 715
visual pathway
defined/function 1120
disorders 1124–9
gliomas 767–9
tumours 766–9
ventral/dorsal development of 1124
vitamin B1 see thiamine
vitamin B2 see riboflavin
vitamin B3 deficiency 1324
vitamin B6
deficiency 421t, 1324
natural occurrence/metabolism 427
patient responsiveness 415–16
supplementation 417, 420
vitamin B9 see folic acid
vitamin B12
deficiency 412, 1325
metabolism 411t
supplements 413
see also cobalamin disorders
vitamin D deficiency 1325
vitamin deficiencies 1323–7
see also specific vitamins
vitamin E deficiency 1132, 1325–6
Vitamin K
administration 92
deficiency 91, 1326
vitamin metabolism disorders 410–17, 421–2
vitreoretinal diseases 1132–3
vocal cords
congenital dysfunction 1243
paresis 131
Vogt-Spielmeyer disease see ceroid lipofuscinoses: CLN 3
vomiting
cyclical 1338
as symptom of hypertension 733
von Hippel-Lindau disease 205, 227–8, 230r, 760–1
clinical manifestations 228
treatment 228
von Recklinghausen disease see Type 1 neurofibromatosis
Waardenburg syndrome 238r, 478r, 498, 1158, 1161–2
Walker-Warburg syndrome 8, 43, 44, 171–4, 173, 185, 322, 392
Wallerian degeneration 1207, 1208
Watson syndrome 214
WDR62 gene, mutations 160, 160
weakness, psychogenic 1454–5
Wegener disease 688
Weil’s disease 574
Werdnig-Hoffman Disease 1181–3
Wernicke disease 438
West Nile virus 614–15
West syndrome 869, 876–80
western equine encephalitis virus (WEEV) 617
Whipple disease 578, 1338
white matter injury/disorders 100–7, 324–5
clinical manifestations 101, 105
incidence 100–1, 106
and lung disease 1334–5
MRI classification system 104r
and multiple sclerosis 675–6
neurodevelopmental outcomes 105–6
neuroimaging 101–3
pathogenesis 103–5
prevention 106–7
swelling 1328
vanishing 475r, 487–8
